spine (Figure 17.28), brain (headaches, imbalance, fits) and marrow (lethargy, infections, anaemia). Whatever the site of the initial metastasis, patients should be staged to assess the extent of metastatic spread by at least a full blood count, biochemistry (including bone and liver chemistry), CT of the chest, abdomen and pelvis; tumour markers (CEA, CA15-3) can be used to monitor the disease.

In general, patients presenting with visceral metastases (e.g. liver, lymphangitic carcinomatosis of lung) will have aggressive, usually endocrine-insensitive, disease with a poor prognosis, whereas relapse in soft tissue, pleura and/or bone is associated with a survival measured in many months or years (and often hormone-sensitive disease).

Principles of treatment

Since there is no evidence that treating asymptomatic metastases alters survival, treatment is aimed at symptom control and can be considered as:

- control of specific symptoms
- systemic therapy to control the disease
- local therapies for local symptoms.

Symptom control

Symptom control should be used in combination; pain control comprises analgesic regimens including non-steroidal anti-inflammatory drugs (NSAIDs), opioid drugs, amitriptyline/carbamazepine/gabapentin, transcutaneous electrical nerve stimulation and psychological control techniques.

Hypercalcaemia often presents as non-specific deterioration of health, confusion, abdominal symptoms, dehydration and ultimately renal failure and coma. Rehydration (oral, intravenous), bisphosphonates and therapy against the underlying cancer is required.

Systemic therapy

Since metastatic breast cancer is a systemic disease, the best way to control it is with effective systemic therapy.

In general, endocrine therapy is considered as first-line therapy, since it is less toxic than cytotoxic chemotherapy. The best predictor of response to endocrine therapy is the hormone receptor status of the primary tumour. A positive ER status is associated with response in about 60% of patients; response to second-line endocrine treatment is half that seen to first-line treatment. Thus, patients with ER-positive tumours will normally be treated with endocrine therapy in the first instance, unless they have advanced visceral metastases (e.g. liver), when the response to hormonal therapy is low and the delay in waiting for a hormonal response may compromise the patient's survival. Such patients should normally be considered for chemotherapy. Patients with ER-negative tumours should be considered for chemotherapy only since endocrine therapy is unlikely to help them; a balance must be struck between achieving response and limiting side effects. Response in ~50% patients (again with response to second-line treatments half of this) may achieve control for 6–10 months.

BOX 17.7 Standard treatments for breast cancer

- Premenopausal or perimenopausal women:
  - Women with low-risk disease should be considered for tamoxifen if ER positive. Aromatase inhibitors should be avoided in premenopausal patients
  - Women with intermediate- or high-risk disease who are ER positive should be offered chemotherapy and tamoxifen
  - Women with intermediate- or high-risk disease who are ER negative should be offered adjuvant chemotherapy including an anthracycline and/or a taxane. Tamoxifen or ovarian ablation holds no benefit
- Postmenopausal women:
  - Women with low-risk disease should be considered for tamoxifen or an aromatase inhibitor if ER positive
  - Women with intermediate- or high-risk disease and ER-positive tumours should be considered for chemotherapy followed by an aromatase inhibitor
  - Women with intermediate- or high-risk disease and ER-negative tumours should, if fit, be considered for chemotherapy

Endocrine therapy

In premenopausal patients with hormone receptor-positive metastatic breast cancer, tamoxifen displays clinical efficacy similar to ovarian ablation. Single agent tamoxifen has been associated with response rates around 30% and a median time to progression of 6 months in both pre- and postmenopausal patients with hormone receptor-positive metastatic breast cancer, with some patients experiencing prolonged stabilization of their disease.

Unlike tamoxifen and raloxifen, fulvestrant is considered a 'pure antioestrogen' because the drug downregulates the ER without agonist properties. Fulvestrant's efficacy has only been established in postmenopausal women with hormone receptor-positive metastatic breast cancer, in whom the drug has demonstrated similar efficacy to aromatase inhibitors. Additional studies have demonstrated improved efficacy with higher doses of fulvestrant.

In the metastatic setting, anastrozole demonstrated similar response rates to tamoxifen but prolonged time to progression when used as first-line therapy for the treatment of postmenopausal women with ER-positive metastatic breast cancer. Letrozole improved both response and time to progression when compared with tamoxifen as first-line treatment for hormone receptor-positive metastatic breast cancer. Similar results were seen with exemestane compared with tamoxifen and the risk of progression was also significantly reduced. Exemestane has also demonstrated activity in patients with metastatic breast cancer refractory to either anastrozole or letrozole, reflecting the different structure and mode of action of exemestane.

Cytotoxic chemotherapy

The principles of using cytotoxic chemotherapy for advanced breast cancer are similar to those for adjuvant therapy (page 400). The choice of cytotoxic agent will be determined by prior adjuvant therapy and the patient's general condition and fitness. The risk of anthracycline cardiotoxicity increases with cumulative dose, so, if anthracyclines have been used adjuvantly, there will, in general, be little scope to use them in the advanced disease setting. In general, first-line therapy for advanced disease patients will be an anthracycline-based combination (unless used adjuvantly) and second line would be a taxane or capecitabine. For patients with good general condition and chemosensitive disease, then third- and fourth-line therapy with drugs such as vinorelbine or gemcitabine can be useful.

Biological therapy

As a single agent, trastuzumab has demonstrated response rates of 15–34% in patients with metastatic HER2-overexpressing breast cancer. A pivotal trial in the metastatic setting demonstrated that the addition of trastuzumab to chemotherapy (either doxorubicin/epirubicin and cyclophosphamide or paclitaxel) improved response rate, median duration of response and overall survival. Because of a higher rate of congestive heart failure in patients treated with trastuzumab in combination with anthracyclines, paclitaxel became the initial chemotherapy backbone approved for use with trastuzumab. Since the initial approval, trastuzumab has been combined with other chemotherapy agents, such as docetaxel, navelbine, capecitabine, carboplatin and gemcitabine in the metastatic setting.

Approximately 60% of tumours that are HER2 positive are also hormone receptor positive. In metastatic breast cancer, the addition of trastuzumab improved response and progression-free survival when combined with anastrozole as first-line therapy in postmenopausal patients with hormone receptor-positive, HER2-positive metastatic breast cancer. The role for continued trastuzumab beyond disease progression remains poorly defined, but the existing limited data suggest that continuation of trastuzumab improves clinical outcome.

Lapatinib is a small molecule inhibitor of the kinase domain of both HER1 and HER2. Early phase studies demonstrated response for both single agent lapatinib and lapatinib given in combination with trastuzumab. A larger randomized study in women with HER2-positive advanced breast cancer who had disease progression while receiving trastuzumab demonstrated improved progression-free and overall survival for the combination of lapatinib and trastuzumab compared with lapatinib alone.

Lapatinib has been combined with endocrine therapy and found to improve clinical benefit and progression-free survival, compared with hormonal therapy alone, in patients with hormone receptor-positive, HER2-positive metastatic breast cancer. Combination therapy with capecitabine and lapatinib improved response (22% versus 14%) and time to disease progression (8.4 versus 4.4 months, compared with single agent capecitabine) in patients with HER2-positive metastatic breast cancer who had received prior anthracyclines, taxanes and trastuzumab. A large randomized phase III trial also evaluated the efficacy of paclitaxel with/without lapatinib in patients with HER2-positive or HER2-uncharacterized metastatic breast cancer. Although there were no significant differences in response, time to progression or overall survival in the intent to treat population, a preplanned, retrospective evaluation of HER2 status identified 86 (15%) patients with HER2-positive tumours. In this small subset of patients, response and time to progression were significantly improved with the addition of lapatinib to paclitaxel. Randomized trials investigating the role of lapatinib in the adjuvant setting are currently accruing patients.

Single agent lapatinib is well tolerated with manageable toxicities of skin rash and diarrhoea, probably related to the drug's inhibition of EGFR. Lapatinib also does not seem to share the cardiac toxicity of trastuzumab with cardiac event rates (symptomatic or asymptomatic decreases in left ventricular ejection fraction) of 2.2% and 1.7% in patients who had received prior anthracycline and trastuzumab, respectively.

Bisphosphonates

Bone is a common site of breast cancer metastasis and skeletal complications can reduce quality of life. Up to 70% of breast cancer patients with bone metastasis experience at least one skeleton-related event, with approximately 50% experiencing a pathological fracture. Metastatic cells stimulate osteoclast-mediated bone resorption and growth factors released from resorbed bone promote tumour growth. Bisphosphonates inhibit osteoclast-mediated bone resorption and are considered standard of care for the treatment of cancer-induced hypercalcaemia. Treatment with bisphosphonates reduces the risk of skeleton-related events by ~17% in patients with clinically evident bone metastasis.

Additionally, treatment of women with advanced breast cancer and no evidence of bone metastasis with oral clodronate has been demonstrated to reduce bone metastasis and other skeletal events, such as fracture. Adjuvant therapy with clodronate has demonstrated mixed results with two trials demonstrating a significant reduction (~30%) in the risk of developing bone metastasis in patients with operable localized breast cancer and a second study demonstrating no benefit in risk reduction of skeletal metastasis, but an improvement in overall survival in favour of clodronate in the adjuvant setting. Larger trials investigating the effects of bisphosphonates in the adjuvant setting are required to give definitive evidence for their use in reducing bone metastasis and/or osteoporosis from prolonged use of aromatase inhibitors. In general, bisphosphonate therapy is well tolerated, with some patients reporting bone pain or flu-like symptoms with initial administration; however, serious complications such as renal failure and osteonecrosis of the jaw have been reported in a small subset of patients receiving therapy with these agents.

Local therapies

Patients need careful assessment of their symptoms and many may be helped by appropriate local surgical interventions. Examples include:

- Drainage of pleural effusions (Figure 17.26) plus instillation of talc as a tumoricidal and pleuradhesis agent.
- Drainage of ascites (Figure 17.27).
- Surgical stabilization of sites of bone weakness due to metastases – most commonly in the long bones. Prophylactic fixation is preferred, but some patients will need fixation following pathological fracture.
- Palliative radiotherapy, most commonly for painful bony metastases (Figure 17.28). A single fraction of 7–8 Gy will give substantial pain relief in 80% of patients but will not be effective if there is mechanical pain. NSAIDs may confer additional benefit.
- Spinal cord compression. This is an oncological emergency and patients require rapid neurosurgical/radiotherapy assessment, usually following an urgent MRI scan to show the nature and level of the block(s) within the spinal canal.
- Brain metastases. High-dose corticosteroids (4 mg q.i.d. dexamethasone) are usually employed to reduce oedema followed by radiotherapy. Local excision plus radiotherapy can be effective for single metastases depending on the site.

- Surgical resection of metastases. A single brain metastasis in a patient who is otherwise reasonably fit should be considered for resection (followed by palliative radiotherapy) in order to optimize local control. Very occasionally, isolated other metastases (e.g. in liver, bone or lung) should be considered for resection but this is an unusual clinical scenario.
- Surgical resection of the primary tumour. In patients with limited extent of metastatic disease that is responding to systemic therapy, resection of the primary tumour should be considered to obtain local control. There is some evidence from retrospective series (with the caution that this implies) that this may improve survival.

Male breast cancer

The incidence of male breast cancer increases with age but still accounts for <1% of breast cancers, and in the USA is the cause of death in only one in 1 000 000 men.

Risk factors include Klinefelter syndrome (testicular atrophy and insufficiency, gynaecomastia), in which the ratio of oestrogen to androgen is elevated and increases the risk of breast cancer some 20 times. *BRCA2* mutation in breast cancer families is associated with breast cancer in male members of the families and hence molecular screening of male relatives in such families may be justified.

Presentation is as a palpable, painless, firm lump that is often eccentric to the nipple and fixed to the chest wall and skin (Figure 17.29). There may be erythema progressing to ulceration through the skin, nipple retraction or a bloody nipple discharge.

Diagnosis

As for female breast cancer, diagnosis is by triple assessment: clinical examination, mammography and core biopsy to allow the distinction between gynaecomastia and male breast cancer. Staging is required if T3 or above.

Histologically, most male breast cancer is ductal; DCIS accounts for 10%; lobular cancer and special types are comparatively rare. Almost all male breast cancers are ER positive, but should be tested by immunohistochemistry.

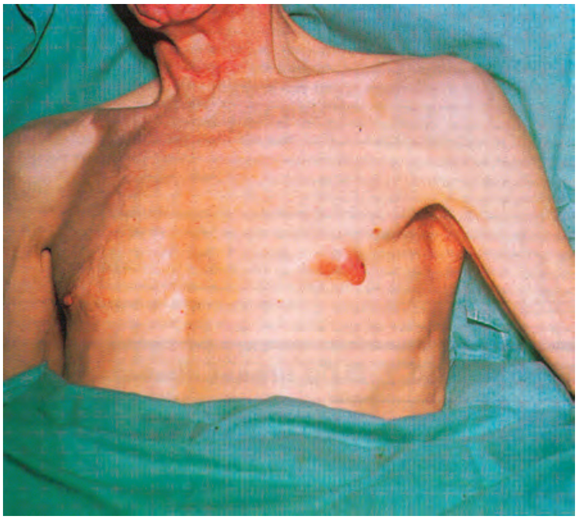

Figure 17.29 Male breast cancer (T4 disease).

Treatment

Modified radical mastectomy, or radical mastectomy if the pectoralis major muscle is directly infiltrated by breast cancer, accompanied by axillary node clearance is the standard treatment even for advanced disease involving the skin or underlying chest wall muscle. Radiotherapy is based on data from female breast cancer, and is used to assist local disease control together with surgery.

While the use of adjuvant endocrine or chemotherapy has not been the subject of the major clinical trials undertaken for female breast cancer, 65–85% of male breast cancers are ER positive and 67% PgR positive. Not surprisingly, endocrine therapy can be effective: tamoxifen (with a 70% response rate) or letrozole and, as second-line therapy, cyproterone acetate or luteinizing hormone releasing hormone analogues have largely replaced oestrogens as therapy. Anthracycline-based chemotherapy, as for female breast cancer, is used in both the adjuvant and palliative settings.

Follow-up

Most patients with breast cancer will complete their primary treatment (surgery, radiotherapy, chemotherapy, etc.) and return to the community. Traditionally, they have then been followed up in the hospital outpatient department. The aim of follow-up is to detect local recurrence (when treatable) or contralateral disease. For those patients with established metastatic disease and/or uncontrolled local disease, continued follow-up is appropriate since they are likely to need ongoing care tailored to the pace of the disease and their needs. For those patients who are apparently disease free, the purpose of follow-up is less clear, but includes detection of local disease recurrence or detection of a second, contralateral cancer or metastatic disease, assessment of treatment morbidity or simply providing reassurance.

Some patients find regular follow-up reassuring but others find it stressful. The optimal frequency and length of follow-up is not defined. It is, however, important that there is a strategy of care agreed between the patient, the GP and the hospital, so that the appropriate care can be offered to the patient should any problems develop.

Detection of distant metastases

Metastatic relapse will present unpredictably and usually between clinic visits. Routine screening for metastases in patients who are asymptomatic does not improve survival. Thus, investigations for metastases should be restricted to patients with symptoms suggestive of metastatic relapse.

Detection of local recurrence

Relapse in the chest wall after mastectomy or in the axilla or supraclavicular fossa is usually detected clinically. Local recurrence after conservation occurs at a constant rate each year, hence follow-up should be continued to 10 years. Following mastectomy the risk of local recurrence is greatest in the first 2–3 years and decreases thereafter. Follow-up may be discontinued, if disease free, at 5 years. Although these relapses may be found at a routine hospital visit, they may also be found by the patient between visits. It is important that the patient can be referred back promptly to the clinic.

Relapse in the treated breast (following conservation treatment) may be found clinically or (more commonly) on follow-up mammography. The latter is therefore recommended every 1–2 years.

Relapse in the contralateral breast

Breast cancer in one breast is associated with an ~1% per annum increased risk of developing cancer in the contralateral breast. The other breast should therefore be examined at each visit and a mammogram performed every 1–2 years.

Morbidity of therapy

Follow-up is also an opportunity to assess the morbidity of treatment, especially locoregional or systemic effects.

Specific considerations include the following.

Arm mobility

Women with breast cancer may develop arm stiffness directly related to their surgery and radiotherapy. Women undergoing breast and/or axillary surgery need shoulder exercises to enable them to recover a full range of arm and shoulder mobility.

Lymphoedema

Lymphoedema of the upper limb may occur in women with breast cancer secondary to lymphatic damage caused by surgery and/or radiotherapy, or because of obstruction caused by local tumour (Figure 17.30). Thus, all patients undergoing surgery and/or radiotherapy treatment to the axilla should receive pretreatment information on lymphoedema. The incidence of lymphoedema has been cited at between 5% and 60%, depending on treatment combinations. Although there is currently no agreed surgical procedure to cure lymphoedema, it is possible to reduce the size of the arm. The most effective management and maintenance comprises multimodal physical therapy (skin care, external support, exercise, massage) and education. Diuretics or pneumatic compression pumps should not be relied upon. Lymphoedema should be treated at the first sign of swelling when management will be more effective. The lymphoedematous arm is prone to streptococcal infection after minor injury (e.g. gardening); patients should be instructed to seek medical attention, including antibiotics, at the first signs of infection (tenderness, redness, increased swelling, pain on movement of the limb).

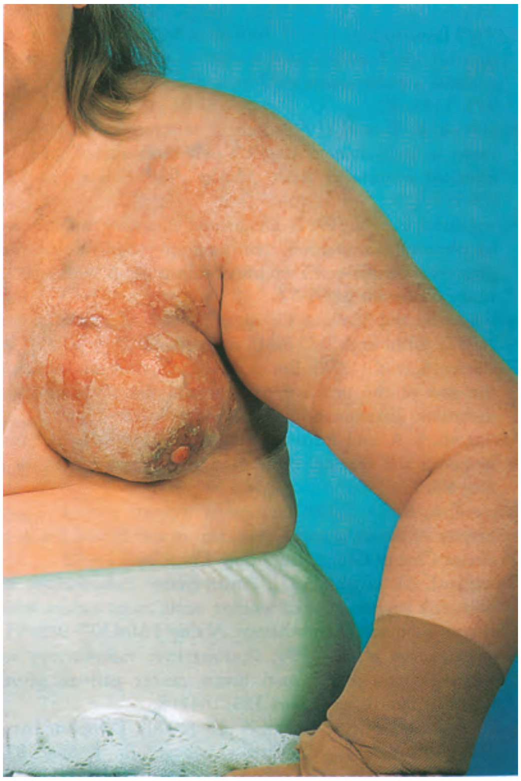

Figure 17.30 Lymphoedema of the left upper limb secondary to advanced breast cancer with chest wall disease and infiltration of the axilla. Note the armlet to symptomatically treat the lymphoedema.

Menopausal symptoms

Menopausal symptoms are a recognized issue for women with breast cancer. Many women who receive treatment for breast cancer subsequently experience menopausal symptoms, either as a result of their adjuvant treatment or as a natural process. The average age at menopause is 50 years, but in 25% of women who develop breast cancer premenopausally and undergo adjuvant treatment it is 10 years earlier. Although HRT is widely advocated for the treatment of menopausal symptoms, its use in women with a personal or family history of breast cancer remains controversial, and alternative methods of coping with the menopause have not yet been fully explored. Some studies show that progestogens such as megestrol acetate and soya protein are useful in alleviating menopausal symptoms.

Women should be informed regarding the potential effect of cancer treatment on their menopausal status, and advised regarding non-oestrogen alternatives and self-care strategies that might alleviate their symptoms.

Prostheses

External breast prostheses are the most common method of restoring breast symmetry following surgery, and a wide variety of shapes and sizes are available. A soft temporary breast prosthesis should be fitted before hospital discharge, and a permanent prosthesis should be fitted either 6–8 weeks postoperatively (or when the wound is fully healed) or following completion of radiotherapy once any skin reaction has resolved. Women should also be given advice on bras, swimwear and replacement prostheses.

Psychological considerations

Women (and men) with breast symptoms may suffer considerable emotional distress, even once a benign diagnosis is made.

Breast cancer is a high-profile disease, the progression and treatment of which results in substantial physical and psychological morbidity.

To participate effectively in decision-making, women and their families need to receive adequate information and sufficient time to discuss treatment options. Breast care nurses and voluntary sector organizations can provide verbal, written and multimedia information. Studies of the physical impact of screening and genetic counselling appear to be reassuring. There is no clear evidence that mastectomy and breast conservation differ in terms of clinically significant anxiety or depression; some studies have found that breast conservation is associated with fewer problems related to body image, although conservation may carry an increased risk of worrying about recurrence. Hence, some women choose mastectomy, although not all women wish to share in the decision-making. Significant numbers of women develop psychological problems after anticancer therapy treatment and some require formal treatment. Psychological factors may influence the course of malignant disease but can certainly be harnessed to combat the side effects of treatment, particularly chemotherapy. Disease recurrence is associated with increased psychological morbidity; formal psychological interventions can be used successfully should it occur.

CHAPTER 18

Disorders of the thyroid gland

SABA P. BALASUBRAMANIAN AND DAVID SMITH

Introduction

Thyroid disease encompasses a wide variety of inflammatory, autoimmune, nutritional and neoplastic pathologies. Although the disease states are defined using well-established criteria, there is a usually a continuum of change within the spectrum ranging from a normal thyroid (structurally and physiologically) to the extremes of disease phenotypes. Understanding where an individual patient lies in this spectrum and initiating an optimal management plan requires a detailed knowledge of the basic sciences and pathophysiology of thyroid disease.

The epidemiology of thyroid disease is very variable. Hypothyroidism is the second commonest endocrine disease and thyroid nodules are widely prevalent in most populations. However, thyroid cancer is an uncommon malignancy and certain types of thyroid cancers [such as medullary thyroid cancer (MTC) and anaplastic thyroid cancer] are very rare. Although surgical management is only required in a small minority of patients with thyroid disease, thyroid surgeons should have an in-depth understanding of the management of patients with 'non-surgical' thyroid disease. We also recommend a multidisciplinary approach bringing together endocrinologists, radiologists, oncologists and surgeons to facilitate discussion and appropriate management of patients with complex benign disease and thyroid cancers.

This chapter starts with a discussion of thyroid embryology, anatomy and physiology followed by sections on clinical problems in thyroid disease – hypothyroidism, hyperthyroidism, thyroid nodules and thyroid cancer.

Thyroid embryology, anatomy and physiology

Thyroid embryology

The thyroid is principally of *endodermal* origin, and is derived from the floor of the pharynx between the tuberculum impar (the medial swelling of the tongue) and the cupola. An endodermal track migrates down the neck in front of the primitive larynx and divides into right and left branches, which develop into the lateral lobes of the thyroid gland. This track remains connected to the tongue (at a point called the foramen caecum, located at the junction of the anterior and posterior parts of the tongue) by the thyroglossal duct. The duct normally closes at around the fifth week, and the only remnant is a shallow blind pit at the foramen caecum. Remnants of the duct may, however, persist and develop into well-differentiated thyroid tissue (ectopic thyroid) or a cystic lesion (thyroglossal cyst). Occasionally, these may be associated with absence of the thyroid in its orthotopic position, reflecting arrest of migration of the thyroglossal duct. Complete failure of descent may result in a lingual thyroid, at the back of the tongue. Papillary carcinoma of the thyroid may rarely develop in an ectopic thyroid gland.

The thyroid is in its normal position just inferior to the cricoid cartilage by the seventh week. Follicles appear and the thyroid begins to secrete hormones by the twelfth week, one of the first organs to do so. The thyroid also has a *neural crest* origin as cells from the neural crest migrate into the ultimobranchial body, which is derived from the ventral part of the fourth/fifth pharyngeal pouch. The ultimobranchial body becomes incorporated into the thyroid and has been thought to develop into the tubercle of Zuckerkandl on the lateral aspects of the thyroid lobes. However, another view is that this may not contribute to any thyroid tissue. The 'neural crest' cells in the ultimobranchial body develop into the parafollicular cells, which secrete calcitonin. Hence, the thyroid gland is derived from both the endoderm of the primitive pharynx (follicular cells) and the ectoderm, i.e. the neural crest (parafollicular cells).

Thyroid anatomy

The thyroid is a highly vascular gland, weighing about 15 g, and consists of two lobes, united in the midline by the isthmus, which overlies the second and third tracheal rings. There may also be a pyramidal lobe, superior to the isthmus and often to the left of the median plane. This is present in 50% of individuals and is the remnant of the thyroglossal tract. A fibrous capsule surrounds the thyroid and extends into the gland as septae. This capsule is enveloped by the visceral layer of the pretracheal cervical fascia. Posteriorly, the gland is attached to the cricoid cartilage and the superior tracheal rings by dense connective tissue (Berry's ligament). This attachment of the thyroid to the trachea causes the thyroid to move on swallowing, which helps distinguish thyroid nodules from other neck lumps.

The arterial supply is from the superior and inferior thyroid arteries, which lie in the plane between the thyroid capsule and the pretracheal fascia. The superior thyroid artery originates from the external carotid artery and divides into an anterior and posterior branch at the superior pole of the thyroid. The external branch of the superior laryngeal nerve (EBSLN) runs inferolateral to the oblique line of thyroid cartilage and has a close relationship with the superior thyroid artery. It typically runs over the inferior constrictor muscle to reach and supply the cricothyroid (in some cases, the nerve passes deep to inferior constrictor muscle and is therefore not routinely seen at operation). Care must be taken to ligate the superior thyroid artery on the capsule of the thyroid at operation and to be aware of the possibility of damage to the EBSLN when applying diathermy to the small branches of the superior thyroid artery. Damage to the EBSLN results in paralysis of the cricothyroid muscle. This muscle tenses the vocal cords, which is important in production of high pitch, as in singing. The inferior thyroid artery originates from the thyrocervical trunk, which arises from the first part of the subclavian artery. It enters the thyroid on its lateral aspect and has a close relationship with the recurrent laryngeal nerve (RLN). On the left, the RLN runs vertically along the tracheo-oesophageal groove and is usually medial to the inferior thyroid artery. On the right, the RLN runs a more lateromedial course and has a more intimate relationship to the branches of the inferior thyroid artery. Superiorly, the nerve passes through the posterior portion of Berry's ligament (an area where it is prone to damage) before entering the larynx, usually adjacent to the inferior cornu of the thyroid cartilage. The RLN is the motor supply to the intrinsic muscles of the larynx. An injury to the nerve causes ipsilateral vocal cord palsy. In about 1% of cases there is a non-recurrent right laryngeal nerve, owing to a vascular anomaly in the development of the aortic arches. In 10% of patients there is a thyroidea ima artery, which arises from the brachiocephalic trunk, and passes into the inferior border of the isthmus.

The venous drainage of the thyroid is via the superior and middle thyroid veins, which drain into the internal jugular and the inferior thyroid veins, which drain into the brachiocephalic vein. The lymphatic drainage of the thyroid is to the prelaryngeal, pretracheal and paratracheal lymph nodes medially and then to the deep cervical lymph nodes laterally around the carotid sheath.

Thyroid physiology

The thyroid gland consists of two main types of cells – follicular and parafollicular cells. The follicle is the basic functional unit of the thyroid and consists of a single layer of cuboidal (follicular) cells around a store of colloid. The follicular cells synthesize thyroid hormone in four stages, which include:

- *Iodide trapping.* Iodide is actively transported (by an ATP-dependent process) into the thyroid follicular cell and then to the apical membrane. The average daily requirement of iodine is 150 g. The normal daily Western dietary intake contains approximately 500 g.
- *Organification.* The iodide is oxidized by the enzyme thyroid peroxidase and then combined with tyrosine to form the inactive iodotyrosines: 3-monoiodotyrosine (MIT) and 3,5-di-iodotyrosine (DIT). The iodotyrosines are incorporated into the soluble protein, thyroglobulin, which is stored as colloid in the follicular lumen of the thyroid.
- *Coupling.* The iodotyrosines in the thyroglobulin are then coupled to form triiodothyronine or T_3 (MIT and DIT) and thyroxine or T_4 (two molecules of DIT).
- *Release.* Colloid is taken up by the thyroid cell by endocytosis to form endosomes. The thyroglobulin is then hydrolysed to liberate T_4, T_3, MIT and DIT. The MIT and DIT are deiodinated and the released iodide reused by the thyroid cell. The active hormones, T_4 and T_3, are secreted into the blood.

The vast majority of the released thyroid hormone is in the form of T_4 (90%). Most of the T_3 (80–90%) is produced by the peripheral conversion of T_4. T_3 is much more potent than T_4. The metabolic activity of thyroid hormone is determined by the amount of free T_3 and free T_4. Thyroxine is very highly protein bound in plasma (99.95% bound to thyroid-binding globulin, transthyretin and albumin, with about 0.05% free). When bound, T_4 is not physiologically active but provides a storage pool of thyroid hormone, which can last 2–3 months (mean half-life of T_4 is 6.5 days). Reverse T_3 (rT_3) is also produced by the deiodination of T_4. It is not physiologically active and increased levels of rT_3 are produced in hyperthyroidism, and periods of excess catabolism (e.g. burns, sepsis).

Peripheral action of thyroid hormone

The principal effects of thyroid hormones are to facilitate normal growth and differentiation and to increase the rate of metabolism. Thyroid hormones act predominantly via a nuclear thyroid receptor (TR), which upregulates gene transcription and thereby increases protein synthesis. T_4 is relatively inactive in the periphery, owing to a low affinity for TR in comparison with T_3.

Thyroid hormone regulation

Thyroid-stimulating hormone (TSH) is the major regulator of thyroid activity, with increased levels causing hypertrophy of the thyroid. TSH is secreted by the anterior pituitary, and is a glycoprotein with an and subunit (the subunit being common to follicle-stimulating hormone, luteinizing hormone and human chorionic gonadotrophin). TSH acts by binding to the TSH receptor on the follicular cell membrane, leading to increased thyroid hormone synthesis, predominantly via cAMP as the second messenger. Thyroid-releasing hormone (TRH) is the most important positive stimulus for the production of TSH. TRH is produced in the paraventricular nucleus of the hypothalamus and passes through the median eminence to the anterior pituitary via the hypophyseal portal system. T_3 has a negative feedback on both the anterior pituitary and the hypothalamus.

Parafollicular cells

The parafollicular, or C cells, secrete calcitonin. Calcitonin is a 32 amino acid peptide that lowers calcium largely by the inhibition of osteoclasts. It is of little physiological importance in humans as there is no disturbance of calcium regulation following thyroidectomy, provided that the parathyroids are preserved. It is a sensitive tumour cell marker for medullary thyroid carcinoma (see Differentiated thyroid carcinoma). Calcitonin also has a role in the treatment of Paget disease of the bone.

Hypothyroidism

Epidemiology

Hypothyroidism is one of the most common endocrine disorders, with approximately 5% of the female population developing hypothyroidism at some stage in their lives. The vast majority are caused by primary hypothyroidism, with secondary (anterior pituitary gland disorders) and tertiary (hypothalamic disorders) hypothyroidism being rare. Primary hypothyroidism is usually caused by autoimmune thyroiditis (the commonest among them being Hashimoto's thyroiditis), or by treatment of other thyroid disease [e.g. following surgery or radioactive iodine (RAI) for thyrotoxicosis]. About one-third of patients undergoing a hemithyroidectomy and up to 70% of patients treated by subtotal thyroidectomy are hypothyroid at 10 years, this being influenced by remnant size and the degree of lymphocytic infiltration of the thyroid. The use of RAI in the management of thyrotoxicosis results in 50% of patients developing hypothyroidism in the first year, with 3% per annum subsequent to that. Lifelong follow-up and monitoring of TSH levels are therefore required for these patients. External beam radiotherapy to the neck can result in subclinical or clinical hypothyroidism in up to 50% of patients (usually 2–7 years after treatment). In addition, certain drugs can cause hypothyroidism, including amiodarone and lithium.

Thyroiditis

Several different types of thyroiditis exist. Although there are overlapping features among the different types, they are commonly classified on the basis of histology and/or aetiology. These include:

- chronic lymphocytic (Hashimoto's thyroiditis)
- Graves' disease (see Thyrotoxicosis)
- subacute granulomatous thyroiditis
- subacute lymphocytic thyroiditis
- postpartum thyroiditis
- postsurgical thyroiditis (e.g. following parathyroid surgery)
- radiation thyroiditis (following RAI and external radiation)
- suppurative thyroiditis (or thyroid abscess)
- Reidl's thyroiditis.

The commonest form of thyroiditis and hypothyroidism in the population is a specific autoimmune form of thyroiditis called Hashimoto's thyroiditis. This has a familial predisposition. Females are more commonly affected (male to female ratio 9:1) with the usual age of onset being 40–50, although it can occur at any age. The usual clinical presentation is with painless thyroid enlargement (a firm, rubbery gland); occasionally the patient may present with pain or pressure in the neck. The gland enlarges owing to the lymphocytic infiltrates and areas of focal hyperplasia, caused by TSH stimulation. In the early stages, free T_4 and T_3 may be normal, with an elevated TSH (subclinical hypothyroidism). The patient may also present with thyrotoxicosis (4%), caused by release of thyroxine, before eventually becoming hypothyroid.

Clinical features

The development of clinical features is variable and often slow and insidious. A significant proportion of patients have mild or non-specific features and the diagnosis is made on biochemistry as part of screening for a variety of medical problems. Common symptoms of hypothyroidism include dry skin, coarse hair, hair loss, brittle nails, weight gain, hoarseness (unrelated to RLN palsy), cold intolerance, paraesthesia, muscle stiffness and aches, drowsiness, lethargy, easy fatigability and constipation. Signs include cool and dry skin, bradycardia, puffy face and hands and slow deep tendon reflexes. Clinical features are less obvious and often atypical in the elderly. In myxoedema (severe and life-threatening hypothyroidism), there is progressive deterioration in mental status, localized neurological signs, hypothermia, hypoglycaemia and hyponatraemia.

Subclinical hypothyroidism is a biochemical entity defined as raised TSH in the presence of normal levels of T_3 and T_4. These patients are usually asymptomatic.

Investigations

Investigations are largely biochemical. A thyroid profile usually includes TSH and free T_4 (free T_3 is sometimes done, especially if T_4 levels are normal). Antimicrosomal antibodies (antithyroid peroxidase) are found in 90% of patients with Hashimoto's thyroiditis, but are not specific as they are also found in 70% of patients with Graves' disease. Antithyroglobulin antibodies are found in 60% of patients and are more specific to Hashimoto's thyroiditis. Thyroid ultrasound or isotope scans are usually not required for the diagnosis of hypothyroidism.

Treatment

The aim of treatment is to normalize the TSH level by giving supplemental thyroxine. Thyroxine is absorbed in the small intestine and has a half-life of 7 days. Care must be taken when instituting therapy in the elderly or patients with coronary artery disease, when a lower dose should be initially administered (starting at 25 g and increasing by 25 g increments every 2 weeks). After TSH levels are stabilized, therapy is monitored by checking the TSH level on an annual basis.

The treatment of subclinical hypothyroidism is debatable and best done in conjunction with a medical endocrinologist. Consensus statements suggest thyroxine treatment in patients with TSH levels persistently above 10.0 mU/L.

Long-term consequences

Patients with autoimmune thyroiditis have an increased predilection for other autoimmune disorders (such as pernicious anaemia). Patients with Hashimoto's thyroiditis also have a higher risk of developing a thyroid lymphoma than the general population. Eighty per cent of all -cell thyroid lymphomas develop on a background of Hashimoto's thyroiditis (Figure 18.1).

Hyperthyroidism

Epidemiology

Hyperthyroidism refers to the state of increased synthesis and secretion of thyroid hormones. Thyrotoxicosis is defined as excess levels of circulating thyroid hormones, which includes hyperthyroidism but also other uncommon conditions in which high levels may be due to destructive thyroiditis and excessive release, ectopic secretion (from struma ovarii or choriocarcinoma) or excessive ingestion of thyroid hormones. Thyrotoxicosis is caused in the vast majority of instances by primary thyroid pathology (including Graves' disease, toxic multinodular goitre and solitary toxic adenoma).

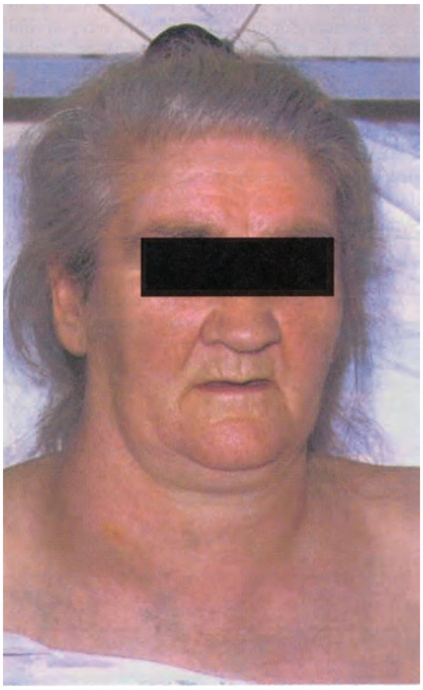

Figure 18.1 Patient who developed lymphoma on a background of Hashimoto's thyroiditis.

Graves' disease

Graves' disease (also called Basedow disease in mainland Europe) is an autoimmune disorder, characterized, in 90% of cases, by the presence of an immunoglobulin G antibody against the TSH receptor. The antibody is termed thyroid-stimulating immunoglobulin or TSH receptor antibody (TRAb) and stimulates the follicular cells, leading to excess production of thyroxine, hyperplasia and hypertrophy of the gland. Graves' disease is commoner in females (female to male ratio 7:1) and is not premalignant. The thyroid in patients with Graves' disease is usually diffusely enlarged, although sometimes multinodularity (or asymmetric enlargement) is noted. Thyroid cancer has occasionally been detected in surgically resected thyroid gland specimens of patients with Graves' disease. The nature of this association is uncertain and a previous presumption of increased aggressiveness of thyroid cancer in such patients has not been established.

Other causes of primary thyrotoxicosis

Plummer disease (described originally in 1913) is the term given to a hyperfunctioning thyroid, which may be either multinodular or a solitary nodule. A *toxic multinodular goitre* usually develops in a large, longstanding multinodular goitre of at least 10 years' duration. A *solitary toxic adenoma* is an autonomous nodule that produces enough thyroid hormone to cause hyperthyroidism. An unusual cause of thyrotoxicosis is the Jod–Basedow phenomenon, which is caused by the excessive release of thyroxine in an iodine-deficient patient on resumption of dietary iodine intake or administration of intravenous contrast. The phenomenon is most commonly observed in patients over 50 years with a longstanding multinodular goitre.

Clinical features

Symptoms include anxiety, tremor, palpitations, hyperactivity, increased appetite, weight loss, fatigue, heat intolerance, diarrhoea, menstrual irregularity and skin changes. Signs include warm and moist skin, irritability, restlessness and other psychiatric manifestations and features of a hyperdynamic circulation (and atrial fibrillation in the elderly). Other uncommon features include myopathy (Figure 18.2), gynaecomastia, decreased fertility, hyperpigmentation, splenomegaly and lymphadenopathy. Patients with Graves' disease may also have an infiltrative dermopathy often affecting the legs. This has been paradoxically termed 'pretibial myxoedema'.

Thyroid eye disease, which is often associated with Graves' disease (see below), manifests in its early stages as prominence of the eyes, irritation and increased watering of the eyes and

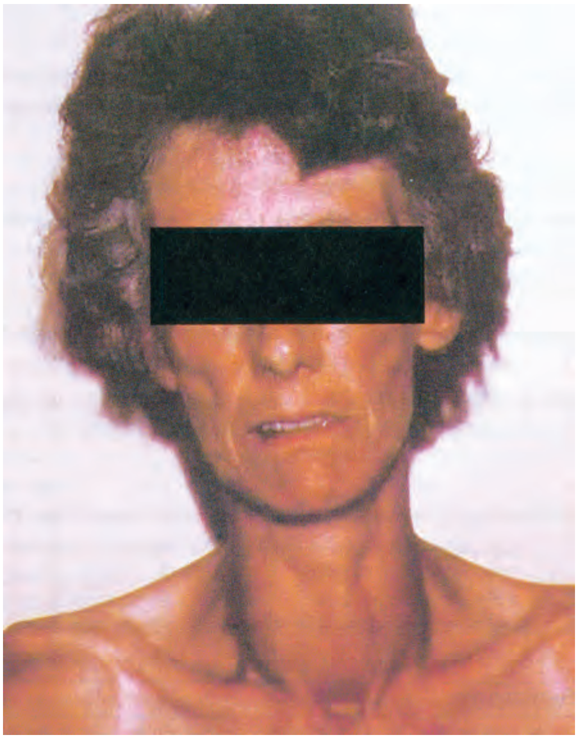

Figure 18.2 Proximal upper limb myopathy in a patient with thyrotoxicosis.

in later stages as periorbital oedema, chemosis (conjunctival oedema), lid and/or globe lag, ophthalmoplegia and visual loss.

Investigations

TSH levels are suppressed in thyrotoxicosis. In Graves' disease, antimicrosomal (thyroid peroxidase antibody) and antithyroglobulin antibodies are raised in 70% of patients, whereas the TRAb is raised in 90% of patients. Antibodies are usually absent in toxic multinodular goitre and solitary adenomas. Ultrasound or isotope scans are generally unhelpful in the investigation of Graves' disease, except in postpartum thyrotoxicosis, when it may be necessary to differentiate Graves' disease from self-limiting postpartum thyroiditis. In a toxic multinodular goitre, isotope scanning will usually show multiple hot areas, and will help determine the presence and extent of retrosternal extension. In a solitary toxic adenoma, an isotope scan will demonstrate the hot nodule with suppression of the extranodular thyroid tissue. Differentiation between a solitary toxic adenoma and a toxic multinodular goitre can help plan the extent of thyroidectomy. Fine needle aspiration (FNA) is usually used to exclude an associated thyroid neoplasm in the presence of a solitary or dominant thyroid nodule.

Treatment of Graves' disease

Antithyroid drugs

These are the mainstay of initial treatment. Although the hyperthyroid state can usually be well controlled, relapse rates are around 50–60%. Male sex, large goitres, high levels of thyroid hormones, high levels of TRAbs and smoking increase the risk of relapse. The thionamides (carbimazole, propylthiouracil and methimazole) block the organification (iodination) of the tyrosine residues on the thyroglobulin molecule, by inhibiting the enzyme thyroid peroxidase. Carbimazole is converted to its active constituent methimazole (which is primarily used in the USA). The traditional dosing regimen is 20–40 mg of carbimazole (100–150 mg of propylthiouracil) to render patients euthyroid and maintaining low-dose treatment for 12–18 months. An alternative treatment regimen ('block and replace' regime) involves using a much higher dose of antithyroid drugs along with thyroxine to maintain euthyroidism. The advantage of this latter regimen is faster control of hyperthyroidism with less frequent use of TSH measurements; the disadvantage being a higher incidence of side effects. Side effects of these drugs include rash, arthralgia and gastrointestinal disturbances; rarer but more serious side effects include agranulocytosis, vasculitis and hepatitis. Treatment with recombinant granulocyte colony-stimulating factor has been reported to shorten recovery time in patients with thionamide-induced agranulocytosis.

Radioactive iodine

RAI uses the high-energy particles of ^{131}I to ablate thyroxine-producing follicular cells. It is the treatment of choice in elderly patients, patients with small glands or those who are unfit for surgery. Contraindications to RAI include pregnancy (RAI freely crosses the placenta and activity in the maternal bladder causes fetal irradiation), breastfeeding (both iodine and pertechnetate are excreted in breast milk) and patients with severe toxicity (as patients may develop thyroid storm if markedly toxic and should be pretreated with beta-blockers). Carbimazole is stopped 48 hours before and restarted 3–5 days after RAI. The usual dose of ^{131}I given is 500–750 MBq and the maximum effects of treatment occur 3–4 months after the dose of RAI. Hypothyroidism is an almost inevitable consequence of treatment (see Hypothyroidism). RAI may exacerbate clinically evident ophthalmopathy and systemic corticosteroids may be indicated to reduce this risk. Although debatable, some studies suggest a small increase in cardiovascular and cancer-related mortality.

Surgery

Traditionally, the standard surgical treatment in Graves' disease was a subtotal thyroidectomy, the aim of which was to leave behind a small volume of thyroid tissue in each lobe so as to leave the patient euthyroid. However, the drawbacks were a risk of recurrent thyrotoxicosis (around 10%) and the observation that up to 70% of patients will develop hypothyroidism at 10 years. The current trend therefore is to perform a near total or total thyroidectomy and immediate institution of thyroxine postoperatively. This serves to eliminate the disease with negligible recurrence rates. There are concerns that the complications such as RLN damage and hypoparathyroidism may be higher with the more radical operation, but this has not been shown to be the case in experienced hands.

Treatment of toxic adenoma/multinodular goitre

For patients with toxic adenoma and toxic multinodular goitre, surgery and RAI are effective and safe treatment options. Factors favouring surgery include contraindications to RAI, large or compressive goitres, indeterminate or suspicious nodules, nodules with retrosternal extension and coexisting hyperparathyroidism needing surgery. Factors favouring the use of RAI include elderly, unfit patients, patients with small nodules and previous neck surgery. Occasionally, elderly patients unfit or unwilling to undergo either surgery or RAI may be maintained on long-term low-dose antithyroid drugs.

Thyroid nodules

Epidemiology

Nodular thyroid disease is common and the incidence increases with age. The prevalence of palpable nodules in areas of adequate iodine intake is 4–7% but autopsy studies and ultrasonography have shown the true figure to be much greater with around 50% of adults having nodules. In areas of severe iodine deficiency, the prevalence can be as high as 90%.

A wide range of benign and malignant pathology can account for patients presenting with a thyroid nodule(s). Malignant diseases are covered later, but the list of benign pathology includes:

- colloid or multinodular goitre (may present as solitary/dominant nodule)
- thyroiditis
- simple or haemorrhagic cysts
- follicular adenomas
- thyroid abscess.

In a multinodular goitre (Figure 18.3), enlargement of the thyroid tends to start as diffuse hyperplasia of the gland, with subsequent areas of focal hyperplasia (which may be dependent on TSH stimulation) and areas of regression and colloid degeneration; a multinodular goitre may be non-toxic (euthyroid) or toxic (Plummer disease). The aetiology of a multinodular goitre is poorly understood, but is thought to be multifactorial: genetic predisposition to dyshormonogenesis, iodine deficiency, drugs (notably amiodarone and lithium), ingestion of brassica vegetables and autoimmunity. Thyroid cancer, however, is rare, affecting around four in 100 000 individuals per year and constituting 1% of all malignancies.

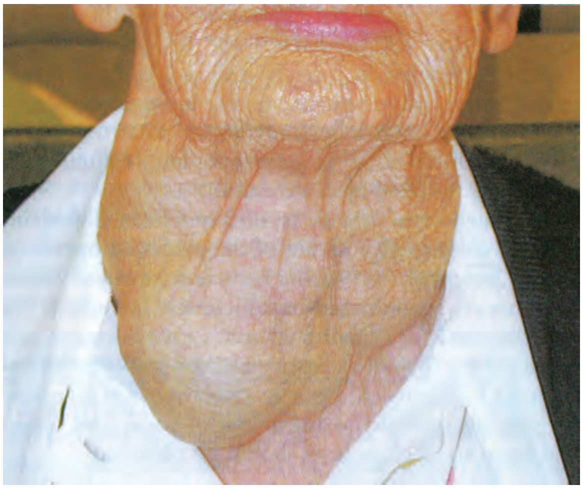

Figure 18.3 Patient with longstanding multinodular goitre.

The difficulty for the clinician and patients in the management of nodular goitre is to strike the right balance that avoids overtreatment of common benign nodular disease (Figures 18.4 and 18.5) and enables early detection and treatment of thyroid cancer. This is compounded by the need for diagnostic excision in the all too common scenario of indeterminate or inconclusive cytology.

Clinical features

The majority of thyroid nodules are asymptomatic and are found fortuitously by the patient or on routine clinical examination. The lumps are largely painless, but the sudden presentation of a painful swelling is almost pathognomonic of haemorrhage into a simple colloid nodule. Patients with thyroiditis sometimes have local discomfort and tenderness. Compressive symptoms such as difficulty in breathing and/or swallowing are usually seen in very large, multinodular goitres. These goitres can cause significant deviation and/or tracheal compression; the latter may be associated with stridor. Compressive or obstructive

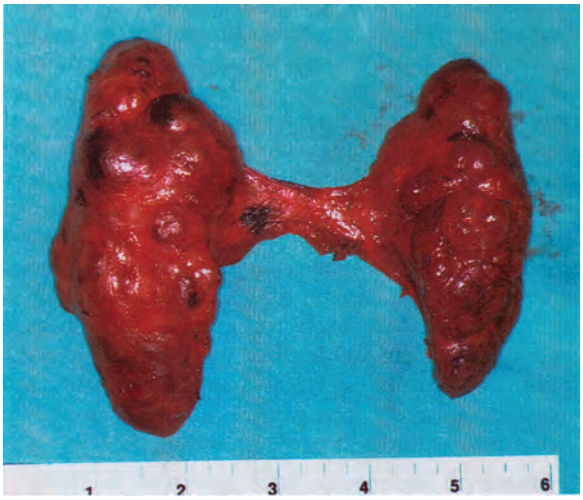

Figure 18.4 Dominant nodule in the right upper thyroid lobe of a multinodular goitre.

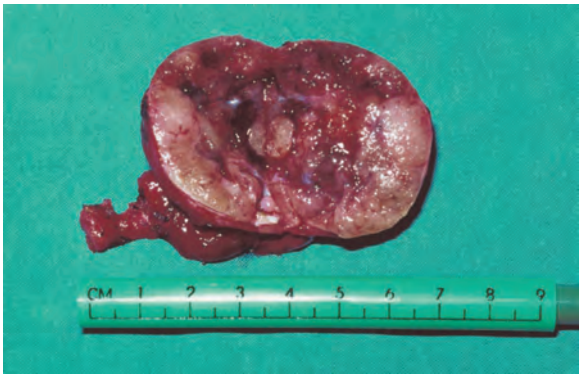

Figure 18.5 Solitary nodule – benign.

symptoms are more common when the goitre grows posteriorly or in a retrosternal direction; around 10% of multinodular goitres will have a retrosternal extension. These goitres may cause compression of large veins at the thoracic inlet leading to dilated veins in the head, neck and upper limbs. Elevation of the arms in conjunction with deep inspiration can often precipitate engorgement of veins in the upper half of the body, flushing and respiratory distress in these patients (Pemberton's sign). Rapidly worsening symptoms especially in association with voice change can be a sign of malignancy, but a malignant tumour can also be extremely slow growing and be present for many years before being discovered. Although the vast majority are benign, features of hyperthyroidism and hypothyroidism should be elicited in all these patients (see previous sections). Nodules in patients with a past history of neck irradiation and a family history of thyroid malignancy clearly have a high likelihood of being malignant. The very young and elderly are at increased risk for malignancy. There is an increased incidence of follicular cancer in iodine-deficient endemic goitrous areas and an increase in papillary cancer in iodine-rich regions. Solitary nodules convey a greater risk of malignancy in males, and a family history of endocrine disease suggests the possibility of medullary thyroid carcinoma. Papillary carcinoma may also be familial and has been described with familial adenosis polyposis (Gardner syndrome) and also ataxia–telangiectasia. Consistency can be misleading as, although a hard fixed nodule is likely to be malignant, a benign colloid nodule can also be hard with dystrophic calcification. Associated cervical lymphadenopathy and features of RLN palsy are highly suggestive of malignancy (Box 18.1). However, associated lymph nodes could be reactive (especially in presence of thyroiditis) and nerve palsy could occasionally be secondary to compression by a longstanding, large multinodular goitre.

Investigations

Fine needle aspiration cytology

Fine needle aspiration cytology (FNAC) is now a routine and important investigation in patients presenting with a solitary thyroid nodule or a dominant nodule in a multinodular goitre. It may be a curative procedure for simple thyroid cysts, although patients with recurrent cysts and those with residual solid areas should be reaspirated or considered for surgery. FNA is, however, not required in patients with multinodular goitre without a dominant nodule and also in patients with a diffuse goitre who are hyperthyroid (as in Graves' disease). Cytological assessment may be performed using a wet-fixed or air-dried preparation or alternatively utilizing a cell block method in which the thyroid architecture is preserved. The authors perform several passes of the needle for each nodule and find good patient compliance with few complications. The procedure can also be easily repeated (Figures 18.6–18.9).

In the UK, the cytology report is usually classified into one of the following categories:

- Thy1 (inadequate or non-diagnostic)
- Thy2 (benign or non-neoplastic)
- Thy3 (indeterminate, possibly neoplastic)
- Thy4 (suspicious of malignancy)
- Thy5 (diagnostic of malignancy).

Thy1 and Thy2 categories are sometimes suffixed as Thy1c and Thy2c, respectively, to indicate the possibility of a cystic lesion. Recently, the Thy3 category has been subdivided into Thy3a to indicate a lesion with atypical features of uncertain significance and Thy3f to indicate the likelihood of a follicular neoplasm. Often, a confident diagnosis of colloid nodule (Thy2) or thyroiditis (Thy2), papillary, medullary and anaplastic carcinoma (Thy5), lymphoma (Thy5) and even

BOX 18.1 Risk factors for thyroid malignancy

- Age – a new thyroid nodule in patients <20 years or >50 years
- Male sex
- Clinical features – consistency, fixation, size, solitary versus multiple nodules
- A history of head and neck irradiation
- Familial history of thyroid malignancy of multiple endocrine neoplasia (MEN) 2
- Recurrent laryngeal nerve palsy
- Cervical lymphadenopathy

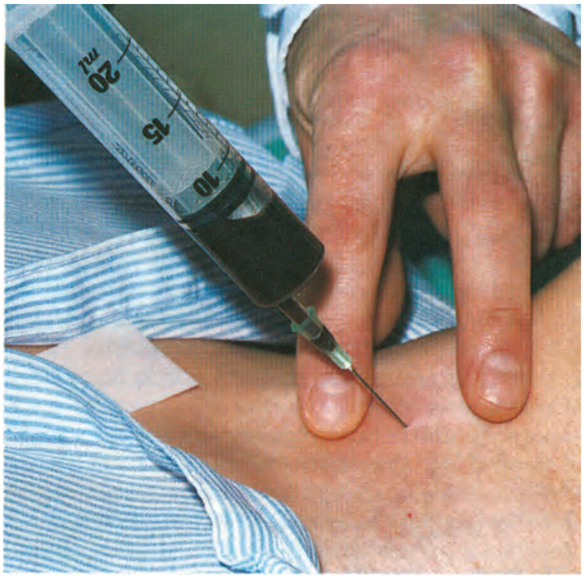

Figure 18.9 Fine needle aspiration cytology: a diagnostic and sometimes also a therapeutic procedure (as seen here with aspiration of a thyroid cyst).

metastatic deposits (Thy5) can be made. A major limitation of the technique is the evaluation of follicular lesions where histology is required to differentiate benign follicular lesion from carcinoma; the latter diagnosis is dependent upon the presence of capsular and vascular invasion. Core biopsy for these follicular lesions has been suggested by some authors, but increases the risk of haematoma and may still be inadequate for a definite histological diagnosis.

The positive and negative predictive values of a clear FNA result are over 98%. However, inadequate specimens should lead to repeat aspiration. Surgery may sometimes be indicated in a patient with repeated inadequate cytology. Benign lesions may be managed conservatively and FNA repeated to confirm the diagnosis. Clinical suspicion, increasing size of nodules, compressive symptoms and associated hyperthyroidism may be indications for surgery in nodules with benign cytology. Patients with indeterminate, suspicious and malignant results should undergo a thyroidectomy. The diagnosis of indeterminate and suspicious lumps may in the future be improved with immunocytochemical techniques.

Blood tests

These should be requested to measure TSH and free T_4 levels. The majority of patients with a thyroid nodule are euthyroid but coexisting thyroid dysfunction may point to the underlying pathology. For example, a hyperthyroid patient with a solitary nodule suggests a benign toxic (autonomous) nodule, whereas hypothyroidism may indicate nodular Hashimoto disease possibly with lymphomatous change. The presence of thyroid dysfunction will also influence further management. Patients with hyperthyroidism who need surgery would need to be made euthyroid with antithyroid drugs. In patients with a positive family history of MTC, serum calcitonin should be measured to aid diagnosis. This is also used for monitoring following treatment of MTC.

Imaging

High-resolution ultrasonography is now often performed as part of the diagnostic work-up of a thyroid nodule. It is sensitive in identifying impalpable nodules as small as 0.3 mm in diameter. Ultrasound detects multinodularity in around 50% of all nodules thought to be solitary on examination. It differentiates cystic from solid lesions and can identify associated lymphadenopathy, which could be a marker for malignancy. Other ultrasound features of malignancy include nodules with spiculated margins, hypoechogenicity and microcalcifications, but none of the findings are accurate enough to dictate clinical management. Its routine use in all patients presenting with a thyroid nodule or a multinodular goitre is probably unnecessary. An ultrasound is, however, quite useful in specific clinical scenarios. Ultrasound is used to characterize and guide FNA of a barely palpable nodule or an impalpable lump detected incidentally on other imaging [such as CT or positron emission tomography (PET)]. For patients being managed conservatively, ultrasound may also help in monitoring nodule size during follow-up. In the follow-up of patients with thyroid cancer, neck ultrasound helps to identify locoregional recurrence.

Chest radiograph, CT and MRI have little role in the differentiation of benign and malignant lumps, but do help to determine the presence and degree of retrosternal extension and extent of tracheal deviation or compression (Figure 18.10).

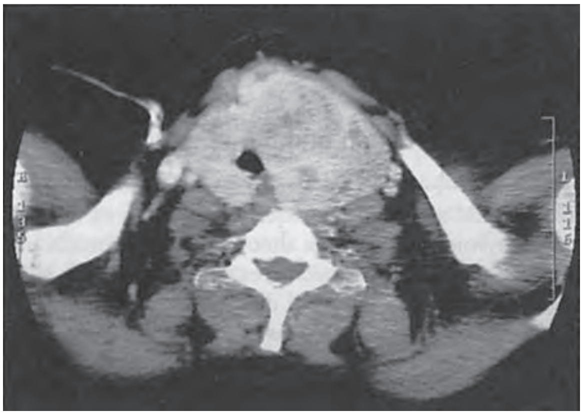

Figure 18.10 CT scan of the neck demonstrating tracheal deviation and compression.

Isotope scanning is not useful in differentiating between malignant and benign lesions and its role is now limited to patients with coexisting hyperthyroidism to aid in the diagnosis of a solitary toxic adenoma and to determine areas of hyperfunction in a patient with toxic multinodular goitre.

Treatment

This section will focus on the management of benign nodular disease. The treatment of the various forms of thyroid cancer will be covered in subsequent sections. An algorithm for the management of nodular thyroid disease is presented in Figure 18.11.

FNAC may be both a diagnostic and therapeutic tool for the management of simple thyroid cysts. However, surgical excision may still be required in a small number of patients in whom there is recurrent cyst formation or a suspicious residual nodule.

A long-term follow-up study of putatively benign thyroid nodules has demonstrated that just over a third of nodules disappear and most nodules reduce in size over a 10–30 year period (Kuma *et al*. 1992). However, 26% of enlarging nodules were found to be malignant. A further report by the same group (Kuma *et al*. 1994) on clinical re-examination, FNAC and ultrasound-guided FNAC to assess nodules over 9–11 years has clearly demonstrated that 99% of benign nodules remain benign, with the majority decreasing in size or disappearing during the follow-up period. The worrying clinical feature remains an increase in nodule size. Clearly there should be a high index of suspicion for lesions that increase in size during follow-up.

Surgery

The majority of multinodular goitres are benign and not associated with significant compressive symptoms and can therefore be treated conservatively. However, surgery is indicated for the following reasons:

- suspected or proven malignancy on FNA
- compression of the trachea or oesophagus
- significant recent growth of a dominant nodule (suggestive of malignancy)
- local neck discomfort
- cosmetic reasons.

The need for surgery is based on the overall assessment of symptoms, clinical risk factors and cytology. Indeterminate, suspicious or malignant cytology are clear indications for surgery. Recurrent cysts and solid nodules that repeatedly yield an inadequate sample on cytology are also indications for surgery. Other scenarios in which surgery is considered include patients with large nodules causing pressure symptoms (e.g. dyspnoea, dysphagia or choking sensation), nodules increasing in size on follow-up and increased patient anxiety especially in the context of a family history of thyroid cancer.

Surgery for nodular thyroid disease usually includes one of the following operations:

- hemithyroidectomy/lobectomy for unilateral disease
- isthmectomy for a solitary nodule confined to the isthmus
- total thyroidectomy for bilateral nodularity and solitary nodules with malignant cytology.

Nodule excisions and subtotal resections of either the lobe or the thyroid gland are no longer performed. In patients with a preoperative diagnosis of thyroid cancer, a prophylactic central node dissection is performed by many authors at the time of the total thyroidectomy. If suspicious/confirmed lateral lymph node metastases are present, a lateral node dissection is also done (see below).

During a hemithyroidectomy/lobectomy for unilateral disease with indeterminate/suspicious cytology, the surgeon palpates the contralateral lobe through the strap muscles. If the other lobe is grossly normal and there is no associated lymphadenopathy,

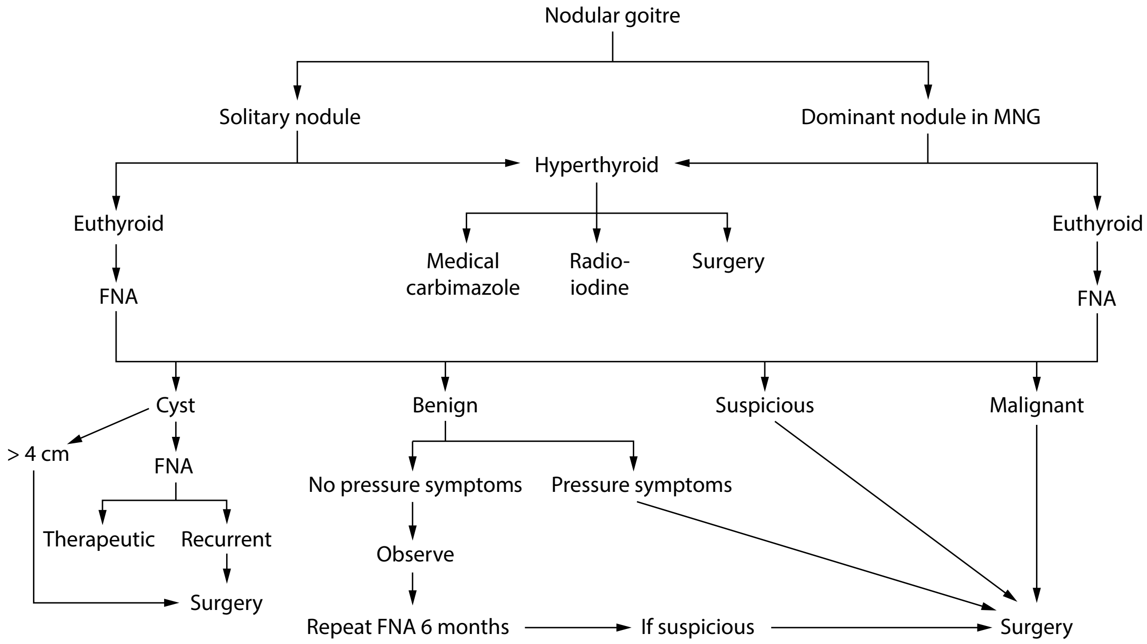

Figure 18.11 Algorithm for the management of a patient with a thyroid nodule. FNA, fine needle aspirate; MNG multinodular goitre.

a total thyroid lobectomy removing isthmus and pyramidal lobe (if present) is performed preserving the parathyroid glands, the EBSLN and the RLN. This is a safe procedure with low morbidity when performed in experienced hands. Frozen section may occasionally be useful in confirming malignancy leading to total thyroidectomy and avoiding a second operation. If there is any doubt (particularly with follicular lesions) then the neck is closed and formal paraffin histology is awaited.

Non-surgical options of treatment of benign non-toxic goitre

Several non-surgical options have been explored in an attempt to avoid surgery in patients with benign non-toxic goitre. RAI is a particularly useful alternative to surgery in patients who are unfit for surgery, unwilling to consider surgery and in those with recurrent disease. RAI may reduce goitre volume by around 50% and improve compressive symptoms. The drawbacks include transient hyperthyroidism, occasional increase in goitre size, late onset hypothyroidism and the theoretical increased risk of malignancy. The lack of a consistent effect may be related to low or patchy uptake in many patients – an argument for higher dose recommended by some authors. More recently, recombinant TSH has been used to increase uptake at lower doses and may prove more effective than RAI alone.

Thyroxine and iodine supplementation have been tried but are not routinely recommended in view of inadequate response rates, side effects (hyperthyroidism, cardiovascular and skeletal problems) and potential for regrowth following cessation of treatment. Percutaneous injection of ethanol has also been tried, but its use is largely experimental.

Thyroid cancer

Thyroid cancer is uncommon; the age-standardized incidence rate in the UK is around three per 100 000 per year. The incidence in the USA is twice that in Europe; the reasons for this are not clear but could be related to the increased use of imaging resulting in the detection of early stage, good prognosis cancers. Most thyroid cancers fall under the category of differentiated thyroid cancer (DTC), among which papillary thyroid cancer (PTC) makes up the vast majority. The various types of thyroid cancer are shown in Figure 18.12, and the risk factors for thyroid malignancy are shown in Box 18.1.

Differentiated thyroid cancer

Epidemiology

These cancers arise from follicular epithelial cells of the thyroid gland. The incidence of DTC in general and PTC in particular has more than doubled in the last 30 years. Interestingly, however, the incidence of follicular thyroid cancer (FTC) has not increased; this is at least partly due to a recent increase in the number of follicular cancers being classified as follicular variant PTC.

Papillary thyroid cancer

PTC accounts for around 80% of all malignant thyroid tumours. The histological diagnosis rests on characteristic nuclear features. Typical PTC shows a complex papillary architecture. It is also classically described as 'psammoma bodies', which are spherical areas of concentrically laminated calcifications in stroma or lymphatic spaces. Many variants of PTC exist and these include encapsulated, microcarcinoma (<1 cm), follicular, oncocytic, clear cell, diffuse sclerosing, tall cell, columnar cell, solid and cribriform variants. PTC typically spreads by the lymphatic route and occult lymph node metastases are thought to be present in around half of patients without any evidence of lymphadenopathy. The prognosis of these cancers in general is very good with >90% 10-year survival. Some subtypes such as the diffuse sclerosing, tall cell and columnar cell variants carry a worse prognosis.

Follicular thyroid cancer

This accounts for around 10% of all thyroid tumours. These tumours also arise from follicular cells, but lack the nuclear features of PTC. Iodine deficiency is thought to play an important role in its development. The cellular appearances are indistinguishable from follicular adenomas and therefore, as explained earlier, cytology is inadequate to differentiate between follicular adenomas and carcinomas. The types of FTC include minimally invasive follicular carcinomas, widely invasive follicular carcinomas, oncocytic follicular carcinomas and clear cell carcinomas. These cancers are often multifocal and spread predominantly by the haematogenous route to organs such as lung and bone. Lymph node metastases are uncommon. Prognosis is slightly worse than PTC; survival is around 85% at 10 years.

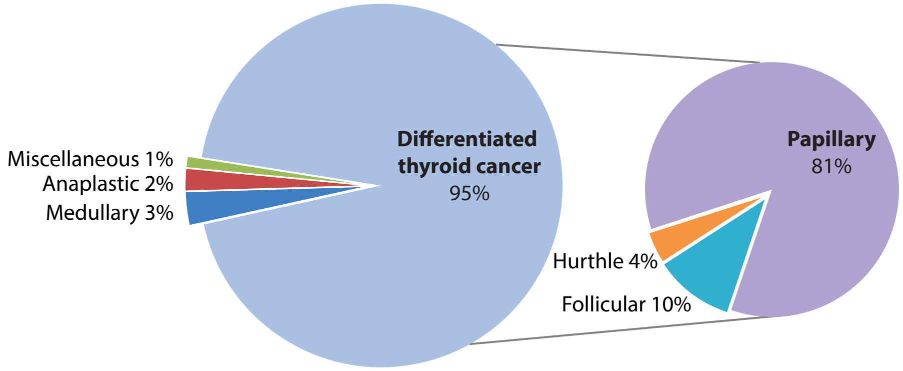

Figure 18.12 Thyroid cancer types and subtypes.

Hurthle cell cancer

Hurthle cell cancer (HCC) is a distinct variant of FTC, although Hurthle cells can be found in a variety of other neoplastic and non-neoplastic conditions. Hurthle cells typically have abundant altered mitochondria that fill up the cytoplasm resulting in the characteristic eosinophilic granular cytoplasm. In HCC, the lesion is composed predominantly (>75%) of Hurthle cells. These have a poorer prognosis than other FTCs and are slightly resistant to radioiodine. In variance with other FTCs, lymph node metastases occur in around 20% of patients with HCC.

Poorly differentiated cancers

These lie in the spectrum between differentiated and undifferentiated (anaplastic) cancers and arise from the follicular epithelium. These are often infiltrative and have necrotic areas and obvious vascular invasion. Insular, trabecular and solid patterns are recognized.

Mixed tumours

These are also recognized, in which varying proportions of the above tumour types are seen.

Prognosis

The prognosis of DTC is in general excellent with overall cure rates of around 90%. In general terms, 80–90% of patients will fall within the 'best' prognostic group, in whom disease-specific death occurs in no more than 2% of patients. In the worst prognosis groups, the 20-year mortality rate is around 75–95%. Some subtypes (tall cell, diffuse sclerosing and columnar varieties of PTC, HCC) and some factors (such as male sex, age >45 years at diagnosis, incomplete resection, extrathyroidal spread, presence of distant metastases) are associated with a worse prognosis and have higher recurrence rates. Several classification systems have been proposed to stratify risk and include the following:

- AMES: Age, Metastases, Extent of primary tumour, Size of presentation.
- AGES: Age, Grade, Extent of primary tumour, Size of tumour.
- MACIS: Metastases, Age, Completeness of resection, Invasion of extrathyroidal tissues, Size of tumour.
- TNM staging (5th edition):
  - *Tumour*
  - Tx: Primary tumour not identified or assessed
  - T0: No evidence of primary tumour
  - T1a: Tumour 1 cm, limited to thyroid
  - T1b: Tumour >1 cm and 2 cm
  - T2: Tumour >2 cm and 4 cm, limited to thyroid
  - T3: Tumour >4 cm, limited to the thyroid or with minimal extrathyroidal extension to strap muscles of perithyroidal soft tissue
  - T4a: Tumour invading subcutaneous soft tissues, larynx, oesophagus or RLN
  - T4b: Tumour invading prevertebral fascia, carotid sheath or mediastinal vessels
  - *Node*
  - Nx: Regional lymph nodes not assessed
  - N0: No regional lymph node metastasis
  - N1a: Level VI node metastases
  - N1b: Metastases to unilateral, bilateral or contralateral cervical nodes (levels I, II, III, IV or V), retropharyngeal nodes or superior mediastinal nodes (level VII).
  - *Metastasis*
  - Mx: Metastasis not assessed
  - M0: No distal metastases
  - M1: Distal metastases present.

Clinical features and investigations

These have largely been discussed in the section on thyroid nodules. The diagnosis of DTC may be made on clinical grounds, by thyroid cytology or following a thyroidectomy. Most cases are diagnosed following a lobectomy or total thyroidectomy for nodules that are apparently benign, indeterminate or suspicious on cytology. In patients with cytology diagnostic of cancer, an ultrasound (with or without CT/MRI in some centres) may help to detect abnormal regional lymph nodes. This will enable an appropriate level lymphadenectomy to be done at the time of thyroidectomy. In patients with clinically palpable lymphadenopathy or locally advanced disease (abnormal regional lymph nodes or a locally infiltrative tumour), CT or MRI of the neck is essential to ascertain the extent of extrathyroidal spread and lymphadenopathy.

Treatment

Thyroidectomy is the primary treatment for most patients with DTC. Most surgeons recommend total or near total thyroidectomy for all patients with DTC but unilateral lobectomy and isthmectomy may be adequate for some *low-risk* patients with DTC such as:

- patients with papillary microcarcinoma (<1 cm)
- minimally invasive follicular cancer without vascular invasion in young patients
- the encapsulated follicular variant of PTC.

In the significant proportion of patients in whom the diagnosis is only made following an isthmectomy or hemithyroidectomy and a completion thyroidectomy is required, this should be performed within 7 days or after 3 months have elapsed from primary surgery to minimize risks of morbidity associated with postoperative scarring.

Lymph node dissection

The need for and extent of lymphadenectomy depends on the type of cancer (PTC and HCC are associated with lymph node spread) and the presence of palpable lymphadenopathy. Lymph nodal spread is usually first to the central compartment (levels VI and VII) and then to levels III, IV and V in the lateral compartment. However, occasionally skip metastases occur. Patients with obvious lymph node metastases need a central compartment node dissection and lateral compartment node dissection on the involved side. Levels I and II are usually spared but if involved should be dissected as well. The role of prophylactic central compartment dissection in patients with PTC and HCC without obvious nodal disease is more controversial. Proponents of routine prophylactic central neck dissection point to the high incidence of occult lymph node metastases in PTC and demonstrate low rates of side effects such as RLN damage and hypoparathyroidism in experienced hands. Opponents of prophylactic neck dissection argue that occult nodal metastases are unlikely to affect long-term outcomes and can be dealt with if and when identified on follow-up. The authors adopt a selective policy and perform a prophylactic central node dissection in patients with high-risk features such as male sex, age >45 years, tumour >4 cm in diameter, extracapsular spread and extrathyroidal invasion.

Radioactive iodine

An ablative dose of RAI (^{131}I) is used as standard adjuvant treatment following total or near total thyroidectomy for DTC. The treatment is based on the premise that thyroid cancer cells in DTC are iodine avid and would be ablated by RAI. RAI is not recommended for patients undergoing only a hemithyroidectomy for low-risk disease. The ablation of any residual thyroid tissue also facilitates the use of thyroglobulin as a tumour marker to screen for residual and recurrent disease. Thyroid hormones are usually withdrawn in preparation for RAI treatment to allow TSH levels to rise and increase iodine uptake by thyroid tissue. Patients receiving RAI within 3–4 weeks after thyroidectomy do not need treatment with thyroid hormones. However, for patients in whom RAI treatment may be delayed or for patients needing further RAI treatment for residual or recurrent disease, treatment with T_3 is started and this is withdrawn for 2 weeks before RAI treatment. Patients are also advised a low-iodine diet for 2 weeks prior to treatment. Although preablation diagnostic ^{123}I is now not routinely used, it may help in assessment of residual thyroid surgery if completeness of resection is not known. Postablation diagnostic scans are often carried out to assess the effectiveness of ablation.

Thyroxine suppression

Normal thyroid cell differentiation and proliferation is TSH dependent. TSH receptors are also present in DTC cells. Thyroxine suppression treatment is based on the principle that high doses of thyroxine would suppress TSH levels and thereby proliferation of thyroid cancer cells. Patients receive lifelong thyroxine, at doses necessary to suppress TSH to undetectable levels. T_3 may be used if follow-up radioactive iodine scans or ablation are required, as it has a shorter half-life than thyroxine, and only requires to be stopped 2 weeks prior to RAI use. Long-term effects of suppressive doses of thyroxine include cardiovascular morbidity and osteoporosis.

External beam radiotherapy

External beam radiotherapy to the neck is used only in patients with extensive extrathyroidal disease and in patients whose tumours are not radioiodine avid.

Follow-up of patients with differentiated thyroid cancer

Recurrent thyroid cancer may occur soon after initial therapy or years later. Patients with thyroid cancer should be followed up lifelong in a multidisciplinary thyroid cancer clinic. A history and examination looking for evidence of recurrent neck lumps and features of thyrotoxicosis and measurements of TSH and thyroglobulin (including thyroglobulin antibody) levels should be done at every visit. Calcium levels should also be measured in patients who have persistent hypothyroidism following surgery. A follow-up diagnostic radioactive iodine scan may be needed in patients with high-risk disease or if the serum thyroglobulin levels are high/rising, which should be minimal or undetectable in patients who have undergone definitive treatment (surgical and radioactive iodine). Diagnostic and ablation scans both require hormone withdrawal, although more recently recombinant TSH has been used as an alternative. Ultrasound scanning of the neck may be necessary in patients with palpable lumps and rising thyroglobulin levels, although it also used routinely for follow-up in some centres. 18-Fludeoxyglucose–PET scanning can help detect recurrent disease in scan-negative patients with rising thyroglobulin levels.

Recurrent differentiated thyroid cancer

Recurrence may be local or regional (in the neck) or systemic. Treatment will depend on the subtype of DTC, the nature and extent of initial treatment and the site of recurrence. Surgery is the mainstay of treatment of local/regional recurrence. Surgery may be followed by RAI scanning with/without ablation and, in some cases, external beam radiotherapy. Distant metastases will usually occur in the lungs or skeletal system. Although distant metastases cause cancer death in 10–15% of patients with DTC, they are compatible with long-term survival. They may present as a result of local symptoms, neurological complications or rising thyroglobulin levels. Radioactive iodine is the mainstay of treatment for recurrent disease. Palliative surgical procedures may be appropriate if there are orthopaedic/spinal complications. It should be remembered that metastases may be solitary. Remission will occur in 50% of patients with distant metastases that take up radioiodine (10 years survival 25–40%).

Medullary thyroid cancer

Epidemiology

MTC accounts for up to 5% of all thyroid cancer. This tumour arises from the parafollicular C cells of the thyroid, which have a neural crest origin. Around a quarter of these cases are familial. The disease may occur in one of four clinical settings:

1. sporadic
2. familial – MEN 2A
3. familial – MEN 2B
4. familial non-MEN-associated MTC.

The mortality rate for MTC exceeds that of DTC; overall, the 10 year survival rate is around 75%. Factors that indicate a poor prognosis include age >40 years at presentation, male sex, extrathyroidal spread, nodal involvement, metastases, tumour aneuploidy, negative amyloid staining and familial disease. However, long-term survival of patients with metastatic disease is common in MTC.

Clinical features and investigation

Sporadic MTC usually presents as a thyroid nodule and/or lymph node enlargement. Associated symptoms include those secondary to airway/oesophageal compression, pain, diarrhoea and rarely Cushing syndrome owing to gut peptide or adrenocorticotrophic hormone release by the tumour. The diagnosis may be confirmed on thyroid cytology or following lobectomy for a thyroid nodule. In all cases, family history for thyroid cancer/phaeochromocytoma should be determined. The absence of a family history does *not* preclude an apparently sporadic MTC being the index case of genetically determined disease.

If the diagnosis of MTC is made on cytology, preoperative investigations should include basal calcitonin and carcinoembryonic antigen (CEA), ultrasound of the neck to identify multiple thyroid lesions (a marker of familial disease) and lymph node enlargement. CT/MRI may identify mediastinal node involvement. Genetic screening (on a venous blood sample) for a *Ret* proto-oncogene mutation is required in all patients to exclude familial disease; but this can wait until after surgery.

Phaeochromocytoma must be excluded prior to operation in all cases by a normal 24 hour urine collection for catecholamines/metanephrines.

In families affected by or likely to be affected by genetically determined MTC, screening for *Ret* mutations in individuals at risk should be performed. Prophylactic thyroidectomy is indicated in family members without clinically apparent disease but who are carriers of the germline *Ret* mutation. The different *Ret* mutations are associated with different degrees of susceptibility and disease aggressiveness and recent recommendations on the age at which prophylactic thyroidectomy should be performed in children positive for this mutation are based on the site of the mutation.

Treatment

The current standard operation in the absence of lymph node metastases is total thyroidectomy and central compartment neck node dissection. Biopsy and frozen section examination of any enlarged jugulocarotid lymph nodes from either side of the neck should be performed. If these nodes are positive they should be removed and a lateral neck dissection should be done. If lymph node metastases are detected preoperatively in the lateral compartment, a selective node dissection of this compartment should be done at the same sitting. If there is evidence of involvement of anterior/superior mediastinal node involvement at presentation, these nodes should be cleared (sternotomy would be required). In all cases the parathyroid gland should be identified and preserved. In MEN 2 patients only enlarged parathyroid glands should be excised. After surgery *replacement* doses of thyroxine are given. There is no indication for TSH suppression or radioactive iodine in the treatment of MTC.

Follow-up of patients with medullary thyroid cancer

Long-term follow-up of these patients is required. At review, basal calcitonin, CEA and TSH levels should be measured in addition to a history and physical examination. Detectable or raised calcitonin and/or CEA levels indicate residual or recurrent disease and warrant a search for locoregional and metastatic disease. This requires the use of high-resolution CT of the neck/chest/liver, and/or one or more of the isotope scans with pentavalant dimercaptosuccinic acid, ^{123}I-metaiodobenzyl guanidine or radiolabelled octreotide. Further treatment decisions (including surgical resection or observation) are made in a multidisciplinary forum and are influenced by the presence of symptoms, levels of tumour markers, findings on imaging, age and associated morbidity.

Patients with MEN 2 require biochemical testing to exclude a phaeochromocytoma and primary hyperparathyroidism at least on an annual basis.

Treatment of recurrent/metastatic disease

Surgery is the treatment of choice for local/regional recurrence. MTC is generally considered resistant to chemotherapy. The response to radiotherapy is generally poor but may be useful in patients with inoperable disease and symptomatic bone metastases. Diarrhoea may be severe and intractable in recurrent disease and should be controlled by the use of antidiarrhoeal agents including codeine phosphate and loperamide.

Undifferentiated thyroid carcinoma

Epidemiology

Undifferentiated or anaplastic thyroid carcinoma, in contrast to well-differentiated thyroid carcinoma, is a highly aggressive tumour, with around 70% of patients having metastases at the time of presentation. This is more common in areas with iodine deficiency and endemic goitre. Undifferentiated thyroid carcinoma may be classified as small cell, large cell or spindle cell, which may resemble sarcomas. Small cell carcinomas must be distinguished pathologically from lymphoma, which has a far more favourable prognosis.

Clinical features and Investigations

Diagnosis can usually be confirmed by a core biopsy under local anaesthetic, as FNA for cytology may not be diagnostic. Patients generally present with a large, hard, ill-defined cervical mass fixed to adjacent structures. There is often a history of a longstanding goitre. The sex incidence is similar and most patients present between 60 and 70 years of age. Occasionally, undifferentiated thyroid carcinoma may develop as a transformation of a previously treated well-differentiated thyroid carcinoma, which may have been in remission for a considerable time.

Treatment

Treatment of these patients is with a multimodal approach using surgery, radiotherapy and chemotherapy. Surgery is feasible and often necessary to relieve symptoms. Even in the absence of extrathyroidal spread, it is only considered a palliative procedure. Often only debulking is possible and a tracheostomy is required. Tracheal/oesophageal stenting should sometimes be considered if surgery is not successful or possible. External beam radiotherapy is usually given to these patients in an attempt to slow tumour progression. Response to chemotherapy is generally poor but regimes containing doxorubicin can give partial remission in around 20% of patients. Undifferentiated thyroid carcinoma is not responsive to ^{131}I therapy.

In some centres, preoperative chemoradiation followed by total thyroidectomy in patients has shown some promise. However, no standard treatment protocol exists currently and efforts are under way to investigate newer chemotherapeutic agents including tyrosine kinase inhibitors in an attempt to improve response. The prognosis remains very poor, with the majority of patients dead within a year of diagnosis.

Thyroid lymphoma

Epidemiology

Thyroid lymphomas are rare, occur more often in women (female to male ratio 3:1) and the incidence increases with age (most patients are aged >60 years). Thyroid lymphoma is often associated with a history of autoimmune thyroid disease (80% of patients).

Clinical features and investigations

The diagnosis is often suspected clinically by the history of long-standing goitre/hypothyroidism and a rapidly enlarging neck mass with a minority complaining of compressive symptoms. FNA is often inconclusive but usually shows plenty of lymphocytes. A core biopsy is needed to confirm the diagnosis and allow immunohistochemical subtyping of the lymphoma. Most thyroid lymphomas are mucosa-associated lymphoid tissue lymphomas and diffuse large -cell lymphomas. CT scanning often shows homogeneous thyroid enlargement without invasion of adjacent structures. CT of the chest, abdomen and pelvis is also done as part of staging of the lymphoma. Other investigations for lymphoma include full blood count, $_2$-microglobulin and bone marrow biopsy.

Treatment

Some patients will present with acute airway obstruction. Intravenous steroids can achieve rapid resolution of symptoms but, wherever possible, it should be given after a tissue diagnosis has been obtained. External beam radiotherapy may also be of value in relieving acute symptoms.

There is no evidence that surgery offers any benefit to patients with lymphoma. Following diagnosis and treatment of upper airway symptoms the patient should be referred to an oncologist. Staging with CT scanning, liver function tests and full blood count is performed. Treatment for this disease includes chemotherapy (the 'CHOP' (consists of cyclophosphamide, doxorubicin, vincristine and prednisolone) regimen) and/or radiotherapy.

Thyroidectomy

It was not until the early twentieth century that thyroidectomy became a safe and acceptable operation with the advent of general anaesthesia, antisepsis and haemostatic techniques. Theodore Kocher of Berne, Switzerland, was the chief protagonist of these methods and, for his lifetime devotion to the development of safe thyroid surgery, was awarded the Nobel Prize in 1909, by which time the previous high mortality had fallen to <1%. Further advances by William Halsted, Charles Mayo, George Crile and Frank Lahey led to techniques that remain the basis of safe thyroid surgery and continue to be practised today by trained endocrine surgeons.

Preoperative preparation

As with all surgical procedures, a full and written informed consent should be obtained after explaining the need for the operation, the implications of having the procedure, the risks of complications (see below), alternative treatment options and any other relevant details the patient might wish to discuss. A higher risk of complications should be emphasized when re-exploration or cancer surgery is performed.

Preoperative preparation should include laryngoscopy to exclude pre-existing unilateral nerve palsy, especially if the patient has undergone previous thyroid surgery. A serum calcium level is also routinely obtained as baseline to compare postoperative calcium levels with.

Surgical principles and approaches

Removal of one or both thyroid lobes, isthmus and additional thyroid tissue, such as the pyramidal lobe, as well as identification and preservation of the laryngeal nerves and parathyroid glands are the key objectives of thyroid surgery. A detailed knowledge of surgical anatomy, meticulous dissection and care to avoid bleeding are crucial to the achievement of these objectives. A number of different instruments and aids are now in use for dissection including the traditional 'tie and cut', bipolar diathermy, clips, ultrasonic dissection and thermal coagulation. However, these cannot replace careful dissection by experienced hands.

The standard approach to a thyroidectomy is through a collar incision in the neck. Endoscopic approaches have been described for small thyroid nodules (<3 cm in diameter), the primary aim of which is to avoid a neck scar. These procedures, however, involve the introduction of a camera and endoscopic instruments through incisions in the chest and axillae; have no proven superiority in terms of clinical outcomes; have a prolonged learning curve; and are not practised by the authors. Further description will only relate to the open approach. It is acknowledged that there will be significant variations in operating technique as practised by surgeons across the world; the following technique is the one that is used by the authors.

Operative steps

General anaesthesia with endotracheal intubation is deployed and the patient is placed supine on an operating table 15° head-up and the neck in near full extension with a sandbag (or inflatable bag) in the interscapular position.

Access

A collar incision is used two finger-breadths above the sternal notch extending to both sternomastoid muscles. The incision is extended through subcutaneous fat and platysma down to the deep fascia and, by a process of blunt and sharp dissection, this plane (anterior to the anterior jugular vessels) is extended superiorly to the level of the thyroid notch and inferiorly to the sternal notch, with the skin flaps then held apart using a self-retaining retractor. The strap muscles on either side are separated by dividing the deep fascia in the midline and retracted laterally. This should be as long as possible to enable full access to the operative field. Transverse division of the strap muscles is not routinely required but may be occasionally used for safe access to a large or vascular goitre. The deeper sternothyroid muscle is usual slightly adherent to the capsule and is separated from it with careful blunt and sharp dissection.

The middle thyroid veins, when present, are divided to increase access to the thyroid lobe, which is then delivered using traction from the index finger on a small swab over the lobe with the strap muscles retracted laterally. The lateral aspect of the thyroid lobe is now exposed from the superior pedicle superiorly to the lower pole inferiorly. The plane between the thyroid, larynx and oesophagus medially and the carotid artery laterally is opened by dividing the loose areolar tissue in this region; this increases the mobility of the thyroid lobe.

Superior pedicle

The upper pole is then retracted inferolaterally to open the space between the superior thyroid vessels and the cricothyroid muscle (Figure 18.13). The branches of the superior thyroid pedicle are divided at their entry into the thyroid on the surface of the capsule well away from the EBSLN, which usually runs along the surface of (or within) the cricothyroid but may also pass between the branches of the vessels where it is in danger of injury if mass ligation of the superior thyroid pedicle is carried out. The superior pole of the lobe may now be delivered partially into the midline. Further ligation of the small vessels entering the thyroid capsule may be required at this stage and care should be taken to avoid injury to the superior parathyroid gland.

The recurrent laryngeal nerve

Medial retraction on the lobe will now bring into view the deeper aspect of the middle third of the thyroid lobe and the adjacent junction between the inferior thyroid artery and the RLN (Figure 18.14). The RLN can be identified in three locations – upper (at the point of entry into the larynx at around the cricothyroid junction), middle (at the junction with the inferior thyroid artery) and lower (between the medial wall of the carotid artery and the lateral wall of the thymus). The nerve is seen following dissection of the overlying fascial layers and recognized as a white cord with an overlying vasa nervosum. The nerve lies in the tracheo-oesophageal groove (especially on the left) and runs upwards, passing anterior, posterior or through the branches of the inferior thyroid artery. However, its course is variable, especially on the right side. The right RLN lies in a more oblique direction. In around 1% of cases the right nerve may be non-recurrent and pass medially close to the inferior thyroid artery before turning to ascend to enter the larynx. These nerves also occasionally divide into branches before entering the larynx where the inferior cornu of the thyroid cartilage is a fairly constant landmark for its point of entry. The nerve is perhaps most in danger at its point of entry into the larynx as it passes through the suspensory ligament of Berry, where it often adopts a curving loop (Figure 18.14), and the nerve must be carefully identified in this region before dividing the suspensory fascia by staying close to the thyroid capsule at all times.

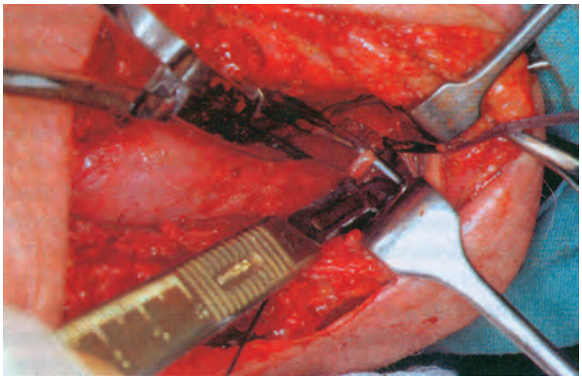

Figure 18.13 Division of the left superior thyroid artery.

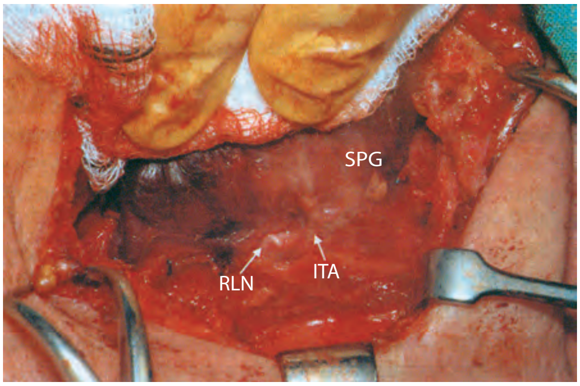

Figure 18.14 Exposure of the neurovascular intersection of the inferior thyroid artery (ITA) and recurrent laryngeal nerve (RLN). The superior parathyroid gland (SPG) can be found within a 2 cm radius cranial to the intersection, usually posterior to the RLN and thyroid gland. Note the looping of the RLN within Berry's ligament close to its insertion beneath the cricothyroid.

The parathyroid glands

The superior parathyroid gland is most commonly found superior to the inferior thyroid artery and posterior to the RLN, and the inferior gland often lies inferior to the inferior thyroid artery and anterior to the RLN. Attempts should be made to identify both the superior and inferior glands during lobectomy, but it may sometimes be appropriate to avoid an extensive dissection simply to identify the parathyroid glands as the dissection increases the risk of devascularizing the glands. In addition to the glands, care should be taken to preserve individual branches of the thyroid arteries supplying them. It is for this reason that the inferior thyroid artery is not ligated at its trunk, so as to preserve the small branches supplying the parathyroid glands. If the parathyroid glands are rendered ischaemic at thyroidectomy the individual gland may be excised and is minced into 1 mm cubes and autotransplanted into a pocket in the sternomastoid muscle.

Resection of the lobe

Dissection is continued by dividing the individual branches/tributaries of the main thyroid arteries and veins close to the thyroid capsule. Further dissection aims to divide the dense fascia binding the thyroid lobe to the trachea and larynx with particular attention to clipping and ligation near Berry's ligament, where troublesome bleeding may obscure the entry point of the RLN to the larynx. The mobilization is now complete and dissection is continued to include the isthmus and pyramidal lobe where present. The cut surface of the contralateral thyroid lobe is usually sutured with fine absorbable sutures to the tracheal fascia to obtain haemostasis.

Wound closure

The sandbag is now removed (or the inflatable bag can be deflated) from under the patient's spine and the neck space is examined for bleeding (occasionally a Valsalva manoeuvre may be performed by the anaesthetist). Haemostasis is secured and the wound is closed in layers (strap muscles, platysma and subcuticular layers) with 3/0 Vicryl or Monocryl. Drains are not required routinely, but may be useful in cases of significant oozing from the thyroid bed to prevent seromas after resection of very large goitres and if a neck dissection has also been done.

Total and subtotal thyroidectomy

In patients undergoing total thyroidectomy for cancer, bilateral multinodular disease or Graves' disease, the opposite lobe will be mobilized in a similar manner to that described above. Central compartment (with/without lateral compartment) node dissection may also be done at the same time (see below for details). Subtotal thyroidectomy, in general, is avoided, although it may be useful in Graves' disease if compliance with thyroxine replacement postoperatively is unlikely. In this procedure, a small remnant (usually 4–5 g of tissue) is left on each side of the trachea and sutured to the trachea with 3/0 Vicryl absorbable sutures to secure haemostasis. Some surgeons instead perform a unilateral total lobectomy leaving a single larger remnant on the contralateral side, which is an acceptable alternative strategy.

Retrosternal goitre

Ligation and division of the superior vessels is essential before any attempt is made to deliver the retrosternal component. This is achieved by introducing a finger down into the mediastinum behind the sternum and using gentle traction, which may be aided by the use of a bent dessert spoon when dealing with a very large multinodular gland. Care should be taken to avoid injury to the RLN, which may occasionally lie on the surface of the retrosternal component. A mediastinal split is seldom necessary.

Variations in technique

There are many variations to the above-described steps, which are useful in different situations. It may be appropriate to mobilize the lower pole first in some instances, especially if there is significant upper pole enlargement and extension towards the base of the skull. Early division of the isthmus is also a useful technique to aid in the mobilization of the lobe, especially in large goitres.

Complications of thyroid surgery

Thyroidectomy is a commonly performed and safe surgical procedure with a low morbidity and negligible mortality when performed by appropriately trained surgeons. General complications are those of anyone undergoing a general anaesthetic such as cardiac events, chest infection and venous thromboembolism, but these are uncommon following thyroid surgery with a current mortality rate in several large series approaching zero. The morbidity of thyroidectomy from its specific complications, however, continues to be a matter of concern (Box 18.2). Clearly, meticulous attention to operative technique is required and this is now an area for the trained endocrine surgeon rather than a general surgeon. Litigation for thyroidectomy complications amount to approximately 5% of general surgical claims, most of which involve RLN injury.

To avoid damage to the RLN a detailed knowledge of its variable anatomy and identification during surgery is essential. Bilateral palsy is exceedingly rare but may lead to temporary or permanent tracheostomy. This is most likely to be a problem in redo surgery when one RLN has already been permanently damaged. The frequency of RLN injury following thyroid surgery should be <1%, although audits of this outcome should reflect case mix and operative experience. The EBSLN is also at risk during thyroidectomy and permanent voice damage following its injury may occur and may be difficult to detect on indirect laryngoscopy. Such injury may be minimized if the nerve is identified and preserved during superior thyroid artery ligation.

Parathyroid damage producing hypocalcaemia is the second largest category of thyroid-related medicolegal claims and, although usually temporary, a long-term hypoparathyroid state has been shown to occur in up to 5% of cases. Most cases occur because of interruption of the arterial supply or obstruction of venous drainage, although inadvertent excision may also occur.

Hypothyroidism after total thyroidectomy is avoided by thyroxine replacement therapy, but can also occur with time after a subtotal resection. Recurrent hyperthyroidism after a subtotal resection presents more of a problem, as reoperation is associated with a significant increase in complications. Radioiodine ablation is probably a safer alternative to redo surgery.

BOX 18.2 Specific complications of thyroidectomy

- Respiratory distress: immediate postoperative period
  - RLN palsy
  - Acute laryngeal oedema
  - Wound haematoma
- Voice change (hoarseness, weakness, loss of high pitch): transient or long term
  - Injury to the EBSLN
  - RLN palsy
- Hypoparathyroidism: transient or long term
  - Bleeding
  - Infection
  - Hypothyroidism
  - Hypertrophic scarring or keloid

Postoperative reactionary haemorrhage is potentially catastrophic but can be avoided with meticulous haemostasis. However, the most serious and life-threatening complication is postoperative airway obstruction due to acute laryngeal oedema, which may or may not be associated with haematoma. The oedema is thought to be related to impaired lymphatic drainage of the larynx causing this internal oedema.

A well-positioned collar incision along a skin crease (if possible) gives adequate exposure and an excellent cosmetic result. However, wound complications occasionally occur and include a suture granuloma (which can be minimized by the use of absorbable suture material or clips), infection (cellulitis, abscess formation), hypertrophic scarring and keloid formation (especially in patients with an underlying predisposition).

Neck dissection

Radical neck dissection was first described by Jawdynski, a Polish surgeon in 1888. It was, however, popularized in the early twentieth century by Crile, a US surgeon, with whose name the operation remains synonymous today. The radical nature of the operation and the associated morbidity led to modifications of the technique in which vital structures such as the sternocleidomastoid, internal jugular vein and the spinal accessory nerve were preserved. These modifications led to the procedure being called 'modified radical' or 'functional' neck dissections and were developed by surgeons including Suarez, Bocca, Gavilan and Ballantyne. Further modifications involving excision of one or more lymph node groups in select compartments (levels) of the neck were termed 'selective' neck dissection.

Neck dissection terminology was standardized in 1991 by the American Academy's Committee for Head and Neck Surgery and Oncology. Lymph node groups were classified into levels, and six levels of the neck were initially described (level VII was added at a later stage). The levels in the neck are described below and depicted in Figure 18.15a,b.

- *Level I* is bounded by the midline medially, the body of the mandible superiorly, the posterior belly of the digastric laterally and the hyoid bone inferiorly. This level is further subdivided into level IA (the submental triangle) and level IB (the submandibular triangle) separated by the anterior belly of the digastric muscle.
- *Level II* is a triangular area bounded by the posterior belly of the digastric/stylohyoid muscle anteriorly, the posterior border of the sternomastoid posteriorly and an imaginary line along the inferior border of the hyoid bone inferiorly. The spinal accessory nerve divides this into a level IIA (anteroinferior to the nerve) and level IIB (posterosuperior to the nerve).
- *Level III* is the area below level II to the level of the cricothyroid notch (clinical landmark) or omohyoid (surgical landmark). The posterior border is again formed by the posterior edge of the sternocleidomastoid and the medial/anterior boundary is the lateral border of the sternohyoid muscle.
- *Level IV* is the area below level III, with the other boundaries being the posterior border of the sternocleidomastoid posteriorly, the clavicle inferiorly and the lateral border of the sternohyoid muscle anteromedially.

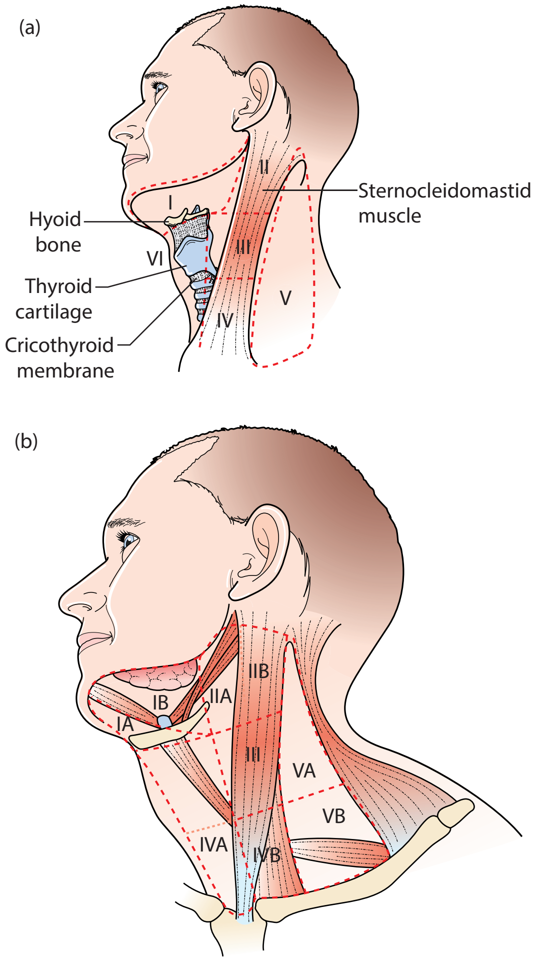

Figure 18.15 (a,b) Levels of the neck (see text for description).

- *Level V* is a triangular-shaped area bordered anteriorly by the posterior border of the sternocleidomastoid, the clavicle inferiorly and the anterior border of trapezius posteriorly. This is further subdivided into an upper VA around the spinal accessory nerve and a lower VB (or supraclavicular nodes) around the transverse cervical vessels; these being divided by the inferior belly of the omohyoid muscle.
- *Level VI* is also called the anterior compartment; this extends from the hyoid bone superiorly to the suprasternal notch inferiorly and the medial border of the carotid sheath laterally.
- *Level VII* is strictly mediastinal and refers to the area behind the manubrium and extends from the suprasternal notch superiorly to the brachiocephalic vein inferiorly.

General principles of neck dissection in thyroid cancer

Thyroid cancers are in general slow growing and lymph node metastases in thyroid cancer have not been shown to influence survival. Although berry picking of involved lymph nodes is to

Table 18.1 The vital structures in the various neck compartments (apart from the carotid sheath vessels, trachea and oesophagus) and consequences of their injury

	Vital structures	Consequence
Central compartment dissection	Parathyroid glands	Hypoparathyroidism
	Recurrent laryngeal nerves	Voice change, aspiration, tracheostomy (very rare)
	External branch of the superior laryngeal nerve	Inability to raise pitch of voice
Lateral compartment dissection	Salivary glands (level I) – very rare	Salivary fistula
	Marginal mandibular branch of the facial nerve (level I) – very rare	Drooping of the angle of the mouth on the ipsilateral side
	Spinal accessory nerve (levels II and V)	Drooping of the shoulder, and neck and shoulder dysfunction
	Hypoglossal nerve (level II)	Atrophy of the tongue and deviation towards the side of the palsy
	Vagus nerve	Vocal cord palsy (see as for the recurrent laryngeal nerve)
	Sympathetic chain	Horner syndrome (ptosis, miosis, anhidrosis, enophthalmos and loss of ciliospinal reflex)
	Cervical plexus injury	Numbness and paraesthesiae (often settles spontaneously)
	Thoracic duct (level V)	Chyle leak/fistula
	Phrenic nerve (level III/IV)	Ipsilateral diaphragmatic palsy
	Brachial plexus (level V)	Sensory and motor deficit affecting the shoulder and upper limbs

be condemned, the other extreme of radical and supraradical neck dissection is largely unnecessary and harmful in patients with thyroid cancer. Selective node dissection is the most commonly employed procedure.

The need for and the extent of lymph node dissection in thyroid cancer has already been discussed. Thyroid surgeons often refer to levels VI and VII as the central compartment and levels II–V as the lateral compartment. The commonest levels involved and operated upon in thyroid cancer are levels VI and VII (central compartment). Prophylactic central compartment neck dissection is routine in MTC and often selective in PTC. Lateral compartment lymph node dissection in thyroid cancer is usually done as a therapeutic procedure (i.e. when lymph nodes are palpable or shown to be pathological) and involves a selective clearance of levels IIA, III, IV and VB. Involvement of levels I, IIB and VA is very rare.

As mentioned previously in relation to thyroidectomy, a clear explanation of the need for and planned extent of lymphadenectomy should be given preoperatively. Complications specific to lymphadenectomy such as seroma formation, wound infection, bleeding from major vessels and damage to surrounding vital structures should be discussed. The vital structures in the various neck compartments (apart from the carotid sheath vessels, trachea and oesophagus) and consequences of their injury are shown in Table 18.1.

CHAPTER 19

Disorders of the parathyroid glands

PAUL R. MADDOX

Parathyroid embryology, anatomy and physiology

Embryology

The superior parathyroid glands originate from the dorsal tips of the fourth pharyngeal pouch, which is incorporated into the lateral aspect of the thyroid along with the ultimobranchial body; this common origin occasionally leads to an intrathyroidal location for the superior parathyroid gland, although this is rare.

The inferior parathyroid glands arise from the dorsal aspect of the third pharyngeal pouch, with the thymus originating from the ventral aspect. Together, they descend as a complex in a plane ventral to the fourth pharyngeal pouch, and the lower parathyroids are therefore found in a more anterior position than the upper parathyroids, usually dissociating from the thymus near the lower pole of the thyroid, but this migration can vary widely. With an absence of migration, the inferior parathyroid gland may be found superior to the upper pole of the thyroid mimicking a superior gland, but surrounding thymic tissue clarifies the true origin. If the inferior parathyroid remains attached to thymus, it will migrate to the anterior mediastinum.

Surgical anatomy

Awareness of the common pathways of migration is invaluable in parathyroid surgery (Figure 19.1). Eighty per cent of the upper parathyroid glands lie within a localized area of a 2 cm radius, cranial to the intersection of the recurrent laryngeal nerve (RLN) and the inferior thyroid artery (ITA). This is a very common symmetrical position for the superior glands, which are usually tucked away posterior to the upper pole of the thyroid. If the glands are sited more anteriorly they are located on the surface of the thyroid frequently beneath its capsule, where there is typically freedom of movement as opposed to prominent thyroid nodules which are fixed. Approximately 1% of superior glands are found in the paraoesophageal or retro-oesophageal space, from where they may descend to the posterior mediastinum owing to the effect of negative intrathoracic pressure of respiration.

More than half of the inferior parathyroid glands are located around the lower pole of the thyroid, with a quarter being found within the thyrothymic ligament or within the thymus itself. As the inferior gland becomes enlarged, it tends to migrate into the thymus within the anterior mediastinum, where up to one-third of all missed parathyroid tumours can be found.

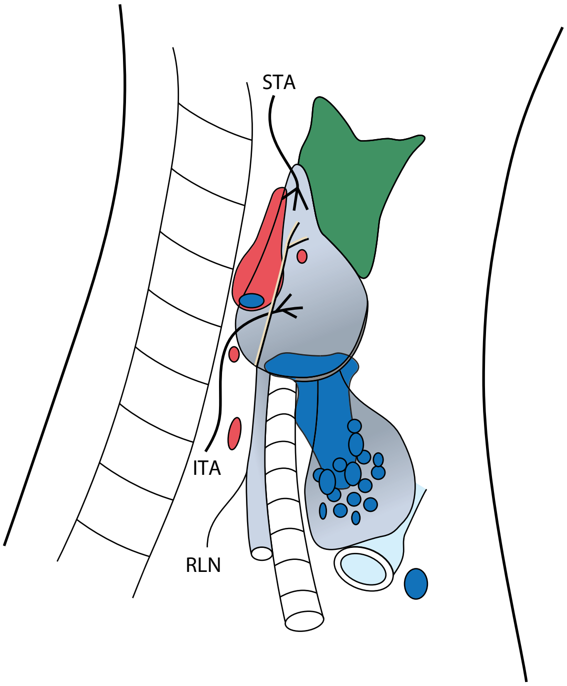

Figure 19.1 Sites of migration rest for superior (shaded red) and inferior (shaded blue) parathyroid glands. RLN, recurrent laryngeal nerve; STA/ITA, superior/inferior thyroid artery.

Parathyroid physiology

The parathyroid glands secrete parathormone (PTH). PTH is a polypeptide with 84 amino acid residues and a molecular weight of 9500. It is formed from preproPTH (115 amino acids), which is cleaved in the endoplasmic reticulum to form proPTH (90 amino acids). Six further amino acids are cleaved in the Golgi apparatus and the PTH is then stored in secretory granules in the chief cells of the parathyroid glands. The N-terminal portion is felt to be the biologically active portion of PTH. The half-life of PTH is only 10–15 minutes, as it is rapidly cleaved by the Kupffer cells in the liver. The main mechanism for the regulation of PTH is a negative feedback with plasma ionized calcium. Accurate measurement of circulating intact PTH is now obtained using two-site radioimmunoassay, with an assay against both the C-terminal and the N-terminal. This enables it to be differentiated from parathyroid hormone-related protein (PTHrP), which has PTH-like activity. PTHrP has a similar N-terminal, but has 140 amino acids, and is found in breast milk, the renal tubules and the brain. PTHrP is also responsible for 80% of the hypercalcaemia associated with malignancy – the humoral hypercalcaemia of malignancy.

PTH has effects on the bone, kidney and the gastrointestinal tract. In the bone, it promotes bone reabsorption, by the activation of osteoblasts to mobilize calcium. In the kidney, PTH increases the excretion of phosphate, by decreasing proximal tubular reabsorption. In normal circumstances, PTH increases calcium reabsorption at the distal tubules. However, this effect is overwhelmed in patients with hyperparathyroidism (HPT) by the raised levels of calcium being filtered, leading to hypercalciuria. This effect helps distinguish primary HPT from rarer causes of hypercalcaemia, such as benign familial hypocalciuric hypercalcaemia (FHH). PTH also converts 25-hydroxycholecalciferol to the active 1,25-hydroxycholecalciferol, which aids the mobilization of calcium from the bone and promotes the absorption of calcium from the gastrointestinal tract.

Hyperparathyroidism

Primary HPT is the inappropriate secretion of PTH associated with excessive growth and abnormal function of one or more parathyroid glands. These abnormalities cause hypercalcaemia in most but not all patients ('normocalcaemic' HPT). The prevalence of HPT is 0.1–2%, being highest in postmenopausal women. HPT occurs most commonly in its sporadic form, familial cases accounting for <5% of cases.

Diagnosis

Although patients with HPT may present with severe classic symptoms and signs, these are relatively uncommon today in the UK. The most common complaints are non-specific and are vague (Box 19.1). The symptoms of HPT do not correlate with the severity of the hypercalcaemia; many patients (at least 30%) are diagnosed consequent to the incidental detection of a raised serum calcium. Although these patients are often described as having asymptomatic HPT, the term mild HPT is more appropriate because truly asymptomatic disease is uncommon. The prevalence of neuropsychiatric symptoms and cardiovascular risk factors in such individuals is frequently ignored.

BOX 19.1 Symptoms and signs of hyperparathyroidism

- Renal
  - Urinary frequency/polyuria and thirst
  - Urinary tract calculi
  - Nephrocalcinosis
  - Renal failure
- Bone
  - Bone and joint pains
  - Chondrocalcinosis
  - Reduced bone mineral density
  - Fracture
- Gastrointestinal
  - Poor appetite
  - Nausea and vomiting
  - Constipation
  - Abdominal pain
  - Peptic ulcer
  - Pancreatitis
- Cardiovascular
  - Hypertension
  - Various myocardial changes
- Neuropsychiatric
  - Depression, psychosis
  - Fatigue, weakness, poor memory

The diagnosis of HPT is confirmed by an inappropriately high level of intact PTH – the biologically active hormone – in a patient with hypercalcaemia. If the PTH level is low normal or suppressed, the hypercalcaemia is not caused by HPT. The differential diagnosis of HPT (Box 19.2) includes hypercalcaemia of malignancy mediated by PTHrP and other growth factors secreted by the primary tumour that stimulate osteoclastic bone resorption and the presence of multiple bone metastases. Patients with FHH should be excluded by the absence of symptoms, a family history of the disorder and/or a failed neck exploration, low urinary calcium and a calcium creatinine clearance ratio <0.01.

Pathology

At least 80% of patients with HPT will have single gland disease – a parathyroid adenoma. Most abnormal glands will weigh 200–1000 mg (normal glands weighing up to 50 mg). They are usually reddish brown in colour and have a low fat content, in contrast to a suppressed normal gland. A remnant of normal compressed tissue may be visible to the pathologist; this 'rim' of parathyroid may be used as a criterion to distinguish parathyroid adenoma from hyperplasia. Multiple gland disease in HPT may be due to multiple adenomas (more frequent in older patients) in up to 10% of patients or parathyroid hyperplasia (sporadic or associated with familial disease). In an individual patient with parathyroid hyperplasia the glands may be of varied size.

BOX 19.2 Causes of hypercalcaemia

- Primary hyperparathyroidism
  - Primary hyperparathyroidism
  - Familial hyperparathyroidism
- Malignancy
- Sarcoidosis
- Vitamin D excess
- Thyrotoxicosis
- Drugs – thiazide diuretics, lithium
- Familial hypocalciuric hypercalcaemia
- Prolonged immobilization

Two histological subtypes are recognized – chief cell hyperplasia and water clear-cell hyperplasia.

Preoperative localization studies

An experienced parathyroid surgeon will cure at least 95% of patients at initial bilateral neck exploration without the need for preoperative localization. On that basis, the routine use of localization studies has not been previously recommended. The use of unilateral neck exploration and the arrival of minimally invasive parathyroid surgery have, particularly in European and US institutions, led to renewed interest in scan-directed first-time surgery with a satisfactory outcome/cost-benefit.

The most frequently used non-invasive localization studies are:

- *Ultrasound*. Published series report that 50–80% of enlarged parathyroid glands can be identified prior to surgery. The skill of the user, the size and position of the abnormal gland and the presence of coexisting thyroid nodules will affect the sensitivity, specificity and accuracy of this technique.
- *Technetium-99m sestamibi (MIBI).* Up to 85% of parathyroid adenomas and 50% of abnormal glands in patients with multiglandular disease can be localized. The use of single photon emission CT (SPECT) allows sagittal and transverse scans and better localization, particularly of ectopic parathyroid tissue.

Therefore, patients with an accurate and reliable localization (concordant scans) of single gland disease (approximately 85%) may be treated with a focused minimally invasive approach.

The use of CT, MRI, selective angiography, selective venous catheterization for PTH gradients and positron emission tomography scans is well described, but these are best reserved for localization of abnormal parathyroid glands when initial surgery has failed.

Natural history of primary hyperparathyroidism

There is no doubt that patients with significant hypercalcaemia and or symptomatic HPT should undergo neck exploration and excision of abnormal parathyroid glands. There is longstanding dispute as to what is appropriate management for patients with minimally elevated serum calcium levels and/or minimal symptoms. In this group, surgery results in a reduction in the HPT-associated risk of death from cardiovascular disease, an increase in cancellous bone density, reversal of neuromuscular deficit and improvement in quality of life. Non-surgical treatment of HPT consists of observation and long-term follow-up. Hormone replacement therapy for postmenopausal women with HPT at risk of osteoporosis does reduce the serum calcium. Although long-term observational follow-up studies show that as many as 25% of untreated patients have progression of their disease, there are no prospective randomized controlled trials on which to base guidelines for treatment. On that basis, a liberal approach to surgery is recommended.

Familial hyperparathyroidism

Multiple endocrine neoplasia type 1 (MEN 1)

An autosomal dominant disorder, the causative gene is located on chromosome 11q13, and is characterized by HPT (90%), multiple neuroendocrine tumours of the pancreas (75%; usually gastrinoma) and pituitary tumours (>30%; usually prolactinoma). The HPT is multiglandular. A surgical intervention less than subtotal parathyroidectomy is associated with recurrence rates of up to 40%. Supernumerary parathyroid glands are common in this disease (up to 20%), most frequently sited in the thymus. The surgical approach should therefore include *at least* subtotal parathyroidectomy and transcervical thymectomy.

Multiple endocrine neoplasia type 2 (MEN 2A and MEN 2B)

An autosomal dominant disorder, the gene is localized to chromosome 10q, and is characterized by medullary thyroid cancer (invariable), phaeochromocytoma (50%) and HPT (25%). Patients with MEN 2B have a Marfanoid phenotype and multiple mucosal ganglioneuromata. The HPT of MEN 2 is less severe; single gland disease is more frequent; and only enlarged parathyroid glands should be removed at operation.

Familial non-MEN HPT is very rare and frequently associated with multiglandular disease, supernumerary glands and parathyroid carcinoma. In some families the disorder is associated with mandibular tumours.

It is recommended that patients and families with genetically determined disease should be treated in specialist centres, as the treatment and screening strategies required for both MEN 1 and MEN 2 require a multidisciplinary approach that includes endocrine surgeons and physicians, clinical and molecular geneticists, interventional radiologists, histopathologists, biochemists and pathologists.

Hypercalcaemic crisis in hyperparathyroidism

Acute severe hypercalcaemia (corrected calcium >3.5 mmol/L) may occur in patients with HPT, often precipitated by intercurrent illness (associated with vomiting/diarrhoea) or diuretic therapy. The clinical presentation may include fatigue, weakness, polyuria, confusion, coma, pancreatitis and cardiovascular instability. Hypotension, pancreatitis and cardiac failure predict a poor outcome.

Treatment

This consists of:

- Aggressive rehydration with normal saline (up to 200 mL/h) to promote a good urine output. This may require monitoring of central venous pressure in elderly or unfit patients. Diuretic therapy is best avoided.
- Bisphosphonates act by inhibiting bone resorption. Treatment is usually by giving pamidronic acid 60–90 mg intravenously over 4–24 hours. Multiple doses may be required.

Surgery should be delayed until the corrected serum calcium is below 3 mmol/L.

Parathyroid carcinoma

The incidence of parathyroid carcinoma is approximately 1% of primary HPT cases. Patients will typically have a long history, calcium levels >3.5 mmol/L (70%), a palpable neck mass (50%) and severe bone disease (60%). At operation, the diagnosis is made on the basis of a firm, adherent grey–white gland (sometimes an atypical 'old' benign adenoma) or local invasion. In this situation:

- biopsy is contraindicated
- *en bloc* resection of the parathyroid gland, thyroid lobe and isthmus and other involved tissue should be performed.

Completion surgery should be performed if the diagnosis is made by the pathologist (a thick fibrous capsule with trabeculated fibrous bands traversing the tumour). Half the patients will have a favourable prognosis, although recurrent disease (local/regional and/or metastases with hypercalcaemia) usually occurs within 3 years.

Surgical approaches to hyperparathyroidism

The definitive treatment for patients with primary HPT is surgery, which should ensure a high rate of cure with a low complication rate. Doppman noted that 'the only localizing study indicated in a patient with untreated primary HPT is to localize an experienced parathyroid surgeon'. It is therefore axiomatic that the surgeon should have a good understanding of embryology and surgical anatomy of the parathyroid glands to ensure a successful outcome (see Parathyroid embryology, anatomy and physiology).

Pathology

The normal shape of a parathyroid gland depends on its location. In loose tissue it classically appears as a light-brown ovoid or sphere floating within surrounding yellow fat, but under a capsule the shape is flat with sharp edges. When enlarged, however, it assumes a spherical shape, indicating hyperactivity of the parathyroid gland. The greatest diameter of a normal parathyroid gland is usually no more than 5 mm with an upper limit of normal weight of 50 mg.

Surgical technique

Unilateral or bilateral exploration

Unilateral neck exploration for primary HPT is controversial because of the concern about missing multiglandular disease and the inaccuracy of preoperative localization tests. Protagonists claim decreased complications and cost-effectiveness for the technique but drawbacks are obviously missing double adenomas or hyperplasia. Retrospective data analysis reveals no differences between the two techniques and to date no prospective studies have compared unilateral with bilateral exploration. Bilateral neck exploration has, therefore, previously been the standard approach because it is safe, avoids missing a second adenoma and avoids unnecessary expensive preoperative localization studies as >95% of patients can be cured when treated by an experienced endocrine surgeon.

However, over the last decade, popularity for a focused unilateral technique has increased and with concordant localization a minimally invasive parathyroidectomy has now become the standard approach for putatively single gland disease.

Cervical exploration for primary hyperparathyroidism

Preoperative preparation is as previously described for thyroidectomy except for the use of methylene blue (5 mg/kg body weight methylene blue in 500 mL dextrose/saline infused intravenously over 1 hour before surgery), which selectively stains parathyroid tissue and is a valuable aid to the difficult case. It is fundamental for the endocrine surgeon to identify all four (or possibly more) parathyroid glands in the neck. Through a collar (skin crease) incision the parathyroid exploration is usually started by searching for the upper parathyroid gland just above the neurovascular intersection of the RLN/ITA on the dorsum of the thyroid gland, retracting the thyroid with a finger on a gauze swab. Careful dissection of the fat and fibrous attachments to the thyroid at this point usually reveals the majority of upper glands. The dissection should be under direct vision at all times to prevent injury to the RLN, which usually runs anteromedially to the upper gland. When it cannot be found in its usual site exploration of the para/retro-oesophageal space is undertaken with digital exploration of the posterior mediastinum and close examination of the upper thyroid pole to inspect for a subcapsular intrathyroidal gland.

The search for the inferior parathyroid gland begins with a thorough inspection of the lower thyroid pole, the thyrothymic ligament and the thymus itself. Usually, the lower parathyroid lies in the fat between the inferior thyroid veins, but rarely it may be found in the anterior surface of the thyroid gland.

Bilateral exploration should be undertaken and in 85% of patients there will be a solitary parathyroid adenoma. The adenoma is gently dissected using a gauze pledget (to push the gland forward) and fine clips (taking care not to break the capsule) to release it from its fascial coverings. The pedicle is defined, clipped and divided, and the adenoma removed (Figures 19.2 and 19.3).

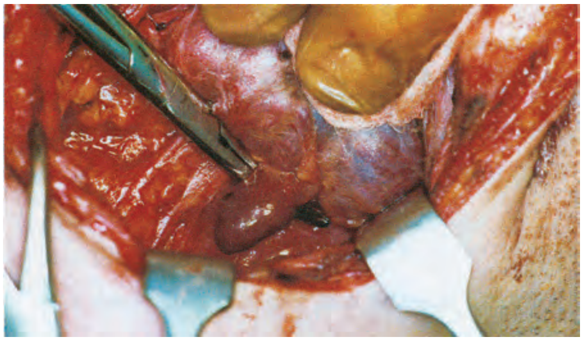

Figure 19.2 Cervical exploration. Left superior parathyroid adenoma (stained with methylene blue) being gently 'teased out' from surrounding fascia.

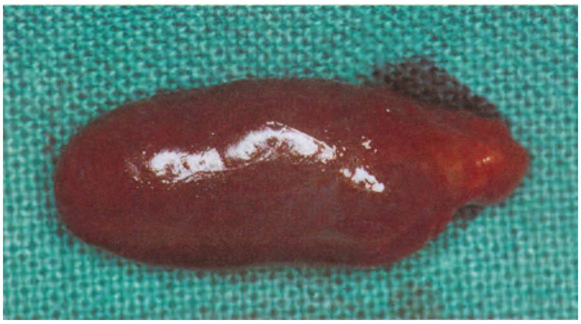

Figure 19.3 Left superior parathyroid adenoma weighing 630 mg; note the intact glistening capsule.

If three normal parathyroid glands are found the adenoma should be removed and examined by frozen section. It is controversial whether a biopsy of one of the normal glands is undertaken but the author does not routinely biopsy unless the appearances at operation are suspicious. If two enlarged glands are found they should be removed and the two normal glands should be biopsied and marked with clips. Microscopic distinction between adenomas and hyperplasia can be difficult and the role of the pathologist intraoperatively is therefore limited to the identification of parathyroid tissue. If all parathyroid glands are enlarged three parathyroid glands should be removed along with a half of the fourth and a thymectomy should be performed, as supernumerary parathyroid glands are frequently located in the thymus. The parathyroid remnant should be approximately 50 mg of tissue and an easily accessible gland with a reliable vascular stalk should be chosen and biopsied first before the others are removed to ensure that it remains viable. An alternative surgical strategy is to remove all four glands and reimplant half of one as an autotransplant into a pocket of the sternomastoid muscle.

Minimally invasive parathyroid surgery

This has now become the standard approach for unilateral disease selected by concordant scans for approximately 80% of cases. Focused surgery is performed through a small (approximately 2 cm) lateral skin crease directly over the site of the abnormal gland. The scar fades to a barely visible line over a few months. This procedure can be performed under local anaesthetic, cervical block or laryngeal mask general anaesthesia, usually in less than 30 minutes and as a day-case procedure. Conversion to a full cervical exploration may be necessary but is easily facilitated by extending the wound along a standard collar incision (approximately 5 cm) but would require a general anaesthetic.

Intraoperative PTH monitoring (with rapid assay) has been advocated as evidence of biochemical cure. Normal PTH levels occur within 10 minutes of removal of the abnormal gland. However, this is an expensive and potentially time-wasting procedure and the author currently prefers to rely on frozen section alone.

Minimally invasive parathyroid surgery is reliable and safe and has now become the first-line treatment for primary HPT with focused imaging from concordant scans.

Secondary hyperparathyroidism

In patients with secondary HPT, familial HPT or MEN 1 syndrome, all parathyroid glands are involved, and the rate of recurrent HPT in these patients ranges from 10% to 15%. A subtotal parathyroidectomy should therefore be performed, leaving behind a remnant of a lower parathyroid (with a clip marker) or autotransplantation is performed as described above. Cryopreservation of some parathyroid tissue may also be considered.

Mediastinotomy

Following a thorough exploration of the neck, if an abnormal gland is not found, normal glands should never be removed and the cervical wound should be closed and full investigation carried out; including high-resolution ultrasound scanning, CT, MRI, sestamibi subtraction scan and selective venous sampling to confirm the location of the ectopic adenoma. This is usually found within the chest (Figure 19.4) in either the anterior mediastinum (for an inferior gland) or posterior mediastinum (for a superior gland). Surgery can then be planned accordingly for either a mediastinotomy or lateral thoracotomy, respectively (Figure 19.5) when inaccessible from the neck. More recently, thoracoscopy or mediastinoscopy has

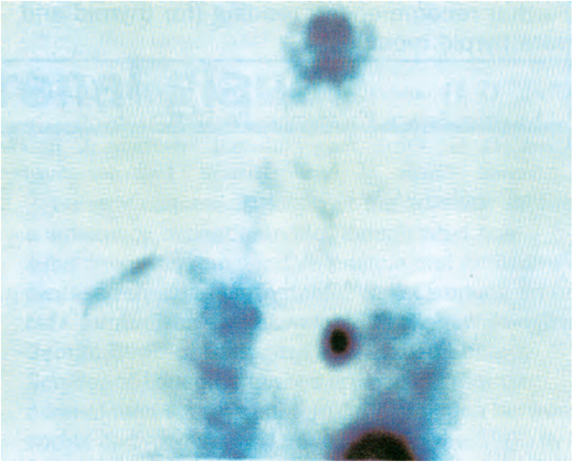

Figure 19.4 Sestamibi scan demonstrating ectopic adenoma of a fifth parathyroid gland in the aortopulmonary window of the middle mediastinum.

been reported to be a successful minimally invasive technique to remove mediastinal adenomas.

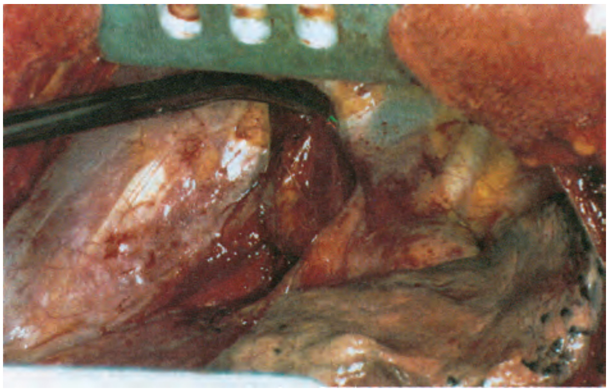

Figure 19.5 Removal of an ectopic fifth parathyroid adenoma (7 g) from the aortopulmonary window through a left fourth rib thoracotomy. (Courtesy of Mr C. Forrester-Wood, Bristol Royal Infirmary, UK.)

CHAPTER 20

Disorders of the adrenal glands

GREG P. SADLER

Introduction

The Roman anatomist Bartholomaeus Eustachius first described the adrenal glands in 1552 in his *Opuscula Anatomica*, referring to them as 'glandulae renibus incumbentes' (glands lying on the kidneys). The function of the adrenal glands, however, remained a mystery to workers for 300 years, until in 1856 the French physiologist Charles Brown-Séquard demonstrated that these glands were essential to life in a series of experiments on dogs and rats. Brown-Séquard had been inspired by a report the previous year by Thomas Addison of London describing the clinical findings of 11 patients in whom the adrenal glands had been found at postmortem to be destroyed, through either tuberculosis or cancer (a condition later termed Addison disease).

General consensus held that the adrenals secreted a substance essential to life, though what this substance was remained an enigma and Addison disease remained untreatable. While working on a cure for Addison disease in 1893 the physiologists George Oliver of Harrogate and Edward Sharpey-Schäfer of London prepared an extract from the adrenal medulla (the anatomical distinction between cortex and medulla had been made in 1805 by Baron Georges Cuvier and the terms coined by Emil Huschke in 1845). The extract failed to cure Addison disease but produced a marked constriction of blood vessels. This preparation was later purified and termed adrenaline (1897) or epinephrine (1901). It was not until the late 1920s when US workers prepared an adrenal cortical extract termed 'cortin' that Addison disease was treated successfully.

The adrenal glands are now known to secrete a wide variety of hormones that regulate many essential physiological functions including blood pressure, carbohydrate, fat and protein metabolism. It is not surprising, therefore, that development of hyperplastic or neoplastic conditions may lead to overproduction of various hormones, resulting in a wide variety of clinical syndromes.

The current-day endocrine surgeon with an ever-increasing diversity of biochemical tests, pharmaceutical agents, localizing modalities and operative techniques has a unique opportunity to correct profound physiological and often life-threatening disturbances and restore the patient to complete normality.

Anatomy

The adrenals are retroperitoneal structures, each weighing approximately 2–6 g and located on either side of the vertebral column within Gerota's fascia, in close proximity to the crura of the diaphragm and the superior poles of the kidneys. The right adrenal gland is triangular or pyramidal in shape with the apex superiorly and the base towards the right kidney. It lies on the right crux of the diaphragm posteriorly, the bare area of the liver anteriorly, the inferior vena cava anteromedially and the superior pole of the right kidney inferolaterally. The left gland is crescentic in shape, related anteriorly to the stomach and pancreas and posteriorly to the diaphragm. Anteriorly the gland is covered by the peritoneum of the lesser sac. Arterial supply is drawn from the aorta, renal artery and inferior phrenic artery, though some tumours (particularly phaeochromocytoma) may demonstrate marked vascular neogenesis. Main venous drainage on the right side is via a short adrenal vein (5 mm) directly to the inferior vena cava, usually entering posteriorly. On the left side drainage is directly to the left renal vein. Frequently venous drainage is supplemented by additional veins running directly to the vena cava or hepatic veins on the right and the phrenic vein on the left.

Macroscopically the adrenal glands are a golden yellow colour, which contrasts with the surrounding perinephric fat. When sectioned the outer cortical layer (which makes up 80% of the normal gland in volume) is lipid rich and golden or yellow, in contrast to the well-vascularized medulla, which tends to be reddish-brown in colour. The cortex consists of three layers. From outer to inner these are the zona glomerulosa (aldosterone production), zona fasciculata (cortisol production) and zona reticularis (androgen production). The adrenals have a rich sympathetic nerve supply from the coeliac plexus but preganglionic fibres from the splanchnic nerves pass through the coeliac plexus to supply the adrenal medulla.

Physiology

The principal hormone secretions of the adrenal gland – aldosterone, cortisol and the androgens (mainly testosterone) – are synthesized via intermediates, such as pregnenolone and progesterone, from cholesterol by a series of metabolic steps, each requiring a specific enzyme.

Aldosterone is a mineralocorticoid with the principal action of stimulating sodium reabsorption in exchange for potassium and hydrogen ions. This occurs in the distal renal tubule, ascending loop of Henle and collecting ducts. Plasma oncotic pressure is increased, thus expanding plasma volume. Synthesis and secretion of aldosterone is regulated by angiotensin II and by plasma levels of sodium and potassium. Aldosterone is produced in the zona glomerulosa in response to a fall in blood volume, registered in the juxtaglomerular apparatus of the afferent tubules of the kidney. These cells release renin, which splits angiotensinogen to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme (ACE). Sodium retention is directly linked to potassium exchange, the rate being dependent on the rate at which sodium is presented to the tubule.

Glucocorticoids, mainly cortisol and small amounts of corticosterone, are produced in the zona fasciculata. The rate of production is directly dependent on adrenocorticotrophic hormone (ACTH) from the pituitary, which in turn is suppressed directly by cortisol, via a direct negative feedback mechanism of cortisol on the pituitary. ACTH secretion is stimulated by corticotrophin-releasing hormone (CRH), produced by the hypothalamus (CRH production is also suppressed by cortisol). Cortisol has a wide range of physiological actions involving fat, carbohydrate and protein metabolism and is subject to a specific diurnal variation in synthesis and production, with highest levels being achieved early in the morning and lowest levels at night.

Androgen production is from the zona reticularis and is also stimulated by ACTH. In the adult, however, the main site of sex hormone production is the gonads. Sex hormones produced from the adrenals play a role in growth and sexual differentiation.

Addison disease and adrenal insufficiency

Adrenal insufficiency was first recognized and described by Thomas Addison in a presentation in 1849. His classic 1855 publication documented the symptoms and physical findings in 11 patients with adrenal destruction noted at postmortem. The major causative factor was tuberculosis, although metastatic carcinoma and atrophy were also documented. The term Addison disease was first used by Armand Trousseau of Paris the following year. Trosseau had read Addison's monograph *On the Constitutional and Local Effects of Disease of the Supra-renal Capsules* and noted the same symptoms, clinical and postmortem findings in a patient with tuberculosis of the adrenal glands.

Addison disease has always been a rare condition and, until recently, a reduction in the numbers of patients with tuberculosis decreased the incidence even further, but the incidence of tuberculosis has risen and this, coupled with AIDS and autoimmune adrenalitis, has meant that the incidence of Addison disease has increased. In 1974 the recorded incidence in Denmark was six cases per 100 000 population.

A number of conditions have now been described that can destroy or interfere with the adrenal cortex, resulting in Addison disease. The most common cause is autoimmune disease, which is responsible for 65% of all cases of primary adrenal insufficiency, and association with other autoimmune conditions such as autoimmune thyroiditis and insulin-dependent diabetes is common. Other causes include tuberculosis, AIDS, sarcoidosis, amyloidosis, haemochromatosis, histoplasmosis, metastatic carcinoma, congenital adrenal hyperplasia, adrenocortical haemorrhage (particularly in anticoagulated patients), adrenal venography or meningococcal septicaemia (Waterhouse–Friderichsen syndrome).

AIDS is increasingly responsible for patients with Addison disease by a number of mechanisms. Adrenal destruction and insufficiency can be caused by infection with *Mycobacterium tuberculosis, Mycobacterium avium-intracellulare*, toxoplasmosis, histoplasmosis and *Pneumocystis carinii*. Neoplastic destruction by Kaposi's sarcoma or lymphoma has also been described. Ketoconazole, rifampicin, phenytoin and corticosteroids, drugs used in the treatment of AIDS-related illness, may all cause adrenal impairment. As patients with AIDS frequently present with similar symptoms to those with Addison disease, a high index of suspicion is required.

Bilateral surgical removal is an obvious cause of adrenal insufficiency. By definition, however, adrenal insufficiency following bilateral adrenalectomy is not Addison disease. Acute adrenal failure may also result following the sudden withdrawal of long-term steroid treatment, precipitating cardiovascular collapse or even death.

Diagnosis

Adrenal insufficiency is characterized by lassitude, weakness, anorexia and amenorrhoea. Physical findings include hypotension, pigmentation of the buccal mucosa (particularly on pressure areas), vitiligo and loss of body hair. In acute and extreme cases drowsiness, confusion, coma and death occur. In the collapsed patient, stigmata of disease for which steroids may be prescribed or bilateral adrenalectomy scars may provide important clues to the diagnosis. Features of adrenal, hypothalamic or pituitary disease may also be present.

The diagnosis of Addison disease may be confirmed by intramuscular injection of 250 μg of tetracosactrin and the plasma cortisol response at 0, 30 and 60 minutes recorded (short-term Synacthen test). In normal patients the plasma cortisol level should rise. The response is absent or impaired in patients with Addison disease. A long-term Synacthen test (depot test) helps to distinguish primary adrenal insufficiency from secondary adrenal dysfunction, usually from pituitary disease. Subsequent investigations including chest and abdominal radiographs and autoantibody screening are directed at establishing the cause of adrenal insufficiency.

Treatment of acute adrenal insufficiency

The signs and symptoms of acute adrenal insufficiency listed above progress rapidly. In patients with meningococcal septicaemia (often children) characteristic petechial skin haemorrhages may be noted in addition to hyperpyrexia, rigors and vomiting. The onset of profound shock with tachycardia and hypotension may occur suddenly. If appropriate therapy is not immediately instituted, coma and death ensue. The most common finding on routine laboratory testing is hyponatraemia, although this is not always present.

Once the diagnosis is suspected patients should be given 100 mg of hydrocortisone intravenously and rapidly resuscitated with intravenous normal saline. Intravenous antibiotics are given immediately if septicaemia is suspected as the underlying cause. Recovery is usually prompt but hydrocortisone (100 mg i.v.) should be continued every 6 hours until the patient is stabilized. Subsequently, patients can be changed to oral hydrocortisone or dexamethasone. Mineralocorticoids are not necessary when the dose of cortisol exceeds 60 mg/day. Chronic adrenal insufficiency will require maintenance therapy with hydrocortisone, usually 20 mg in the morning and 10 mg in the evening. Additional mineralocorticoid may be necessary in patients with impaired salt-retaining ability (0.05–0.10 mg fludrocortisone). Hypertension, oedema and hypokalaemia are signs of overtreatment. Fatigue, hypotension and hyperkalaemia are signs of undertreatment. The relative potencies of various steroid preparations are shown in Figure 20.1.

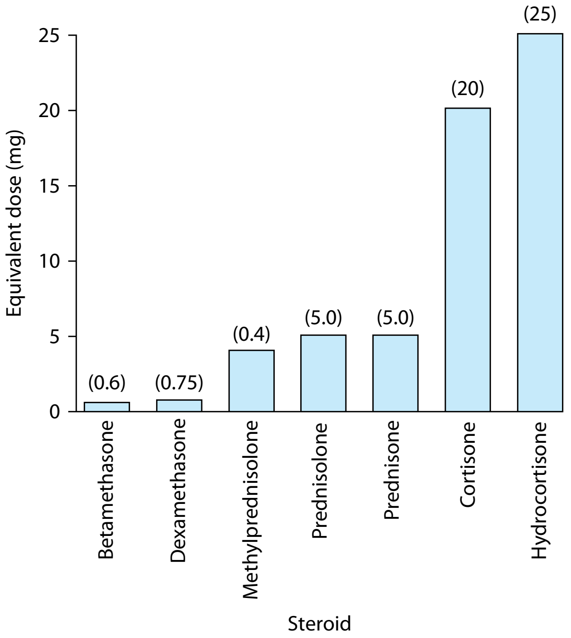

Figure 20.1 Relative potency of steroid compounds.

Surgery and steroid replacement therapy

- *Bilateral adrenalectomy.* Hydrocortisone sodium succinate is given i.m. (or i.v.) with the premedication and a further 100 mg given at the time of gland removal. In the postoperative period hydrocortisone 100 mg 6 hourly i.v. is continued for between 48 and 72 hours, reducing to 50 mg 6 hourly before the introduction of 20 mg of oral hydrocortisone in the morning and 10 mg at night. Mineralocorticoid is given as oral 0.05–0.1 mg fludrocortisone acetate daily.
- *Unilateral adrenalectomy* normally does not require steroid cover but, if performed for Cushing syndrome because of an adrenal adenoma, hydrocortisone sodium succinate 100 mg i.m./i.v. is given with the premedication and a further 100 mg given during the operation and continued 6 hourly, reducing with the introduction of 20 mg of oral hydrocortisone in the morning and 10 mg at night. Gradual reduction of steroid replacement is made on a monthly basis with complete weaning often taking up to 12–18 months, as the remaining adrenal gland recovers normal function.
- *Surgery in the hypoadrenal patient*, e.g. after bilateral adrenalectomy and in patients with adrenal suppression from steroid therapy. If these patients are having major surgery, additional steroids are required: hydrocortisone sodium succinate 100 mg i.m./i.v. is given with the premedication and a further 100 mg i.v. given during the operation and continued 6 hourly until the patient is able to return to the usual oral replacement steroid dose. If the postoperative period is prolonged, e.g. after a gastrointestinal operation, the parenteral hydrocortisone is reduced to 50 mg and then 25 mg 8 hourly until the patient is able to take oral medication.

For most minor surgery, in which oral intake is not restricted, intramuscular hydrocortisone is only required for 24 hours postoperatively and for minimal surgical procedures, such as endoscopy, a single dose of hydrocortisone 100 mg is all that is required. Patients who are on steroid therapy, who have undergone bilateral adrenalectomy or who suffer from primary hypoadrenalism must be fully advised by the medical staff on the nature of their condition and the symptoms to be expected with inadequate steroid replacement. They are instructed to double the usual dose of steroid immediately and seek medical assistance in the event of illness or severe stress. The crucial importance of this treatment must be emphasized. All patients should carry a steroid warning card and the wearing of a Medic Alert bracelet is to be encouraged. Patients who have had total adrenalectomy in some hospitals in the USA are given a steroid-containing syringe for emergency self-administration.

Congenital adrenal hyperplasia (adrenogenital syndrome)

The principal hormone secretions of the adrenal gland – aldosterone, cortisol and the androgens (mainly testosterone) – are synthesized via intermediates, such as pregnenolone and progesterone, from cholesterol by a series of metabolic steps, each requiring a specific enzyme. A deficiency in one of the enzymes (inherited in an autosomal recessive manner) leads to a deficiency in cortisol and/or aldosterone production. The lack of negative feedback to the pituitary results in excessive ACTH production. The growth-stimulating effect of ACTH leads to the development of bilateral adrenal hyperplasia.

The most common cause of adrenal hyperplasia is a deficiency of the enzyme 21-hydroxylase (90% of cases). This enzyme catalyses progesterone to deoxycorticosterone and 17-OH progesterone to 11-deoxycortisol. Deficiency leads directly to lack of production of aldosterone and cortisol. The backlog of metabolites is subsequently diverted into production of the androgens dehydroepiandrosterone, androstenedione and testosterone. Other enzyme deficiencies reported include 11 -hydroxylase, 3 -hydroxy steroid dehydrogenase and 17 -hydroxylase. Impaired production of aldosterone leads to *salt wasting* from excessive urinary salt loss. This is characterized in the newborn by vomiting and failure to feed and thrive.

The condition termed *congenital adrenal hyperplasia* is fortunately rare, with a reported incidence of one in 5000 to one in 15 000. Excessive androgen production in the female fetus leads to virilization, pseudohermaphroditism with ambiguous external genitalia, clitoral enlargement and fusion of the genital folds. In the male fetus the effects of androgen excess are not so obvious but penile enlargement occurs during childhood and pseudoprecocious puberty may ensue (infant Hercules). Early epiphyseal closure leads to short stature in adult life.

Diagnosis

Lack of the enzyme 21-hydroxylase leads to excess of the precursors progesterone and 17-OH progesterone. Measurement of the plasma level of 17-OH progesterone by radioimmunoassay is the most reliable method of confirming the diagnosis.

Treatment

Hydrocortisone (5 mg/day in divided doses) is administered to replace the glucocorticoid deficiency and totally suppress ACTH drive. Adequate suppression can be monitored by assessing 17-OH progesterone levels in urine and plasma. *Salt wasting* is treated by intravenous normal saline and mineralocorticoid replacement. Early diagnosis, adequate medical therapy and careful follow-up should ensure that growth development, fertility and life expectancy are all normal.

Cushing syndrome

The physiological and clinical features of Cushing syndrome are due to excessive levels of circulating glucocorticoids. The predominant clinical features of the disease include moon-type facies, truncal obesity with prominent interscapular fat pad formation, abdominal striae, diabetes and hypertension. The causes of Cushing syndrome are divided into two main groups: ACTH dependent and non-ACTH dependent.

Adrenocorticotrophic hormone-dependent Cushing syndrome

Cushing disease

Harvey Cushing (a Boston, MA, neurosurgeon) described the classic clinical features of the syndrome in 1932. He termed the condition 'pituitary basophilism', indicating that the condition was caused specifically by a pituitary basophil adenoma. Pituitary (ACTH)-dependent Cushing syndrome (referred to as Cushing disease) accounts for 70% of all cases of the syndrome. An ACTH-producing pituitary adenoma or microadenoma is responsible in approximately 75% of patients. Tumours are small (usually <1 cm) and malignancy is rare. The primary defect is probably located in the hypothalamus with overproduction of CRH. Chronically raised ACTH levels result in adrenal cortical hyperplasia and cortisol excess. ACTH secretion is still subject to negative feedback but at a higher set point than normal. Women are affected eight times more commonly than men and the disease is most common between 35 and 50 years of age.

Ectopic adrenocorticotrophic hormone syndrome

Ectopic ACTH production accounts for 10% of cases of Cushing syndrome and is caused by a spectrum of tumours originating from neuroendocrine cells. The commonest cause is a small cell carcinoma of the lung (previously referred to as oat cell tumours). Other causes include thymoma, medullary thyroid cancer, phaeochromocytoma, pancreatic islet cell tumours, certain ovarian cancers, pancreas, stomach and bronchial carcinoids.

The first case of ectopic ACTH syndrome was described by Brown in 1928, although the term 'ectopic ACTH syndrome' was originally coined by Liddle and colleagues in 1962. Cases caused by benign carcinoids may be difficult to diagnose as the onset of Cushing syndrome may be insidious over several years. The tumours may also be small and therefore difficult to locate.

In patients with small cell carcinoma of the lung, the onset of symptoms is usually rapid, making the diagnosis easier. Tumours are aggressive and the primary malignancy frequently kills the patient before significant or severe effects of glucocorticoid excess supervene. The peak incidence of ACTH syndrome is in the fourth and fifth decades and the condition is twice as common in men as in women.

Non-adrenocorticotrophic hormone-dependent Cushing syndrome

The commonest cause of the syndrome is the administration of steroids for the treatment of other conditions. This iatrogenic group will not be considered further.

Adrenal tumours

Approximately 20% of cases of Cushing syndrome are caused by either benign adrenal adenoma (10%) or frankly invasive adrenocortical carcinoma (10%). Benign adenoma is more common in adults and malignancy more common in the young. Excessive glucocorticoid secretion suppresses ACTH production from the pituitary, resulting in atrophy of the contralateral adrenal gland.

Macronodular adrenal cortical hyperplasia

This unusual condition, in which ACTH-independent cortisol secretion results from bilateral adrenal nodular hyperplasia, is sometimes seen in the young and may be associated with severe osteopaenic bone disease. The cause is unknown.

Primary pigmented nodular adrenal cortical disease

Primary pigmented nodular adrenal cortical disease producing autonomous adrenal hyperfunction occurs in conjunction with cardiac, breast and cutaneous myxomas. The adrenal nodules in this rare condition are normally small and the adrenal glands may even appear to be normal on imaging. Lentigines are found on the face, lips and conjunctivae. Pituitary adenomas and neuroectodermal tumours also occur.

Clinical features of Cushing syndrome

The most common features of Cushing syndrome are truncal obesity, weight gain, facial plethora, hirsutism, mild or moderate hypertension, menstrual irregularities, bruising and abdominal striae (Figure 20.2).

Obesity is caused by excessive cortisol stimulating appetite and promoting gluconeogenesis, which releases glucose for fat synthesis. Patients develop plethoric, rounded 'moon-like' facies, whereas truncal fat distribution results in interscapular fat pad formation. In contrast, the toxic effect of cortisol on muscles leads to muscle wasting and weakness. The proximal limb muscles are affected most and patients may develop a 'lemon on a stick' appearance.

Skin changes result from excessive cortisol depleting skin collagen. Thinning of the skin, striae and excessive bruising (either spontaneously or with minor trauma) are all features. In ACTH-dependent Cushing syndrome, high levels of ACTH melanocyte-stimulating hormone cause skin pigmentation. This is more commonly encountered in ectopic ACTH syndrome due to malignancy and Nelson syndrome (high ACTH levels following bilateral adrenalectomy for pituitary disease).

Hirsutism and acne from excessive androgen secretion are often distressing features for the patient. Adrenocortical carcinoma should be suspected, particularly if virilisim is marked.

Poor wound healing is a direct outcome of decreased collagen synthesis and increased protein catabolism. This is an important consideration in all patients in whom surgery is contemplated, particularly when an anterior abdominal approach is employed.

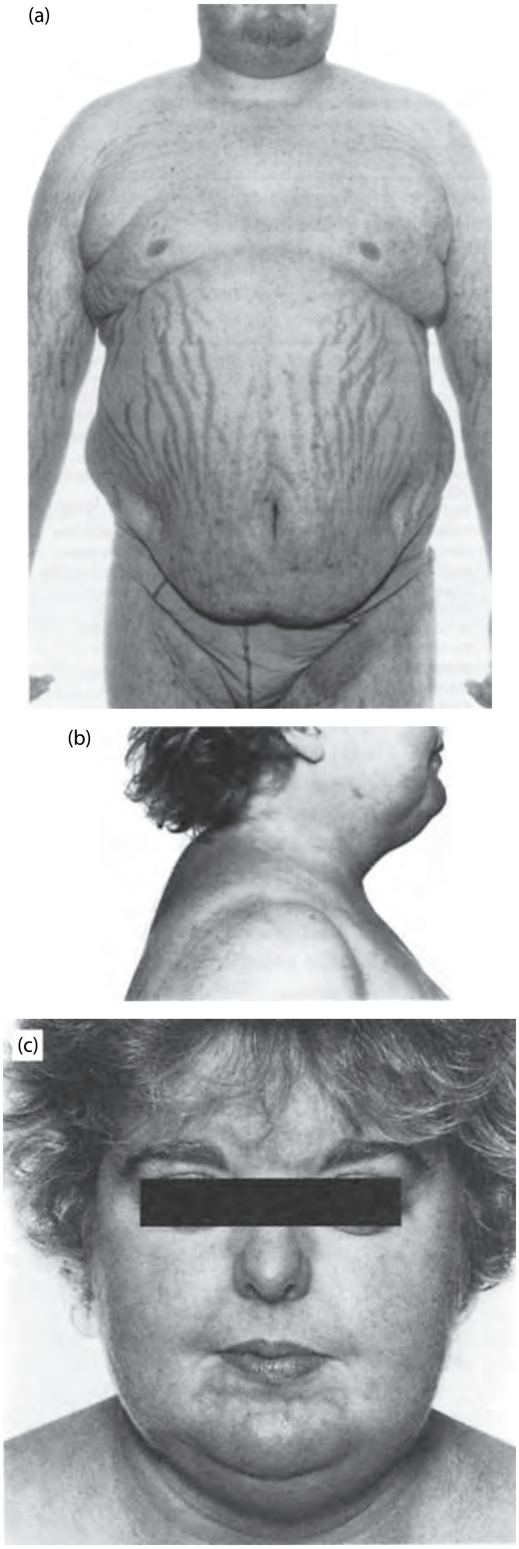

Figure 20.2 Cushing syndrome. (a) Marked truncal obesity, abdominal striae and wasted limbs. (b) Interscapular fat pad. (c) Plethoric moon face.

Hypertension and oedema are a consequence of the glucocorticoid effects of cortisol resulting in salt and water retention. Congestive cardiac failure is present in 20% of patients. Untreated this is a major cause of mortality in Cushing syndrome.

Diabetes mellitus develops in approximately 15% of patients because of the action of cortisol on carbohydrate metabolism. An abnormal glucose tolerance test, however, may be present in 70% of patients.

Osteoporosis is common (70%) and may lead to pathological fractures, particularly in the ribs, and also vertebral collapse. Urinary calcium excretion is raised (hypercalciuria), leading to renal stone formation and hypocalcaemic alkalosis.

Menstrual disturbance, male impotence, psychiatric illness and growth retardation (particularly in children) are also associated features of Cushing syndrome.

Differential diagnosis

The clinical features of Cushing syndrome may be mistakenly confused with those of the obese diabetic, particularly when there is a plethoric face or hirsutism. Polycystic ovary syndrome, with sterility and hirsutism, also poses diagnostic difficulties, but Cushing syndrome rarely causes hirsutism alone. Alcoholic patients can present with pseudo-Cushing syndrome, the signs and symptoms of which resolve following cessation of excessive alcohol intake.

Biochemical investigation of Cushing syndrome

Cushing syndrome will be initially suspected on the basis of the above clinical features. It is then necessary to confirm the presence of hypercortisolism, and subsequently identify the cause of excessive cortisol production:

- *Plasma cortisol levels* (under ACTH control) in normal individuals exhibit a diurnal variation. The highest levels are recorded at 09.00 (<140–800 nmol/L) and the lowest at midnight (<190 nmol/L). Loss of this diurnal variation is frequently exhibited in Cushing syndrome. Plasma cortisol levels recorded at 09.00 and particularly at midnight are elevated above normal limits. False-positive and false-negative observations may be caused by acute illness or depression. Even the relatively minor trauma of venepuncture can falsely elevate midnight levels.
- *Urinary free cortisol* in 24 hour urine collection is invariably raised in Cushing syndrome. Normal values are <360 nmol/day for men and <280 nmol/day for women.
- *Dexamethasone suppression tests.* In normal individuals ACTH secretion and cortisol production may be suppressed by the administration of an exogenous corticosteroid (dexamethasone). Although patients with Cushing syndrome may also exhibit ACTH suppression, it is far less marked than in normal individuals. *Overnight dexamethasone test:* 2 mg of dexamethasone (a powerful corticosteroid) is administered orally at midnight and plasma cortisol levels are measured at 09.00. When results of the overnight test are equivocal a *low-dose dexamethasone* test may be performed: plasma cortisol levels are measured prior to oral administration of dexamethasone 0.5 mg 6 hourly for 2 days. Suppression of plasma cortisol levels is seen in normal patients but rarely in patients with Cushing syndrome.
- *Insulin-induced hypoglycaemia* fails to produce a rise in plasma cortisol levels in patients with Cushing syndrome. The test is useful in differentiating between patients with the syndrome and those with depression, who may have elevated basal cortisol levels.

Identification of the cause of cortisol excess

Having confirmed a diagnosis of Cushing syndrome, the following tests are used to establish whether the disease is ACTH or non-ACTH dependent (i.e. pituitary or non-pituitary in origin):

- *Plasma ACTH measurement by radioimmunoassay.* Patients with adrenal tumours have low or undetectable levels of plasma ACTH (<10 pg/mL) compared with patients with pituitary disease, who tend to have elevated levels, although in some patients with pituitary disease ACTH levels may be in the normal range. In patients with ectopic ACTH syndrome, levels may be very high, sometimes in excess of 200 pg/mL.
- *High-dose dexamethasone test.* Patients are given 2 mg of dexamethasone 6 hourly for 2 days. In nearly all patients with pituitary disease (ACTH dependent) serum cortisol levels are suppressed. In contrast, patients with non-ACTH-dependent disease (adrenal tumour, adrenal nodular hyperplasia and ectopic ACTH syndrome) show little or no suppression. False-positive and -negative results do occur and are more likely to be encountered in patients with adrenal nodular hyperplasia and ectopic ACTH syndrome than in patients with adrenal tumours.
- *Metyrapone test.* This test is now rarely performed. Metyrapone is an 11 -hydoxylase inhibitor that blocks the final step in cortisol synthesis, reducing plasma cortisol levels, stimulating ACTH secretion and increasing production of the cortisol precursors (compound S). The test is performed by giving patients Metyrapone 750 mg (125 mg/4 hourly). A 24 hour urine collection is performed on the day before, the day of and the day after Metyrapone administration and 17-hydroxycorticosteroid (17-OHCS) levels are measured. In normal patients and patients with pituitary disease (ACTH dependent) urinary excretion of 17-OHCS is increased. In contrast, the majority of patients with adrenal tumours exhibit a decrease in 17-OHCS urinary excretion. Patients with nodular hyperplasia or ectopic ACTH syndrome usually demonstrate an impaired or absent response to Metyrapone.

Choice of test in Cushing syndrome

When Cushing syndrome is suspected clinically, diagnosis is usually confirmed by:

- measuring plasma cortisol (09.00 and midnight)
- measuring urinary free cortisol
- performing a low-dose dexamethasone test.

Confirming the cause of Cushing syndrome is best achieved by:

- measuring basal plasma ACTH
- performing a high-dose dexamethasone test
- in cases of diagnostic difficulty, performing a Metyrapone test.

Localizing procedures in Cushing syndrome

Pituitary tumour (Cushing disease)

MRI is considered the investigation of choice in localizing pituitary tumours and approximately 85% of pituitary adenomas are detectable by this technique. MRI, however, may fail to identify microadenomas of 5–10 mm in size. In these patients, bilateral selective catheterization of the petrosal sinus and ACTH measurement after CRH stimulation is the most sensitive test in confirming the presence of a microadenoma. Plain skull radiography is not helpful in identifying pituitary tumours even with thin-section tomography. CT scanning, although formally popular, will identify only approximately 50% of tumours.

Adrenal tumour

CT scanning is very effective in localizing adrenal tumours even as small as 1 cm in diameter. When an adrenal tumour is suspected as the cause of Cushing syndrome, early CT scanning may prove useful to focus other investigations. Adrenal tumours >6 cm on CT scanning are more likely to be malignant. Scanning of adrenal tumours with ^{131}I-6 -iodomethylnorcholesterol (NP59) or selenium-75 cholesterol has now been abandoned. It is unreliable and the isotopes are now unavailable in many countries (UK in particular) (Figure 20.3). MRI has increasingly become a popular modality for scanning adrenal tumours. In-/out-of-phase modality scanning may be useful in distinguishing high fat content in benign adrenal tumours (Figure 20.4).

Ectopic adrenocorticotrophic hormone

Ectopic ACTH-producing tumours are often small and may be difficult to locate. Chest radiography may identify benign or malignant bronchial tumours. CT or MRI scanning may aid in locating bronchial, pulmonary, thymic or pancreatic tumours, which may be the source of ACTH production. The adrenal glands are enlarged and usually demonstrable on CT scan (Figure 20.5).

Treatment of Cushing syndrome

Medical treatment

Patients with Cushing syndrome (either pituitary or adrenal in origin) in whom surgery is contraindicated may be treated by long-term Metyrapone therapy. This 11 -hydroxylase inhibitor reduces circulating levels of cortisol by inhibiting its synthesis from 11-deoxycortisol. Metyrapone is also useful in the preparation of patients with Cushing syndrome for definitive treatment such as adrenalectomy, trans-sphenoidal microsurgery or pituitary irradiation. Initial dosage is 250 mg 8 hourly, increasing over a week to 500 mg 6 hourly. In full dosage complete adrenal blockade is achieved, necessitating replacement therapy with 0.25 mg dexamethasone twice daily. Side effects of Metyrapone are often unpleasant and include nausea, vomiting, hirsutism and acne.

Other drugs have also been used in the medical management of Cushing syndrome, including ketoconazole, which reduces cortisol levels by inhibiting cytochrome P450 enzymes,

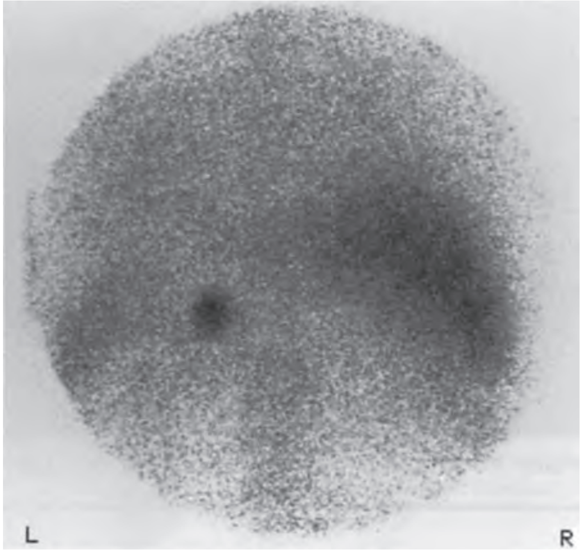

Figure 20.3 Selenocholesterol scan of a patient with Cushing syndrome due to an adenoma in the left adrenal gland. This technique has now been abandoned owing to unreliability, lack of isotopes and increased accuracy of CT/MRI.

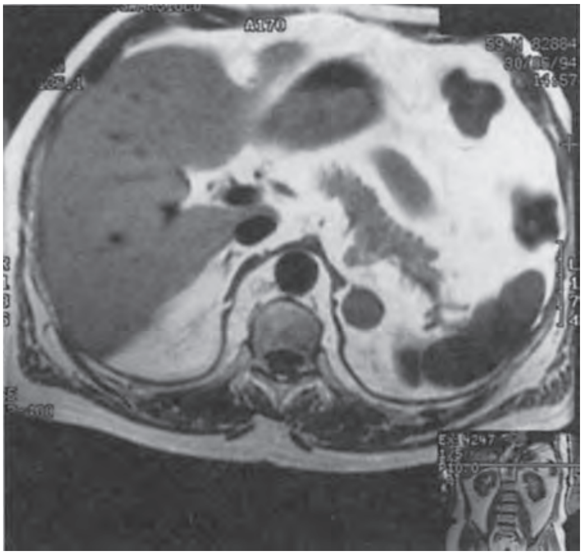

Figure 20.4 MRI scan of a patient with Cushing syndrome due to an adenoma in the left adrenal gland.

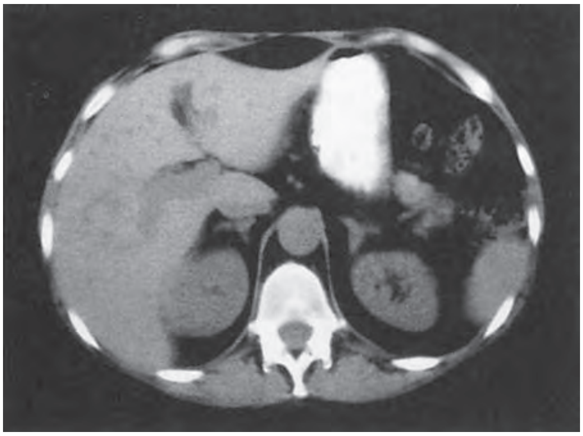

Figure 20.5 CT scan of the abdomen showing bilateral enlarged hyperplastic adrenal glands in the ectopic adrenocorticotrophic hormone syndrome.

aminoglutethimide, which inhibits the conversion of cholesterol to pregnenolone, bromocryptine, a dopamine agonist, and mitotane (discussed in Adrenocortical carcinoma).

Trans-sphenoidal microsurgery for pituitary disease

Selective removal of the pituitary basophil microadenoma by trans-sphenoidal microsurgery is currently the treatment of choice for patients with Cushing disease. When tumours have been localized preoperatively and removed completely at operation by an experienced surgeon, cure rates are high (80–90%). These patients rarely require pituitary replacement therapy. When tumours are not localized preoperatively and not readily identified at operation, partial hypophysectomy (removing two-thirds of the gland) is usually performed. Cure rates in these patients fall in comparison with the former group.

Pituitary surgery will be complicated by pituitary insufficiency when complete hypophysectomy is performed. Patients may require replacement therapy with one or more of the following agents: corticosteroid, thyroxine, testosterone, oestrogen and antidiuretic hormone (diabetes insipidus). Complications such as infection, meningitis or anosmia occur rarely.

Pituitary irradiation

Radiotherapy using either an external proton beam, linear accelerator or interstitial irradiation using gold-198 or yttrium-90 is also effective. Resolution of the clinical syndrome, however, is more protracted and may take 6–18 months. Pituitary insufficiency occurs in about 50% of patients but less frequently in children, making pituitary irradiation treatment an appropriate and acceptable therapy.

Bilateral adrenalectomy

Formerly the treatment of choice in Cushing disease, improved techniques in pituitary surgery have meant that bilateral adrenalectomy is reserved for the following situations:

- when pituitary surgery has failed or is technically not feasible
- for palliative treatment of patients with ectopic ACTH syndrome
- for patients with primary adrenal hyperplasia
- for patients with rapidly progressive or severe hypercortisolism.

Prior to surgery, treatment with Metyrapone is necessary to reduce cortisol production and correct metabolic defects. Diabetes mellitus and hypertension should be controlled if present. Appropriate venous thrombosis prophylaxis and support stockings are employed. Adequate steroid replacement therapy is essential in this procedure, the details of which are outlined earlier in this chapter. Adrenalectomized patients are dependent on lifelong glucocorticoid and mineralocorticoid replacement therapy.

A rare, late complication of bilateral adrenalectomy in patients with Cushing syndrome was first described by Nelson and colleagues in 1960. This condition is characterized by the development of an ACTH-producing pituitary tumour following bilateral adrenalectomy, accompanied by skin hyperpigmentation, headache, visual field defects and hypopituitarism. The condition may be controlled by hypophysectomy or pituitary irradiation. Prophylactic pituitary irradiation in patients undergoing bilateral adrenalectomy will reduce the incidence of Nelson syndrome.

Overall, results for bilateral adrenalectomy in the treatment of Cushing disease are good. Montgomery and Welbourn (1978) reported 65% of patients in remission at 5–15 years following surgery with 50% alive at 20 years.

Unilateral adrenalectomy

When Cushing syndrome is caused by an adrenal adenoma the treatment of choice is unilateral adrenalectomy, with most endocrine surgeons currently favouring a laparoscopic approach. The contralateral adrenal gland is suppressed in this condition and patients require steroid support both peroperatively (at tumour removal) and postoperatively. Complete weaning off steroid replacement may take more than a year. Cure rate and long-term survival are excellent.

Summary

The causes and treatment of Cushing syndrome are summarized in Figure 20.6.

Adrenocortical carcinoma

Pathology

Adrenocortical carcinoma is a rare tumour responsible for 10% of all cases of Cushing disease with a peak incidence in the fourth and fifth decades. Tumours are usually >5 cm in diameter and may be palpable. Macroscopically, they have a lobulated appearance, are greyish pink in colour and exhibit areas of haemorrhage and necrosis (Figure 20.7). They may invade local structures such as pancreas, kidney, diaphragm and bowel. Venous invasion is also common and may be gross to involve the inferior vena cava. Microscopically tumours display numerous mitoses, nuclear pleomorphism and vascular invasion. Sometimes the true malignant potential may not be apparent on conventional histological appraisal.

Adrenocortical carcinomas are aggressive malignancies with a high recurrence rate after surgery and a poor response to radiotherapy. Distant metastases to liver, lungs, bone and skin are common and are often found at the time of presentation. Most forms of treatment are disappointing and only a minority of patients survive beyond 2–3 years.

Tumours are divided into two groups: functioning (60%) and non-functioning (40%). The former account for 10% of all cases of Cushing syndrome. Functioning tumours are more common in younger patients (<40 years) and exhibit a female to male ratio of 4:1. The clinical picture is dependent upon the hormone or hormones secreted. In contrast, non-functioning tumours are more common in older patients (>40 years) and exhibit a female to male ratio of 2:1 but may produce steroid precursors such as pregnenolone.

Surgical staging

Adrenocortical carcinomas may be staged into the following groups:

- Stage I: tumour <5 cm in diameter, with no local invasion, nodal or distant metastases.

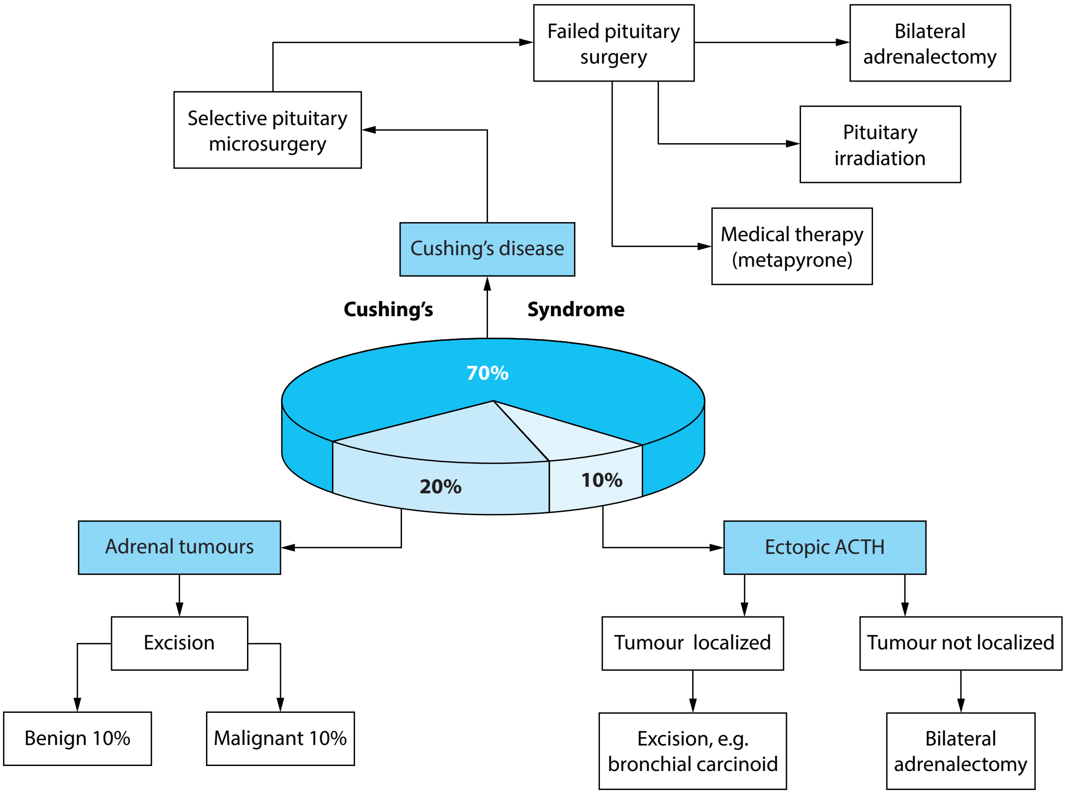

Figure 20.6 Causes and treatment of Cushing syndrome. ACTH, adrenocorticotrophic hormone.

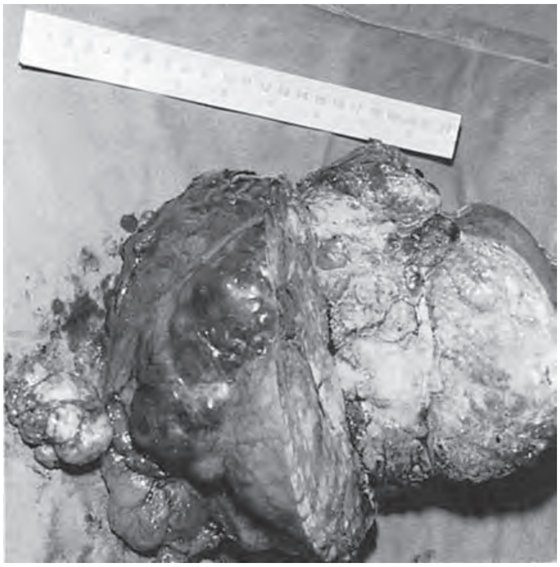

Figure 20.7 Gross specimen of adrenocortical carcinoma: haemorrhagic cut surface of a partly necrotic tumour.

- Stage II: tumour >5 cm in diameter, with no local invasion, nodal or distant metastases.
- Stage III: tumour with local invasion or local lymph node metastases but no distant metastases.
- Stage IV: tumour with local invasion *and* local lymph node *or* distant metastases.

At presentation approximately 70% of patients have either stage III or stage IV disease.

Clinical presentation

Non-functioning or minimally functioning tumours may grow to a massive size (>20 cm) before they become clinically apparent. Despite the term 'non-functioning' these tumours do produce steroid precursors and measurement of dehydroepiandrosterone may be of value in the diagnosis of malignant disease. Patients usually present with weight loss, fatigue, abdominal pain or in rare incidences with haemorrhagic necrosis of the tumour leading to acute pain, fever and/or shock. A palpable abdominal mass may be present. Functioning tumours secrete excessive steroids which may cause Cushing syndrome, hyperaldosteronism, virilization, feminization or a mixed clinical picture. Indeed a mixed hormonal secretion is highly suspicious of malignancy.

The development of Cushing syndrome in a child is likely to be due to an adrenocortical carcinoma. It occurs in association with virilization, acne and amenorrhoea in the young female, virilization in a prepubital female and feminization in the male. In contrast to benign secreting tumours the onset of symptoms is likely to be rapid. Functioning tumours may also be large at presentation. Adrenocortical cancers are not ACTH dependent and, like benign adrenocortical tumours, fail to suppress with high doses of dexamethasone.

Preoperative imaging with CT or MRI will provide valuable information regarding tumour size, local invasion and distant metastases (Figure 20.8a,b). The presence of inferior caval invasion can also be determined by MRI, rendering caval venography unnecessary (Figure 20.8c).

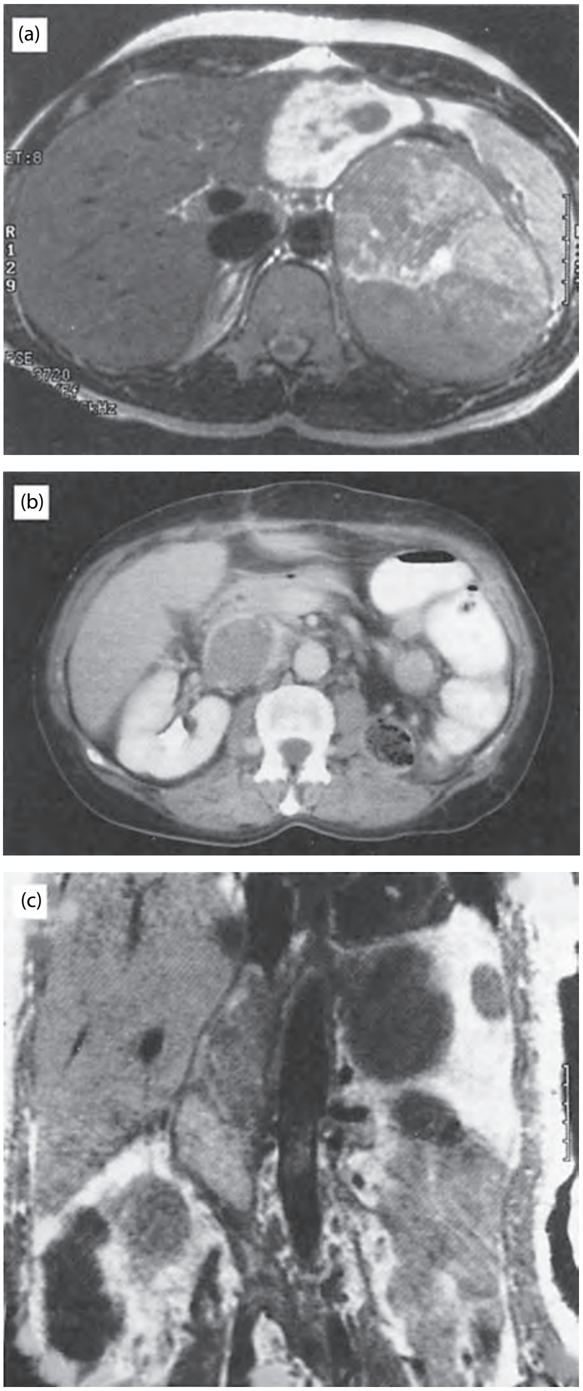

Figure 20.8 (a) MRI scan of a patient with a massive left adrenocortical carcinoma. (b) CT scan showing the tumour within the lumen of the inferior vena cava (IVC). (c) MRI scan showing tumour invasion of the IVC.

Treatment

Surgical resection offers the only prospect of cure. Unfortunately most patients at presentation have advanced incurable disease and only palliation is possible. In patients with stage I or II disease, aggressive surgical resection in the form of an *en bloc* resection, sacrificing adjacent organs such as the spleen, kidney and distal pancreas, is necessary to achieve adequate clearance. Occasionally large tumours require a thoracoabdominal approach and clearance of an involved inferior vena cava may be best achieved using cardiopulmonary bypass. Should local recurrence occur, further surgical resection has been shown to lead to prolonged survival. Steroid replacement should be given at the time of adrenalectomy for functioning tumours and maintained postoperatively.

These tumours demonstrate little radiosensitivity and radiotherapy has proved disappointing. Chemotherapy with mitotane (o,p'-DDD) has been of value particularly when used in patients prior to the development of metastatic disease following surgical resection for stage I and II disease and in an individual subsequently undergoing repeated surgical resection for recurrent disease. It is unlikely however that this agent significantly improves overall survival. Mitotane induces selective necrosis of the zona fasiculata and zona reticularis and results in destruction of the contralateral adrenal gland. Replacement steroid therapy is therefore essential. Metyrapone is useful in controlling the symptoms of cortisol excess in patients who are unfit or unsuitable for surgery.

Survival rates for adrenocortical carcinoma are poor and are dependent on disease stage at presentation. The overall 5 year survival is as low as 16% but stage I and II disease may have a survival of more than 50% compared with 0% for those with stage IV tumours.

Aldosteronism

Primary aldosteronism

Primary hyperaldosteronism is a rare syndrome characterized by hypertension, hypokalaemia, hypernatraemia and suppressed plasma renin activity (PRA). It is caused by excessive aldosterone secretion from the zona glomerulosa of the adrenal cortex. This potentially curable condition accounts for <1% of all patients with hypertension and was first described by Dr Jerome Conn in 1955, 3 years after the hormone aldosterone had been identified.

Excessive aldosterone production causes expansion of plasma volume and elevation of the blood pressure (see Physiology). The rise in blood volume and sodium ion concentration is detected by the juxtaglomerular apparatus and renin secretion falls in response. Loss of potassium and hydrogen ions in the urine leads to hypokalaemia and metabolic alkalosis.

Adrenocortical adenoma (Conn's tumour) is by far the most common cause of primary hyperaldosteronism, accounting for approximately 85% of cases. Other less common causes are bilateral adrenocortical hyperplasia (idiopathic hyperaldosteronism), aldosterone-producing adrenocortical carcinoma, glucocorticoid-suppressible hyperaldosteronism (familial type 1), non-glucocorticoid-suppressible hyperaldosteronism (familial type 2, which may be an adenoma or hyperplasia) and aldosterone-producing ovarian carcinoma.

Pathology

Conn's tumours are classically unilateral, <2 cm in size, project from the adrenal gland and have a characteristic golden or canary yellow appearance (Figure 20.9). Tumours are composed of lipid-laden clear cells and occur more frequently on the left side. Bilateral tumours are found in 10% of patients.

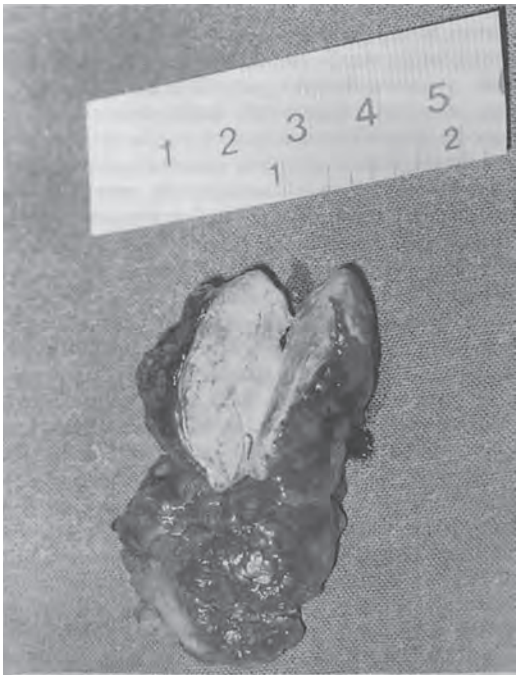

Figure 20.9 Conn's adrenal adenoma – gross specimen.

The remainder of the adrenal cortex in patients with Conn's tumours is not always normal. Microscopic and/or macroscopic nodular hyperplasia is a frequently associated feature, present in approximately 40–50% of patients.

Idiopathic hyperaldosteronism is found in 10–15% of patients with primary hyperaldosteronism. The disease is bilateral and composed of both diffuse and focal areas of microscopic and macroscopic hyperplasia. Nodule formation is frequently present, probably caused by hypertensive vascular changes. The nodules are capable of producing cortisol but not aldosterone. The dividing line between solitary adenoma, adenoma in a background of zona glomerulosa hyperplasia and hyperplasia with no dominant nodule is somewhat blurred. Indeed variations may represent a spectrum of disease. Identifying the cause of primary hyperaldosteronism is crucial and has a direct bearing on appropriate management.

Clinical presentation

The syndrome of primary hyperaldosteronism is characterized by continuous hypertension, which is often severe but rarely malignant. Patients may present at any age but more commonly between the third and fifth decades. Conn's tumours occur twice as commonly in women, although idiopathic hyperplasia is equally distributed between sexes and tends to occur at a later age.

The duration of hypertension prior to diagnosis is reported to be around 7 years and may be resistant to usual antihypertensive medication. When hypokalaemia is marked, patients may experience muscle weakness, cramps, headaches, polydipsia, polyuria and nocturia. In rare cases where hypokalaemia is particularly severe, patients may experience episodes of intermittent flaccid paralysis or even tetany. Symptoms of hypokalaemia may be brought on by the administration antihypertensive diuretics, particularly the thiazides. On rare occasions excessive salt intake may also cause episodes of hypokalaemia. Patients may be symptomless and the diagnosis is often only suspected when routine biochemical analysis characteristically reveals hypokalaemia associated with mild hypernatraemia.

Biochemical investigation and diagnosis

When hyperaldosteronism is suspected clinically, confirmation of the diagnosis is obtained by demonstrating elevated plasma aldosterone concentration (PAC) with suppressed PRA. This contrasts with secondary hyperaldosteronism, where both PAC and PRA are raised. Prior to carrying out biochemical studies potassium stores should be replenished (hypokalaemia inhibits aldosterone secretion) and drugs affecting renin–aldosterone regulation should be discontinued for 4–6 weeks. This includes spironolactone, ACE inhibitors and all diuretics. In patients in whom hypertension is marked, antihypertensive medication may be continued with agents such as prazosin and guanethidine, although calcium channel blockers and beta-blockers probably do not significantly affect results.

Primary hyperaldosteronism is confirmed if in a hypertensive patient PAC is increased (normal 2.2–15 ng/dL) in association with PRA being suppressed below normal (0.2–0.5 ng/dL). It has been suggested that a PAC/PRA ratio of >50 is diagnostic. Urinary potassium excretion should be in excess of 40 mmol/day.

Aldosterone suppression test

When results are equivocal further evaluation is deemed necessary. Diagnosis of primary hyperaldosteronism in this situation may be confirmed by failure to demonstrate suppression of urinary aldosterone secretion in response to a sodium load. Caution is necessary in performing these tests as biochemical disturbances can be severe and marked hypokalaemia may ensue. Patients should therefore be normokalaemic prior to testing and have potassium supplementation throughout the test. Oral sodium loading takes place over 3 days at a dose of 9 g/day; on the third day a 24 hour urine collection is made and urinary aldosterone, potassium and sodium levels are measured. The 24 hour urinary sodium excretion should exceed 200 mEq (documenting adequate sodium loading) and the diagnosis of hyperaldosteronism is confirmed if aldosterone levels exceed 12   g.

Differentiation between adenoma and idiopathic hyperplasia

Following diagnosis of primary hyperaldosteronism it is necessary to distinguish between an aldosterone-producing adenoma (APA) and idiopathic hyperplasia (IHA). This distinction has important therapeutic implications, as only cortical adenomas are likely to benefit from surgery. Aldosterone-producing cortical adenomas remain relatively unresponsive to angiotensin but still respond to ACTH and follow the corticotrophin circadian rhythm. In idiopathic hyperplasia there is a hypersensitivity to angiotensin II. These mechanisms can be used as the basis for a test to distinguish between the two conditions.

PAC is measured after overnight recumbency and after the patient has been ambulatory for 4 hours. In those with adenomas, PAC falls, whereas in patients with idiopathic hyperplasia PAC rises. Although this test is not absolutely reliable Young reported an overall accuracy of 85% in 246 patients in a collective review of the literature.

Reports of subtypes of primary hyperaldosteronism termed primary adrenal hyperplasia and aldosterone-producing renin-responsive adenoma (both responding to unilateral adrenalectomy) further confuse the issue.

Localization

CT scanning has proven to be reliable in localizing Conn's tumours >1 cm in size in more than 90% of patients. Identification of an obvious adrenal cortical adenoma increases confidence of the diagnosis of Conn's tumour versus idiopathic hyperplasia in patients with primary hyperaldosteronism. Tumours are usually homogeneous with decreased attenuation both before and after contrast enhancement because of their low lipid content. Most tumours measure <2 cm but those smaller than 1 cm may be missed, particularly in thin patients with little perinephric fat. MRI has also proved useful in identifying tumours and may well become the method of choice (Figures 20.10 and 20.11).

The most accurate functional method of localizing Conn's tumours remains selective venous catheterization (Table 20.1). The technique, however, is invasive and potentially hazardous, with reported extravasation of contrast, intra-adrenal haemorrhage and adrenal necrosis; these complications however are not common.

As the functioning adenoma may be small (4–8 mm) and incidental non-functioning adrenal adenomas, relatively common. Localization with selective venous catheterization is advocated in all patients with Conn's, to avoid the mistake of removing non-functioning adenomas on the wrong side. Difficulty in placing the catheter into the right adrenal vein (which is short and at 90° to the cava) may lead to sampling errors. These errors can be minimized by simultaneously measuring cortisol and employing the aldosterone–cortisol ratio as an indicator of any true increase in hormone concentration.

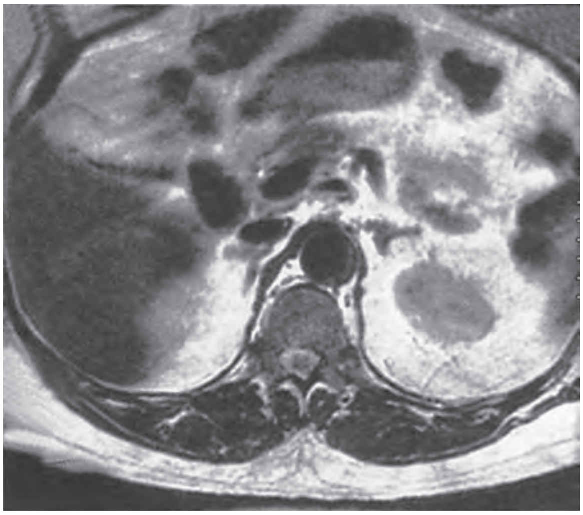

Figure 20.10 MRI scan of the abdomen in a patient with Conn syndrome due to a microadenoma in the left adrenal gland.

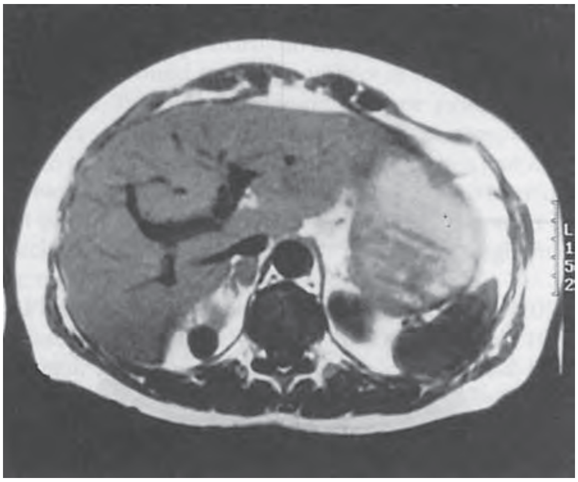

Figure 20.11 MRI of the abdomen in a patient with Conn syndrome due to right adrenal cortical adenoma.

Table 20.1 Selective venous sampling results in the patient with microadenoma shown in Figure 20.10

Vein	Aldosterone (A) (pmol/L)	Cortisol (C) (nmol/L)	A/C ratio
Right adrenal	2910	5300	0.5
Left adrenal	17 000	1810	9.4
Peripheral	660	320	2.1

Treatment

Once an aldosterone-secreting cortical adenoma is confirmed biochemically and localized by CT or radioisotope scan the treatment of choice in patients deemed medically fit for surgery is unilateral adrenalectomy. Traditionally an open posterior approach has been used, but this is a tumour which lends itself to laparoscopic adrenalectomy very well and is now currently the preferred technique for most endocrine surgeons. Patients are prepared for surgery by correction of hypokalaemia and hypertension, usually with spironolactone 100 mg/day. Those in whom hypertension responds well to spironolactone preoperatively tend to have a more favourable outcome from surgery.

Patients with idiopathic hyperplasia, those in whom hypertension persists following adenoma excision and those who are unfit for surgery because of medical reasons should be treated with spironolactone. Potassium-sparing diuretics also have a significant effect in controlling blood pressure and restoring potassium balance.

Postoperative follow-up

Unilateral adrenalectomy for adenomas has been reported to improve hypertension in the majority and to achieve normotension in 44–98% of patients, although the average cure rate appears to be about 70% at 1 year. Some patients may have persistent hypertension immediately postoperatively and others develop further hypertension over a period of time.

Sex and age have been demonstrated to be the only two significant prognostic factors in determining operative success. The older the patient, the less likely adrenalectomy is to restore normotension. This is probably because long-term hypertension causes irreversible pathological changes in blood vessel walls and coexisting causes of hypertension are also present. Hypertension is also more likely to be labelled 'essential' in elderly patients than in younger ones, which may lead further to a delay in diagnosis and thus long-term vessel damage. Women also have a more favourable response to adrenalectomy than men, possibly because female hormones confer a protective effect on blood vessels.

Summary

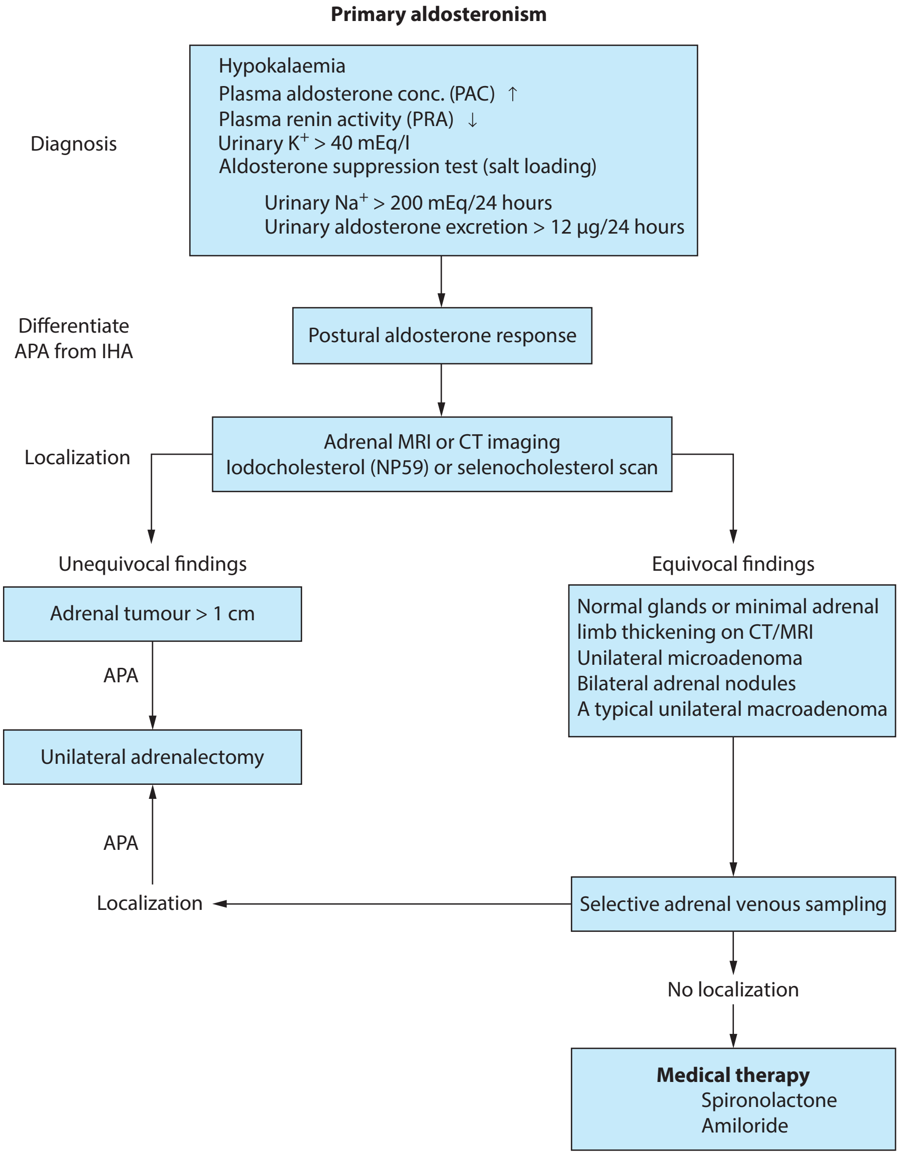
The investigation and treatment of primary aldosteronism is summarized in Figure 20.12.

Secondary hyperaldosteronism

Severe hypertension from cardiovascular or renal disease may be associated with excessive secretion of aldosterone termed secondary hyperaldosteronism. Hypertensive stimulation of the juxtaglomerular apparatus produces renin, which in turn leads to aldosterone secretion via the renin–angiotensin mechanism. Raised PRA therefore distinguishes secondary hyperaldosteronism from primary hyperaldosteronism (in which PRA is suppressed), this being an important clinical distinction.

Phaeochromocytoma

Phaeochromocytoma is a functioning tumour of the catecholamine-producing chromaffin cells. Derived from the Greek *phaeo* meaning dusky and *chroma* meaning colour, the tumour is characterized by a syndrome resulting from excess catecholamine production. The condition was first described in 1886 by Frankel, following a postmortem that had demonstrated bilateral adrenal tumours in an 18 year old patient who had presented with hypertension, sudden collapse and death. The term phaeochromocytoma was first used by Pick in 1912 but it was not until 1926 that the first successful



Primary aldosteronism
Diagnosis
Hypokalaemia

surgical removal of such a tumour was performed by Roux in Lausanne, a feat repeated by C.H. Mayo in the USA during the following year.

In recent years, advances in biochemical diagnosis, accurate preoperative localization, preparation with -and -adrenergic receptor-blocking agents and enhanced surgical skills have meant that patients with phaeochromocytoma can expect a favourable outcome from appropriate treatment.

Pathology

Most tumours are unilateral, more common on the right side and range considerably in size from 1 cm to more than 15 cm. Weight varies accordingly but usually tumours are between 50 and 200 g. Sporadic tumours are usually unilateral and unifocal. In contrast, familial tumours are more likely to be bilateral (50–70%) and multifocal.

Macroscopically, tumours are well encapsulated, frequently cystic-containing areas of haemorrhage and necrosis. When sectioned the cut surface is pinkish grey in colour and highly vascular.

Chromaffin cells are of neuroectodermal origin and although located primarily in the adrenal medulla they may also be found in small numbers in the sympathetic ganglia. Tumours developing in these extra-adrenal sites are termed *catecholamine-secreting paragangliomas.* These tumours are more common in children and may be located along the course of the sympathetic chain but predominate at the aortic bifurcation (the organ of Zuckerkandl). Approximately 40% of paragangliomas are malignant.

Phaeochromocytoma has been termed the ‘10%’ tumour. Approximately 10% are extra-adrenal, 10% bilateral, 10% malignant, 10% are in children and 10% are familial, associated with other genetically determined conditions such as multiple endocrine neoplasia (MEN) types 2A and 2B, von Hippel–Lindau disease or von Recklinghausen’s neurofibromatosis.

Histologically, diagnosis of malignancy in these tumours is rarely possible as many lesions, both benign and malignant, exhibit evidence of capsular and vascular invasion. The only reliable indicator of malignancy is demonstration of local invasion into adjacent structures such as the renal or inferior vena caval veins, or localization of tumour in sites other than the sympathetic chain such as bone, lung and liver.

Incidence

Phaeochromocytoma may be found at postmortem in approximately 0.1% of hypertensive patients. The incidence in the population is of the order of one or two cases per 100 000, and approximately 800 deaths per year occur in the USA from phaeochromocytoma. The condition remains undiagnosed in 35% of sufferers during their lifetime. In patients in whom phaeochromocytoma is not diagnosed, death may ensue from myocardial infarction or cerebrovascular accident during or immediately after even a minor surgical operation. A high index of suspicion is therefore necessary to make the diagnosis and avoid this potential catastrophe.

Clinical presentation

Hypertension is by far the most common manifestation, mimicking ‘essential’ hypertension by being continuous in 50% of patients but paroxysmal in the remaining 50%. Excess norepinephrine (noradrenaline), epinephrine (adrenaline) or dopamine secretion predisposes to hypertension usually associated with palpitations, sweating and headache. So commonly are these symptoms associated with phaeochromocytoma that the absence of all three has been said to rule out the diagnosis in patients with hypertension.

Events which raise intra-abdominal pressure such as bladder emptying, sexual activity, defaecation or exercise may trigger attacks that may last from several minutes to several hours. Other less common causative factors are alcohol, drugs (notably tricyclic antidepressants) and foods containing high levels of tyramine. In undiagnosed patients, labour or invasive procedures such as angiography may precipitate particularly severe hypertensive episodes resulting in peripheral circulatory failure and even cardiac arrest.

The incidences of myocardial infarction, hypertensive encephalopathy, cerebrovascular accident and catecholamine cardiomyopathy are all raised in these patients. Other manifestations of phaeochromocytoma, resulting from increased levels of catecholamines, are flushing, pallor, pupillary dilation, Raynaud’s phenomenon, fever, tremors, nausea, weakness, vertigo, anxiety and an impending sense of doom. Gastrointestinal manifestations may be generalized abdominal pain, pseudo-obstruction, ileus, ischaemic enterocolitis and acute megacolon. Malignant tumours may also be responsible for glucose intolerance and severe hyperglycaemia.

Physical examination frequently reveals a thin, pale, anxious patient. Hypertension may be severe and, in contrast to essential hypertension, 70% of patients exhibit a postural drop in blood pressure usually associated with concomitant tachycardia. An abdominal mass may be present in up to 15% of patients, palpation of which may precipitate paroxysmal symptoms and should be conducted with care in patients in whom there is a high index of suspicion. Clinical features such as a thyroid nodule, Marfinoid habitus or neurofibromatosis may be suggestive of familial disease such as MEN 2A, MEN 2B or von Recklinghausen’s disease.

The differential diagnosis includes ‘essential’ and ‘labile’ hypertension, anxiety neurosis and other psychiatric disorders, hyperthyroidism, diabetes mellitus and functional bowel disorder. It is not surprising therefore that phaeochromocytoma has been labelled the great ‘mimic’ with all the attendant diagnostic difficulties.

Investigation and diagnosis

Diagnosis of phaeochromocytoma is provided by establishing catecholamine excess, followed by localization of the tumour. Armstrong and colleagues described the metabolic pathways of catecholamine production and excretion, which provide the basis for biochemical investigation of phaeochromocytoma. Dopamine, norepinephrine and epinephrine are formed in the chromaffin cells of the adrenal medulla from phenylalanine and tyrosine. Norepinephrine and epinephrine are converted to normetadrenaline and metadrenaline prior to excretion in the urine. These metanephrines are then further converted to vanillyl mandelic acid (VMA), also excreted in the urine.

Diagnosis is thus established by 24 hour urine collection in an acidified container and measurement of the metanephrine and VMA content of the urine. Epinephrine, norepinephrine and dopamine are also assayed by high-pressure liquid chromatography, reducing the possibility of drug interactions producing spurious results. In borderline cases, measurement of plasma free catecholamine levels may be helpful during acute hypertensive attacks but is otherwise unnecessary. Pharmacological provocation tests are potentially dangerous and are only of historic interest.

Localization

Once the diagnosis of phaeochromocytoma has been confirmed the exact site of the tumour or tumours must be identified. MRI is now established as the localizing procedure of choice, in preference to CT (Figures 20.13–20.15). Tumours are displayed as low-signal intensity T_1 weighted images with a characteristic, almost unique, hyperintense signal on T_2 weighted images. This contrasts with non-functioning adrenal adenomas, which have the same signal characteristics as normal adrenal tissue. MRI is of particular value in locating extra-adrenal paragangliomas, especially those located in the urinary bladder and paracardiac regions (Figure 20.16). MRI negates the need for contrast enhancement of tumours necessary with CT imaging, thus avoiding the potential hypertensive crises which contrast material can precipitate, although a recent report suggest that use of non-ionic contrast material is probably safe.

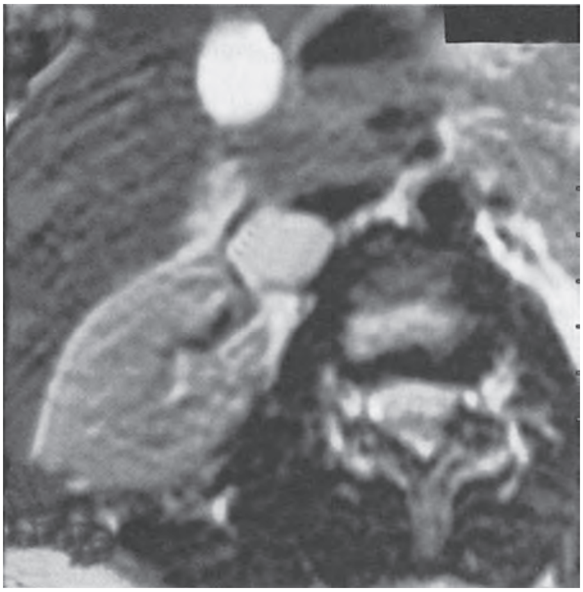

Figure 20.16 MRI scan (T_2 weighted) of an extra-adrenal phaeochromocytoma situated close to the right renal hilum.

When MRI or CT has failed to accurately localize the tumour ^{23}I-metaiodobenzylguanidine (MIBG) or indium-111 pentetreotide may be useful (Figures 20.17 and 20.18). MIBG has been reported to have a sensitivity of 90% and a specificity of 100% in tumour localization, although to achieve this it may be necessary to repeat the scan several times in the 72 hour period after administration of the tracer. Invasive procedures such as selective venous catheterization and selective adrenal angiography are no longer deemed necessary in tumour localization.

Treatment

Catecholamine-secreting tumours are treatable causes of hypertension, and surgical resection of the tumour following

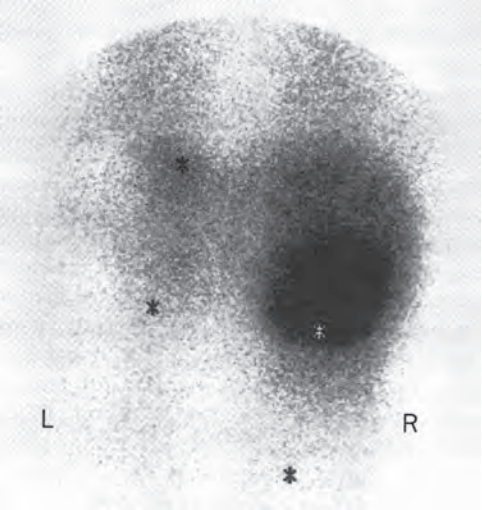

Figure 20.17 MIBG (metaiodobenzylguanidine) scan of a malignant right phaeochromocytoma.

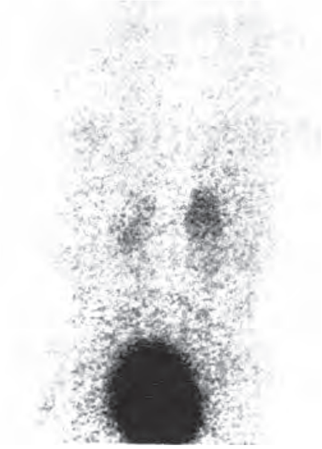

Figure 20.18 MIBG (metaiodobenzylguanidine) scan of a 5-year-old boy with bilateral phaeochromocytoma (right tumour within the adrenal gland, left tumour extra-adrenal).

pharmaceutical control of hypertension is the recommended management. Patients who have medical contraindications to surgery or patients have widespread metastatic disease from malignant phaeochromocytoma (in whom there is little hope of obtaining a surgical cure) will not be considered candidates for surgery. These patients in this group may benefit from treatment with -methyl- -tyrosine, an inhibitor of catecholamine synthesis which can reduce circulating levels by as much as 50%, offering some symptomatic control. Recent studies with the tyrosine kinase inhibitor sunitinib indicate that patients with metastatic phaeochromocytoma due to specific conditions (e.g. von Hippel–Lindau disease) may benefit from this drug.

Preoperative control of hypertension

Anaesthetic induction or even minimal manipulation of adrenal or extra-adrenal phaeochromocytomas may cause dramatic and dangerous fluctuations in blood pressure. It is therefore vital to control blood pressure preoperatively. The agent of choice in the routine patient is the long-acting -adrenergic blocker phenoxybenzamine. Medical control of hypertension in a patient thought to have a phaeochromocytoma should be commenced once the tumour is suspected, prior to any localizing procedures. Untreated patients are at significantly increased risk of myocardial infarction, cerebrovascular accident, acute heart failure, arrhythmias and sudden death.

Treatment with non-competitive alpha-blockade allows expansion of the intravascular volume, with concomitant fall in blood pressure, leading to the essential benefit of reduced frequency and intensity of peroperative hypertensive episodes. A disadvantage of alpha-blockade is the risk of hypotension following removal of the tumour and withdrawal of the -agonist activity of the catecholamines.

Phenoxybenzamine should be commenced at least 7–10 days prior to surgery. The initial dose should be 10 mg b.d., increasing by 10–20 mg/day, until hypertension is controlled and the patient experiences orthostatic hypotension. Often a dose up to 160 mg/day is required to achieve this effect. Patients should be encouraged to take liberal fluids and salt to help replace the expanded intravascular volume. Side effects of phenoxybenzamine include sedation, weakness, lassitude, nausea, nasal congestion and pedal oedema.

Three to four days prior to surgery, gentle beta-blockade with propranolol 40 mg/day is instituted. The use of preoperative beta-blockade had been somewhat controversial, although it is of particular use in patients with pure epinephrine-secreting tumours and those experiencing tachycardia and arrhythmias. Asthma and cardiac failure are absolute contraindications to the use of beta-blockers and -adrenergic blockade should not be used without prior alpha-blockade, as unopposed vasoconstriction can lead to potentially catastrophic hypertension.

The use of selective alpha$_1$-blockers, such as prazosin hydrochloride, and the newer alpha$_1$-blockers, such as terazosin and doxazosin (which selectively block postsynaptic alpha$_1$ receptors and have a shorter duration of action), may allow a reduction in blood pressure without the reflex tachycardia associated with non-competitive alpha-blockade. Labetalol, which has - and -adrenergic blocking properties, has a much shorter action than phenoxybenzamine and may be employed by anaesthetists peroperatively in controlling blood pressure. Other drugs reported to control blood pressure in phaeochromocytoma are calcium channel blockers such as nifedipine. Use is somewhat controversial but a claimed advantage of nifedipine is that patients are unlikely to experience unpleasant orthostatic hypotension.

Anaesthesia for phaeochromocytoma

Close co-operation among endocrinologist, anaesthetist and surgeon should ensure that the patient arrives in theatre in the optimal condition for surgery. Subsequently a co-ordinated team approach between surgeon and anaesthetist should ensure a safe outcome.

Patients are prepared for surgery by insertion of central venous and arterial lines. Electrocardiograph monitoring and intravenous access are essential and urinary catheterization is helpful. Swan–Ganz catheterization to monitor pulmonary wedge pressure has been advocated but its use is probably best restricted to patients in whom cardiac function is known to be seriously compromised, especially those with catecholamine cardiomyopathy.

Anaesthesia is best maintained by isoflurane rather than halothane, which has the potential for unwanted cardiac arrhythmias. A range of pressure-regulating agents (phentolamine, sodium nitroprusside, norepinephrine and dopamine) should be available in order to maintain and control blood pressure on a minute-to-minute basis throughout the procedure. Intravenous lidocaine (50–100 mg) is of value in controlling arrhythmias. Propranolol (1 mg) may also be of benefit. Cardioversion equipment must be readily available.

Danger periods during surgery for phaeochromocytoma include induction, intubation and peroperative handling of the tumour. Another crucial period may be immediately after tumour resection when hypotension can ensue. This situation is best managed by a co-ordinated effort by the surgeon and anaesthetist. Volume expansion with blood or colloids is usually sufficient but in refractory cases it may be necessary to give an epinephrine or a dopamine infusion. Failure of the blood pressure to fall following tumour removal may suggest a second tumour or undiagnosed metastatic disease. When bilateral adrenalectomy is performed the procedure must be covered with hydrocortisone 100 mg preoperatively on induction and further hydrocortisone at the time of gland removal. Intravenous hydrocortisone (100 mg 6 hourly) is continued postoperatively, reducing as full oral steroid replacement therapy is instituted.

Surgery for phaeochromocytoma

Surgical approaches for phaeochromocytoma have changed over recent years. Formerly an anterior transabdominal approach was advocated, through either a midline or a bilateral subcostal incision. This approach enabled a laparotomy to be performed to accurately identify the site of disease and to ensure that no lesion was overlooked. Transabdominal access is especially necessary in large tumours, particularly on the right side where the disease may extend posterior to the vena cava and lead to problems of vascular control. In rare instances a thoracoabdominal procedure may be necessary.

As localizing techniques improved a unilateral focused approach was advocated, usually via the posterior or posterolateral route. The advent of laparoscopic adrenalectomy and the increasing refinement of localizing procedures such as MRI has meant that now a unilateral, focused, endoscopic approach has become virtually the routine surgical method for removal of phaeochromocytomas. This may be accomplished for tumours up to 6 cm in diameter via a transabdominal laparoscopic approach (favoured by most surgeons) or a posterior route (technically more difficult), appropriate for smaller tumours.

Technical aspects are covered in the section on adrenal surgery in this chapter (Adrenalectomy) but special considerations in surgery for phaeochromocytoma include minimal handling of the tumour (made easier by a laparoscopic approach), complete haemostasis (venous ooze is a potential hazard in the alpha-blocked patient) and close communication with the anaesthetist.

Extra-adrenal phaeochromocytomas are managed by a variety of surgical approaches depending on their location. In the case of bladder tumours, partial, segmental or even total cystectomy may be necessary, particularly when tumours are suspected to be malignant.

Postoperative management

Postoperatively intensive care monitoring of arterial blood pressure, central venous pressure and urinary output is vital. Requirements for intravenous fluid replacement of blood and plasma expanders will be largely determined by the above measurements. Often large amounts of fluid will be necessary because of the relative disproportion between vascular capacitance and circulating blood volume following the removal of the chronic catecholamine vasoconstrictor drive. Residual phenoxybenzamine can also cause fluid loss into the retroperitoneal space.

When hypotension persists, haemorrhage rather than refractory vasodilation should be considered. Care should be taken to avoid overtransfusion leading to pulmonary oedema. Blood glucose levels should also be closely monitored, particularly in the first 6 hours postoperatively as dangerous, even life-threatening, hypoglycaemia may ensue, requiring glucose infusion. When hypertension persists this may be due to residual tumour, metastatic disease or chronic renal damage secondary to longstanding severe hypertension.

All patients should have urinary catecholamine and VMA measurements repeated after resection and annually thereafter. In patients with malignant disease the true nature of the condition may not become apparent for many years, thus long-term follow-up is advised and even benign tumours may occasionally recur. Overall, however, prognosis in well-prepared patients undergoing careful elective surgery is excellent, with low morbidity and mortality.

Phaeochromocytoma in special circumstances

Unsuspected phaeochromocytoma encountered during surgery

This potentially fatal condition presents a considerable challenge to both surgeon and anaesthetist. Warning signs include unexplained tachycardia, arrhythmias or hypertension during anaesthetic induction, at attempted tumour removal or for surgery for a completely unrelated condition in an unprepared patient. Should these warning signs go unheeded patients may develop cardiac failure, pulmonary oedema and fatal cardiac arrest. In this situation alpha-blockade should be instituted immediately and the procedure terminated. The patient should then undergo full investigation, preparation and localization prior to excision of the tumour at a later date.

Malignant phaeochromocytoma

Malignancy occurs in about 10% of phaeochromocytomas but this rises to 40–50% in extra-adrenal tumours. The difficulties of

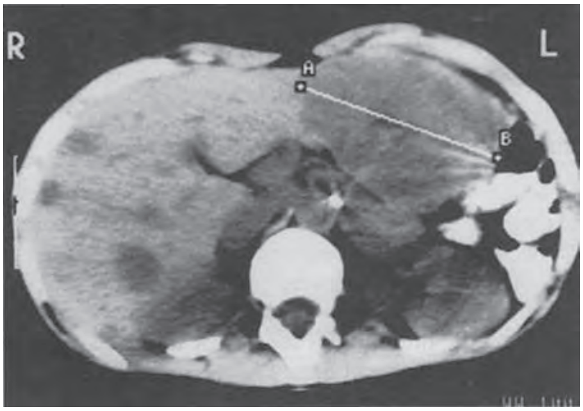

Figure 20.19 CT scan of recurrent malignant phaeochromocytoma in the left adrenal tumour bed. Multiple metastases are seen in the right lobe of the liver.

diagnosing malignancy histologically have already been referred to. Surgical resection remains the principal therapeutic measure.

Localization of metastatic disease may be aided by an MIBG scan, although this has a false-negative rate of approximately 10%. In some instances ^{131}I-MIBG may have a therapeutic as well as a diagnostic role. When possible, recurrent disease should be resected, debulked or ablated (Figure 20.19). Chemotherapy has not proved very effective but radiotherapy has been reported to occasionally provide useful palliation, particularly in bony metastases. New agents such as sunitinib (see above) may in future offer some symptomatic relief in very specific patient groups with metastatic or non-resectable disease.

Survival rates in malignant phaeochromocytoma are between 35% and 40% at 5 years, although on rare occasions patients with distant metastases have been reported to survive longer. Extra-adrenal tumours, however, carry a less favourable prognosis.

Phaeochromocytoma in pregnancy

Phaeochromocytoma in pregnancy is a potentially lethal condition: maternal mortality of 40% and fetal mortality of 40–56% have been reported. Hypertension is common in pregnancy and phaeochromocytoma may be mistaken for pre-eclampsia. Therefore, catecholamine excess should be excluded in all hypertensive pregnant women. A high index of suspicion should be maintained in pregnant women who present with unexplained cardiovascular collapse, in those who exhibit severe or labile hypertension in early pregnancy, or in patients who have a positive family history. Maternal and fetal mortality rates are greatly reduced if the diagnosis is made prior to the onset of labour as hypertensive paroxysms will be precipitated by uterine contractions, anaesthesia or caesarean section.

Following diagnosis, tumours may be localized with MRI, avoiding excessive use of radiographs.

After instigating the usual alpha-blockade and beta-blockade 2–3 days preoperatively in the first and second trimesters surgical excision of tumours may be performed. Some patients may elect for termination of the pregnancy. In the third trimester caesarean section followed by removal of the phaeochromocytoma under the same anaesthetic is appropriate (Figure 20.20). Vaginal delivery should be avoided at all costs.

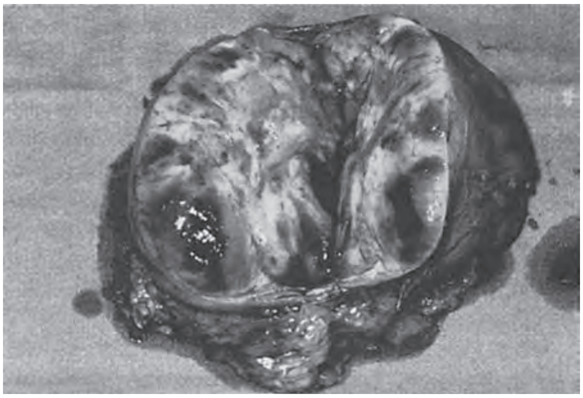

Figure 20.20 Gross specimen of phaeochromocytoma diagnosed during pregnancy and excised at 36 weeks synchronously with caesarean section delivery. The tumour shows typical haemorrhagic appearances on the cut surface.

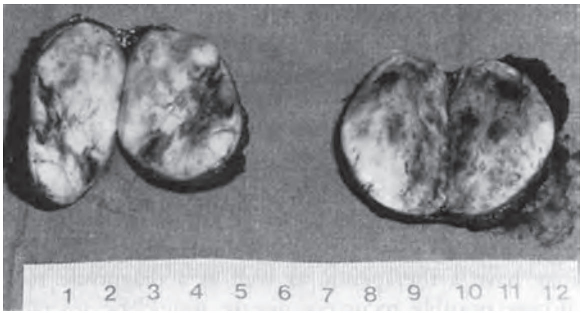

Figure 20.21 Gross specimen of bilateral phaeochromocytoma excised from a 5-year-old boy.

Phaeochromocytoma in children

When phaeochromocytoma occurs in children there is an increased incidence of bilateral, multiple and extra-adrenal tumours because of the association with MEN 2 syndromes (Figure 20.21). In contrast to adults the tumours are less commonly malignant and the hypertension more often sustained. Hypertension in children always demands the fullest investigation and surgical resection of a phaeochromocytoma is usually followed by an excellent clinical result.

Phaeochromocytoma and multiple endocrine neoplasia 2A and 2B

MEN is a syndrome characterized by medullary thyroid carcinoma and phaeochromocytoma. In the MEN 2A variant, primary hyperparathyroidism is also associated, whereas in MEN 2B patients have characteristic facies, Marfinoid habitus, skeletal abnormalities and mucocutaneous ganglioneuromas. Hyperparathyroidism does not occur in MEN 2B.

Germ-line mutations in the *Ret* proto-oncogene are responsible for MEN 2A and 2B. The gene is inherited in an autosomal dominant fashion with high penetrance and variable expression. All patients with MEN 2 will develop medullary

thyroid cancer but development of phaeochromocytoma is variable.

When present adrenal disease in MEN 2 is bilateral, passing through a phase of hyperplasia to nodularity and multiple phaeochromocytomas. Once the disease has been confirmed through measurement of urinary catecholamines and their metabolites, bilateral adrenalectomy should be performed. Some advocate unilateral adrenalectomy when the disease appears localized to one side but this approach remains controversial as the natural history of the disease clearly indicates that bilateral disease eventually develops in all affected individuals (Figure 20.22). After adrenalectomy careful follow-up is mandatory in all patients, but after unilateral adrenalectomy this is especially pertinent in order to monitor the development of disease in the contralateral gland.

Summary

The investigation and treatment of phaeochromocytoma is summarized in Figure 20.23.

Other adrenal tumours

Adrenal incidentaloma

Increasing use of sophisticated imaging modalities such as ultrasound, CT and MRI, and the ever-increasing resolution that both software and hardware are achieving, has meant that the number of incidentally discovered adrenal masses has increased over the past 10 years. Silent adrenal masses are now identified in 0.5–4.5% of patients undergoing CT for reasons other than suspected adrenal pathology, a figure approaching the incidence of incidentalomas identified at postmortem (1.5–5.7%). Adrenal incidentalomas present the clinician with a diagnostic problem, particularly in excluding malignancy tumour but also with respect to functioning potential.

The essential step in the investigation of an incidentally discovered adrenal tumour is to establish whether the lesion is functioning. Biochemical screening should include measurement of electrolytes, 24 hour urinary VMA and metanephrine levels, and 09.00 and midnight serum cortisol and aldosterone. The 1 mg overnight dexamethasone suppression test should exclude Cushing syndrome.

The majority of incidentalomas (35–95%) are benign, non-functioning adrenal adenomas. They are more prevalent in older women and in obese, diabetic patients. Tumours are classically smooth, round and <3 cm in size. They are homogeneous and enhance only minimally after contrast injection on CT. With MRI, signal intensity is the same as normal adrenal tissue; this is helpful in distinguishing secondary metastatic lesions in the adrenal, which tend to have intense T_2 weighted images (Figure 20.24). Calcification, haemorrhage and necrosis are uncommon.

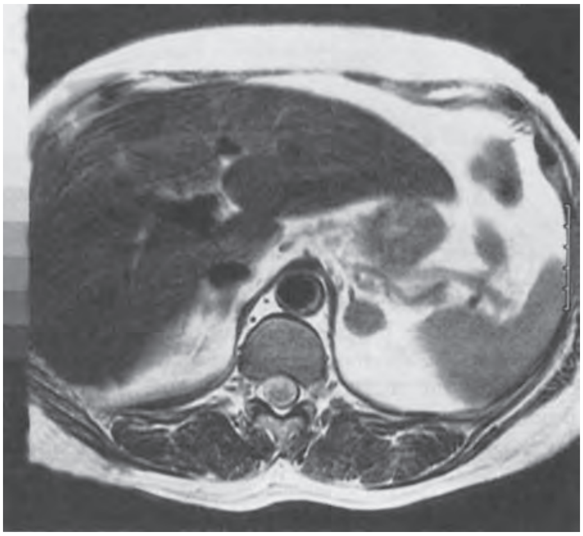

Figure 20.24 MRI scan of a non-functioning left adrenal incidentaloma.

In-/out-of-phase MRI scanning is useful in characterising the fat content of adrenal incidental adenomas and identifying them as benign. In rare instances in which tumours are not characterized, then positron emission tomography scanning may be useful in larger (>4 cm) tumours.

Cytology may aid in the diagnosis of malignancy. Following the exclusion of a phaeochromocytoma, fine needle aspiration cytology can be selectively and carefully employed if a secondary adrenal malignant deposit is suspected.

Adrenal cysts also cause diagnostic confusion. These are usually small and symptomless but when large may present as a tumour mass displacing the kidney. Drainage under ultrasound or CT guidance is recommended and the fluid sent for cytological analysis. Adenomyelolipomas are benign, non-functioning tumours which have a characteristic appearance on MRI and only require excision if there are significant symptoms.

The incidence of malignancy in adrenal tumours increases with size of lesion and for this reason surgical resection is recommended for all lesions >4 cm. MRI or CT scans demonstrating non-homogeneity may also influence the decision to perform surgery.

Smaller lesions can be monitored by interval CT, MRI or ultrasound scans and excision considered when there is an increase in size. Surgical excision should also be performed in patients under 50 years of age because of the increased malignancy risk for adrenal lesions in the younger subject.

Secondary adrenal tumours

Many malignant neoplasms metastasize to the adrenal glands. Among the more common tumours are breast, bronchus and melanoma. Adrenocortical hormone production may be reduced when large metastases cause significant adrenal destruction resulting in an acute Addisonian crisis.

Neuroblastoma

Presentation

These tumours of neural crest origin and occur mainly in children, with over 60% presenting in the first year of life. They occur in the adrenal medulla, adjacent retroperitoneal tissue and along the sympathetic ganglia. The majority of the tumours occur in the abdomen (75%), the remainder occurring in the thorax (20%) and neck (5%). Aggressive malignancies, they invade adjacent local structures such as kidney, spleen, liver and pancreas. Metastatic spread occurs early via the bloodstream and lymphatics and is frequently present at initial presentation. Two distinct patterns of metastatic spread are recognized: Hutchinson's type (tumour on the left side producing metastases to the orbit, skull and long bones) and Pepper's type (tumour on the right side with metastatic spread to the liver).

Approximately 50% of children with this tumour present with a large, symptomless abdominal mass. The other 50% present with symptoms including anorexia, nausea, vomiting and diarrhoea (tumours producing vasoactive intestinal peptide). Over 90% of neuroblastomas produce catecholamines and hypertension and/or flushing may be a feature. A 24 hour urine collection for VMA, metanephrines and catecholamines is therefore mandatory in these patients. Dumb-bell tumours (tumours extending into the spinal canal) may produce neurological symptoms. The main differential diagnosis of neuroblastoma is nephroblastoma (Wilms' tumour).

Tumour staging

Tumours are staged with a combination of chest radiograph, CT/MRI scanning and skeletal survey. MIBG scintigraphy may be useful in identifying primary tumours as well as residual or recurrent tumour:

- Stage I: tumours are confined to the adrenal gland and are totally excised.
- Stage II: tumours extend beyond the organ of origin but do not cross the midline; ipsilateral lymph nodes may be involved.
- Stage III: tumours cross the midline.
- Stage IV: distant metastatic spread present.

Treatment

Surgical excision remains the mainstay of treatment. When complete excision is not possible, tumour debulking followed by either radiotherapy and/or combination chemotherapy with vincristine and cyclophosphamide may be of benefit. Radiotherapy is of particular benefit in painful metastatic deposits.

Prognosis

Prognosis is dependent on age and tumour stage. Children aged <2 years have a better 2 year survival rate than their older counterparts (77% compared with 38%). The 2 year survival rate worsens with stage: stage I (100%), stage II (82%), stage III (42%) and stage IV (30%). Factors improving stage-specific prognosis include a high urinary VMA to homovanillic acid ratio and low serum neurone-specific enolase level.

Adrenalectomy

Background

The first description of an adrenalectomy was provided by Thornton in 1890. He employed an approach to the right adrenal gland using an incision for cholecystectomy, previously described by Carl von Langenbüch of Berlin in 1882. For many years the adrenal glands were approached via incisions described for renal surgery. Unfortunately these incisions were frequently too low to gain adequate exposure and surgeons began to site incisions progressively higher. In 1932 Lennox Broster of London (a pioneer of adrenal surgery) described a posterior, intercostal, transpleural adrenalectomy. He had performed a laparotomy a few weeks previously in the same patient to inspect the adrenals and look for any extra-adrenal tissue. In 1936 Hugh Young of Baltimore, MD, devised a simultaneous, bilateral, posterior approach, enabling him to inspect both adrenal glands, a technique associated with little postoperative morbidity. Prior to the advent of CT scanning, exploratory laparotomy played a pivotal role in both localizing adrenal and extra-adrenal tumours and providing access for adrenalectomy. With modern-day localizing techniques, however, this approach has become virtually obsolete.

The main approaches to the adrenal glands are anterior and posterior or posterolateral. The description by Gagner in 1992 of an endoscopic technique has provided surgeons with the additional option of performing adrenalectomy as either an 'open' or a 'minimally invasive' (endoscopic) procedure. Each method of adrenalectomy has both advantages and disadvantages and the approach of choice is dependent on a number of factors including tumour pathology, tumour size, patient physique, previous surgery and the personal preference of the surgeon. Despite the various options, adrenalectomy still provides the modern-day endocrine surgeon with a significant surgical challenge.

Open anterior approach

With improved localization techniques the *open anterior approach* tends to be reserved for the removal of large (<6–8 cm), malignant or potentially malignant tumours or in patients in whom localizing procedures have been equivocal. It provides excellent exposure of one or both adrenal glands and enables examination of the abdominal viscera and sympathetic chain to search for extra-adrenal tissue. The patient is placed supine on the operating table and a transverse, subcostal incision made. This may either be unilateral or be extended across the midline when exposure of both adrenal glands is required. Alternatively a vertical midline incision may be preferred. The major disadvantages of this approach are:

- in patients with Cushing syndrome, when wound complications including infection and dehiscence contribute significantly to morbidity
- it necessitates entering the peritoneal cavity producing a postoperative ileus
- there is an increased incidence of atelectasis, pulmonary collapse and chest infection.

Laparoscopic 'anterior' approach

Laparoscopic adrenalectomy can be performed effectively and safely. This approach was quickly popularized and subsequent reports confirmed its feasibility. Most surgeons currently use a lateral flank approach with the patient lying with the side to be operated on uppermost. A pneumoperitoneum is created and three or, when needed, four laparoscopic ports are inserted below the costal margin. Ports should be either 5–12 mm or 5 mm in size depending on the kit available to the surgeon and personal choice. Placing all 5–12 mm ports enables the camera to be moved from port to port to improve visualization. A significant advantage of the flank approach is that once the spleen is mobilized on the left side it acts as a retractor under its own weight. Similarly the liver on the right requires minimal retraction.

The anterior laparoscopic approach allows excellent visualization of the adrenal glands and the vascular pedicles both sides, particularly the adrenal veins. It is an ideal approach for Conn's tumours and smaller phaeochromocytomas (<6 cm) as the adrenal vein can be divided early in the procedure. Operative times have dramatically improved with experience and new instrumentation to an extent that bilateral laparoscopic adrenalectomy is now readily performed.

Right-sided laparoscopic adrenalectomy

Four subcostal ports are placed, with the most medial port being a 5 mm port to allow liver retraction, and the other three 5–12 mm ports. The liver is elevated and the inferior vena cava identified. The peritoneal reflection of the liver onto the back wall is incised and the liver elevated further. The peritoneum alongside the cava is incised revealing the adrenal gland. The dissection proceeds carefully cephalad alongside the cava until the adrenal vein is identified. This is gently mobilized and then taken between clips. Once the adrenal vein is divided the adrenal gland can be elevated off the posterior abdominal wall and freed either using a hook or with a device such as the Harmonic Scalpel or LigaSure. The adrenal gland is dissected free usually in a medial to lateral direction. Normally there are no obviously large individual arteries to be divided between clips but this can change in the case of large tumours, particularly phaeochromocytoma (which may on occasion be very vascular). Care must be taken not to place dissecting graspers through the capsule of the adrenal gland or to tear the liver capsule by vigorous retraction too early in the procedure as both events often cause troublesome bleeding that hinders visualization.

The gland is placed into a retrieval bag and removed via the lateral port. Wounds are closed with a subcuticular stitch.

Left-sided laparoscopic adrenalectomy

Three ports are usually sufficient to allow successful mobilization and removal of the left adrenal gland. The most medial port may be a 5 mm port, the other two 5–12 mm. Care should be take not to place the ports too medially as, if a fourth port is needed, space must be left for this to be placed without causing problems. The splenic flexure of the colon should be fully mobilized inferiorly to allow identification of the renal vein. The lienorenal ligament is divided and the spleen mobilized medially. Gerota's fascia is divided allowing the spleen to be further mobilized medially. Dividing the fascia allows identification of the adrenal gland. Looking for the gland too early (prior to dividing Gerota's fascia) is a cause of surgeons struggling to find a left gland. In this situation it is possible to mistake the tail of the pancreas for the adrenal, increasing potential morbidity.

Once identified (usually running cephalad alongside the medial aspect of the kidney, not superior to it) the gland it traced inferiorly to identify the adrenal vein, usually found in the 6 o'clock position relative to the gland. As on the right side, division of the vein between clips allows the adrenal to be elevated off the posterior abdominal wall and dissected free. The gland, once freed, is placed in a retrieval bag and removed via the lateral port.

Right-sided tumours vary more than those on the left side in terms of difficulty. Identification of the tumour is much easier on the right than on the left. With small tumours, identifying and dividing the adrenal vein is often very straightforward. However, a large right-sided tumour extending behind the cava and under the liver, often with very short adrenal vein, can become an extremely difficult procedure, even for very experienced adrenal surgeons. On the left side, in obese patients identification of the gland can sometimes prove very difficult. When the gland cannot be located, it is likely to be found more medially and inferiorly than expected. Tracing the renal vein to find the adrenal vein can sometimes be useful and indeed many surgeons teach this technique routinely. Failing to fully mobilize the spleen is usually the cause of access problems on the left side; on occasion it may be necessary to place a port to allow the spleen to be retracted.

Postoperatively patients can be mobilized quickly and inpatient stay is significantly reduced compared with open adrenalectomy. Perhaps the major advantage of laparoscopic adrenalectomy is seen in patients with Cushing syndrome. Wound size is markedly reduced in these patients and consequently the wound-associated morbidity has dramatically improved.

Anterior laparoscopic adrenalectomy is unsuitable for adrenal tumours >8 cm and for malignant and potentially malignant tumours. A relative contraindication is previous abdominal surgery. Identification of smaller left-sided tumours may prove difficult.

Open posterior approach

This approach has now been largely abandoned owing to the poor view and the morbidity and pain associated. The posterior approach to the adrenal gland was originally described by Hugh Young in 1936. Most endocrine surgeons used to favour the Turner–Warwick modification of the posterior approach, in which the eleventh or twelfth ribs are removed extrapleurally. This incision may also be slightly modified by making a 'hockey stick'-shaped incision that initially runs parallel to the spinal column.

The main disadvantages of this approach are restricted visualization and access, particularly on the right side where the right adrenal vein is short and may be difficult to secure.

Posterior endoscopic approach

The posterior endoscopic approach to the adrenal glands has now become an established approach. It has been popularized by Professor Martin Walz, Essen, Germany. It is suitable for smaller tumours (<4 cm), particularly Conn's tumours, patients needing bilateral adrenalectomy (failed treatment of pituitary Cushing disease, bilateral phaeochromocytoma) as there is no need to turn the patient from one side to the other and in patients in whom previous abdominal surgery may make the anterior approach difficult or hazardous. Patients are positioned as for an open posterior approach and a balloon is inserted and inflated in the retroperitoneal space below the twelfth rib. Ports are inserted into the artificial space and the adrenal gland is visualized. The major drawbacks with this approach are:

- difficult anatomical orientation compared with the anterior laparoscopic approach
- very limited operating space
- normal endoscopic instruments may be too long
- even minor bleeding may cause significant visualization problems.

Because of these problems the approach has not initially proved popular with surgeons. The approach, however, does offer an alternative technique in patients with suitable adrenal tumours and many endocrine surgeons, having gained experience in the anterior laparoscopic approach, are now learning this technique to further enhance their range of operative options.

CHAPTER 21

Disorders of the abdominal wall, peritoneal cavity and retroperitoneum

SIR ALFRED CUSCHIERI

Surgical anatomy

The two terms abdomen (or abdominal cavity) and peritoneal cavity are not strictly synonymous. The abdomen (or abdominal cavity) refers to the musculoaponeurotic and bony walls that enclose a region lined on the inside by the peritoneum. By contrast, the peritoneal cavity denotes the space enclosed by the peritoneal lining and contains some but not all of the abdominal viscera. The retroperitoneal space lies behind the posterior wall of the peritoneal cavity and contains adipose and areolar 'packing tissue' in which lie the retroperitoneal organs. This is continuous with the rest of the extraperitoneal space and is filled with the same packing tissue separating the musculoaponeurotic anterolateral walls from the peritoneal membrane. Underneath the packing tissue is a fascial layer (endoabdominal fascia) that covers the muscles of the back and this is continuous with the transversalis fascia anterolateral on both sides.

The abdominal cavity is subdivisible into the abdomen proper and the pelvis. When viewed from one side of the sagittal plane, the pelvis lies below and behind the abdominal cavity as a basin-shaped extension with a centrally sloping muscular floor (pelvic diaphragm) part of which (the pubococcygeus) is continuous with the muscular coat of the rectum. The upper boundary of the abdominal cavity is made up of the diaphragm and, because of this, a substantial part of the abdominal cavity (almost equal to the thoracic cavity) lies under the lower rib cage. The anterolateral walls of the abdomen are made up of the musculoaponeurotic layer: the recti muscles on either side of the midline anteriorly separated by a median raphe (linea alba) and three pairs of flat wide muscles (external oblique, internal oblique and transversus abdominis).

The peritoneal cavity itself consists of the greater sac (or general peritoneal cavity) and the lesser sac (also known as the omental bursa), which lies behind the stomach, lesser omentum and transverse colon/mesocolon, and below the inferior surface of the liver. The two sacs communicate on the right side via a small slit (foramen of Winslow), the anterior fold of which, sometimes referred to as the hepatoduodenal ligament, contains the bile duct, common hepatic artery and the portal vein. It provides a readily accessible site for temporary occlusion of the hepatic inflow vessels during hepatic resections and in the event of bleeding from the hepatic vascular parenchyma or the hepatic arteries (Pringle's manoeuvre).

Anterolateral abdominal wall

The subcutaneous fat becomes divisible into two layers in the lower part of the abdomen: superficial fatty Camper's fascia and the deep membranous Scarpa's fascia that inserts into the fascia of the thigh below and parallel to the inguinal ligament. The deep fascia of the anterolateral wall is thin and covers the superficial abdominal muscles. The two musculoaponeurotic halves of the anterior abdominal wall are joined by the midline linea alba, which essentially consists of interwoven fibres of the rectus sheath forming a distinctive pattern. At the umbilical pit the skin is adherent to the linea alba and this marks the narrowest point of the abdominal wall (consisting of skin, linea alba and attachment of the ligamentum teres).

Thinning and stretching of the linea alba especially in females after multiple pregnancy results in separation (divarication) of the two rectus muscles with an intervening bulge. In the upper half of the anterior abdominal wall, the rectus muscles have both an anterior and a posterior sheath. This arrangement changes at the level of the anterior superior iliac spines where the posterior sheath is absent with its lower margin forming a crescentic outline referred to as the arcuate line (linea semicircularis). Hence, below this point, the abdominal wall is weaker. Internally the anterior abdominal wall is covered by the transversalis fascia, which is separated from the parietal pneumoperitoneum by intervening areolar fatty tissue. The fat of this layer tends to become more abundant and the connection between the peritoneal membrane and the abdominal wall looser in the lower abdomen and pelvis.

Just above the umbilicus, the parietal peritoneum is carried backwards as a two-layered membrane (falciform ligament) that is attached to the anterosuperior surface of the liver and the diaphragm. It contains a variable amount of fat (excessive and pendulant in the obese) and along its lower margin the round ligament or ligamentum teres, which is attached to the recessus of Rex at the bottom of the umbilical fissure of the liver. It represents the obliterated left umbilical vein, which connects with the left portal vein in the fetus. The muscles and skin of the anterolateral abdominal wall are supplied by the following nerves, which run in the neurovascular plane between the internal oblique and transversus abdominis muscles:

- thoracoabdominal (inferior intercostal) nerves (T7–T11)
- subcostal nerves (T12)
- ilioinguinal and iliohypogastric nerves (LI).

Below the umbilicus five structures lying between the peritoneum and the parieties form ridges or folds separating shallow fossae. In the midline, there is the median umbilical ligament (urachus, remains of the allantois), which forms a slender fibrous band between the apex of the urinary bladder and the umbilicus. The medial umbilical ligaments (obliterated portions of the umbilical arteries) run upwards and medially one on either side of the median umbilical ligament with which they merge at the umbilicus. The inferior epigastric vessels arising from the external iliac arteries run upwards and medially lateral to the medial umbilical ligaments to supply the rectus muscles and eventually enter the rectus sheath beneath the arcuate line. They form the lateral umbilical folds. Inadvertent damage to these vessels especially during laparoscopic surgery can lead to substantial haematoma formation. The named peritoneal fossae on either side are:

- supravesical: between median and medial umbilical folds
- medial inguinal: between the lateral and medial umbilical folds (site of direct inguinal hernia)
- lateral inguinal: lateral to the lateral umbilical folds (inferior epigastric arteries), includes the deep inguinal ring (site of indirect inguinal hernia).

The iliopubic tract is a condensation of the transversus abdominis fascia overlying the inner surface of the inguinal ligament when viewed from the peritoneal side (laparoscopic surgery) and separates the inferior edge of the deep inguinal ring from the femoral canal and vein below. In the early days of laparoscopic hernia surgery, this region was referred to as the triangle of doom in view of iatrogenic damage to the femoral vessels and nerve when the surgeon dissected or clipped below the iliopubic tract.

Inguinal and femoral canals

Inguinal canal

This is an oblique channel above and parallel to the medial half of the inguinal ligament and averages 4 cm in length. It contains the spermatic cord in the male and the much more tenuous round ligament of the uterus in the female – hence the inguinal canal is intrinsically weaker in the male accounting for the much higher incidence of inguinal hernia. The canal starts at the internal (deep) inguinal ring situated just lateral to the inferior epigastric artery at the midpoint of the inguinal ligament, where the transversalis fascia extends as a cone inside the internal ring and actually forms the internal spermatic fascia (innermost lining of the spermatic cord).

The vas deferens (round ligament in the female) and the testicular vessels enter the inguinal canal at the deep ring and these together with the artery to the vas deferens (derived from the inferior vesical artery), cremasteric artery (from inferior epigastric), genital branch of the genitofemoral nerve, pampiniform plexus, sympathetic fibres and lymphatic vessels form the contents of the spermatic cord. This acquires two further sheaths in its passage down the inguinal canal on its way to the scrotum – the cremasteric fascia (from the internal oblique) and the external spermatic fascia (from the external oblique aponeurosis).

The other important structure in the inguinal canal in both sexes is the ilioinguinal nerve, which lies external to the spermatic cord in the male. The external or superficial inguinal ring is a slit-like opening in the external oblique aponeurosis situated just above and lateral to the pubic tubercle. Its margins are known as the crura (medial and lateral) and are held together by means of the intercrural fibres. Normally the spermatic cord exits the inguinal canal beneath these intercrural fibres, which are supposed to prevent stretching of the superficial inguinal ring. The anterior wall of the inguinal canal is made up of the aponeurosis of the external oblique; the posterior wall by the transversalis fascia throughout reinforced medially by the fibres of the conjoint tendon.

There is considerable controversy regarding the importance of the transversalis fascia in contributing to the strength of the posterior wall of the inguinal canal, and, hence, to the pathogenesis of inguinal hernia, with some regarding it as a crucial factor that must be taken into consideration during fascial repair. Others consider that the strength of the posterior wall of the canal is largely dependent on the conjoint tendon. The arching fibres of the internal oblique and transversus abdominis form the roof of the inguinal canal, whereas the floor is made of the grooved inguinal ligament (Figure 21.1). This expands medially to form the lacunar ligament – a crescentic extension from the inguinal ligament to the pectineal line of the pubis that forms the medial margin of the femoral ring/canal.

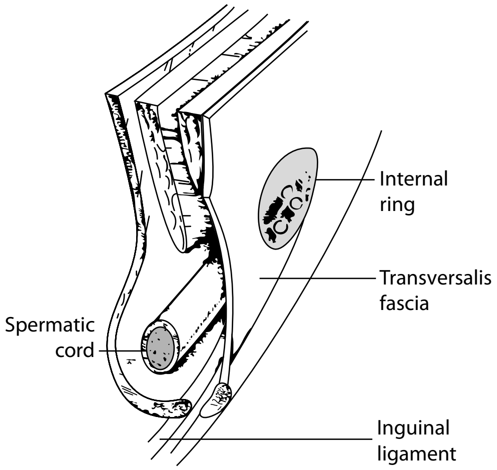

Figure 21.1 The internal view of the deep inguinal ring and cord contents. [Derived from Nyhus LM, London RE (eds). *Hernia*, 2nd edn. Philadelphia, PA: Lippincott, 1978.]

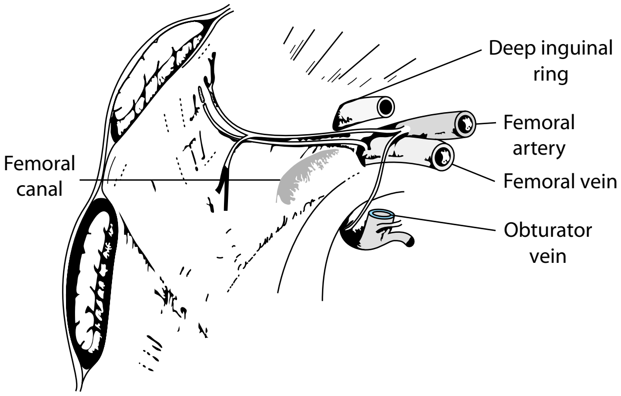

Figure 21.2 The inner aspect of the inguinal region which demonstrates the position of the femoral canal in relation to the femoral vessels and obturator foramen. [Derived from Nyhus LM, London RE (eds). *Hernia*, 2nd edn. Philadelphia, PA: Lippincott, 1978.]

Femoral canal

The cone-shaped femoral fascial sheath (derived from the endoabdominal fascia) extends into the thigh below the inguinal ligament and has three components from lateral to medial – lateral compartment (femoral artery), intermediate compartment (femoral vein) and medial compartment (femoral canal). The femoral canal itself is funnel shaped with an average length of 1.25 cm and with its oval base (the femoral ring) upwards (facing the abdominal cavity). Below it tapers to the junction of the long saphenous with femoral vein. The femoral canal normally contains loose connective tissue and a few lymphatics, and sometimes one of the deep inguinal nodes (Figure 21.2).

The boundaries of the femoral ring are the sheath covering the femoral vein laterally, the edge of the lacunar ligament medially, the inguinal ligament anteriorly and the superior pubic ramus and pectineus posteriorly. Normally it is sealed by a condensation of extraperitoneal fatty tissue known as the femoral septum, which is covered superiorly by peritoneum.

Laparoscopic anatomy of the anterior abdominal wall

Detailed knowledge and familiarity with the laparoscopic anatomy of the infraumbilical region of the anterior abdominal wall has assumed great surgical importance since the advent of laparoscopic hernia repair, which has largely replaced open repair especially for direct and indirect inguinal hernia in most centres worldwide in view of its advantages over the open surgical approach. This knowledge is essential both for ensuring good and lasting repair of the hernia without recurrence and for avoiding complications, all of which are avoidable. When viewed laparoscopically, the infraumbilical region of the anterolateral abdominal wall with the parietal peritoneal has the following landmarks consisting of folds and fossae created by the folds, which provide orientation during hernia repair:

- Folds:
  - Median umbilical ligament: ascends in the median plane to the umbilicus from the apex of the urinary bladder (represents the obliterated allantoic duct).
  - Medial umbilical ligaments, one on either side of the median umbilical ligament (represents the obliterated umbilical artery on both sides and can be traced down to the internal iliac artery).
  - Lateral umbilical ligaments, one on either side and lateral to the medial umbilical ligament consisting of a ridge of peritoneum over the inferior epigastric arteries accompanied by two veins, which skirt the medial border of the internal ring and pass upwards to the posterior rectus sheet and muscles on either side of the abdominal wall.
- Fossae (one on each side), which are formed by shallow depressions between the folds:
  - Supravesical fossa: between the median and medial umbilical folds.
  - Medial umbilical fossa: between the medial and the lateral umbilical ligaments – site of origin of direct inguinal hernia.
  - Lateral umbilical fossa: lateral to the lateral umbilical ligament – site of origin of indirect inguinal hernia (Figure 21.3).

Anatomy of the preperitoneal (extraperitoneal) space

This is essentially the anatomy of the preperitoneal space, a detailed knowledge of which is essential for the safe execution of both approaches for laparoscopic (posterior) inguinal hernia repair: TAPP (Trans-Abdominal PrePeritoneal) and TEP (Total Extra Peritoneal). The most important component of the preperitoneal space, apart from it vessels and nerves, is the transversalis fascia, which provides strength to the groin between the arch of the transversus abdominis muscle superiorly and the inguinal ligament inferiorly. The transversalis fascia consists of two layers: anterior, adherent to the rectus muscle, and posterior, which faces the parietal peritoneum (space of Borgos). The two fuse near their insertion in the pectineal (Cooper's) ligament. The anterior layer of the transversalis fascia is adherent to the rectus muscle and faces the peritoneum. The iliopubic tract and ileopectineal arch are formed by condensations of the transversalis fascia. The iliopubic tract extends from the superior pubic ramus to the anterior superior iliac spine with the inguinal ligament but distinct from it, and appears as a white line forming the superolateral boundary of the

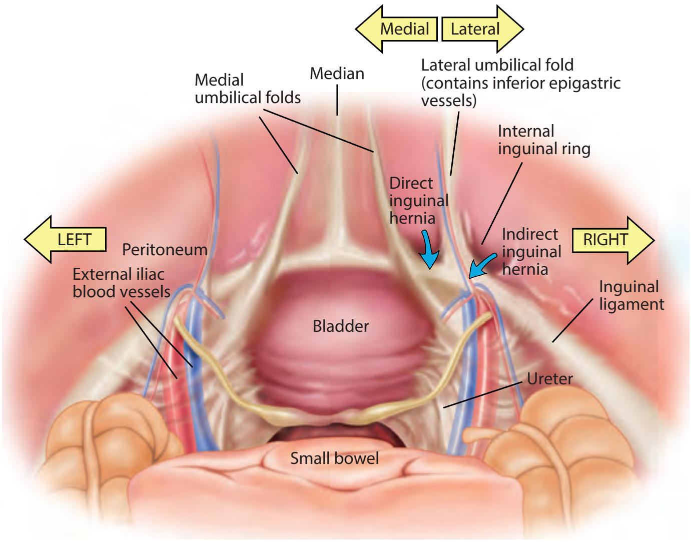

Figure 21.3 Laparoscopic view of the anterior abdominal wall.

'triangle of pain', the inferomedial border of which is formed by the gonadal vessels: the triangle of pain is so called in view of risk of nerve injury/entrapment if anchorage of the mesh (by staples) is performed within this triangle. The ileopectineal arch is a tough fibrous arch that attaches to the inguinal ligament and provides partial insertion for the internal oblique and transversus abdominis muscles and provides support for the lateral part of the groin.

Limits of the preperitoneal space

The posterior layer of the transversalis fascia separates into two compartments: (1) anterior, also known as the vascular space, and (2) posterior, known as the space of Bogros after the French anatomist who first described it. Medially the preperitoneal space is continuous with the prevesical space (space of Retzius), the dissection of which is necessary during laparoscopic hernia repair to provide sufficient space to enable good overlap of the mesh of the hernia defect.

The nerves most commonly injured during laparoscopic (posterior) inguinal hernia repair together with their manifestations are:

- Lateral femoral cutaneous nerve (commonest injury) – pain and numbness in the upper lateral aspect of the thigh known as meralgia paraesthetica.
- Femoral branch of the genitofemoral nerve – sensory changes in the femoral triangle, scrotum and labia (numbness/paraesthesia), reduced cremasteric reflux, ejaculatory dysfunction and hip pain on walking.
- Intermediate cutaneous branch of the anterior branch of the femoral nerve – pain and hyperaesthesia in the groin and thigh, weakness/atrophy of the quadriceps, painful hip joint movement. Hyperextension reproduces the pain.

These nerves are usually injured by entrapment during mesh fixation. Other less common injuries to the nerves may be caused by pressure. These include traction injuries to the ilioinguinal, iliohypogastric and the genital branch of the genitofemoral nerves.

In the performance of TAPP the surgeon must identify the following structures on entry into the peritoneal cavity:

- inferior epigastric vessels
- the two medial umbilical ligaments
- the spermatic vessels
- the vas deferens
- trapezoid of disaster: area at the meeting of the vas deferens and testicular vessels where the external iliac vessels can be injured.

The inferior epigastric vessels enable the differentiation of direct from indirect inguinal hernia. The importance of identification of the medial umbilical ligament is for the surgeon to avoid extending the dissection medial to it as this may risk injury to the urinary bladder. The spermatic vessels form the medial border of the triangle of doom and the lateral border of the triangle of pain. The vas deferens forms the medial border of the triangle of doom/trapezoid of disaster.

Following opening of the peritoneal trapdoor in TAPP, the following structures have to be identified:

- the internal inguinal (spermatic) ring
- iliopubic tract
- pectineal (Cooper's) ligament
- femoral canal.

The iliopubic tract separates the inguinal from the femoral canal, which lies posterior to it. During mesh fixation, staples or sutures should not be place below the ileopubic tract.

Posterior abdominal wall and retroperitoneum

From both anatomical and functional aspects, this is best considered from its ventral aspect. In the midline are the bodies, transverse processes and the intervertebral discs of the five lumbar vertebrae. Laterally the musculoaponeurotic wall (external and internal oblique and transversus abdominis muscles) extends from the twelfth rib to the pelvic brim. The psoas muscles take origin from the bodies and transverse processes of the upper four lumbar vertebrae and are joined by the iliacus muscles on their lateral aspect. Posteriorly and laterally, the quadratus lumborum muscles form the remaining support for the lumbar nerves and vessels (Figure 21.4). The lower part of the posterior abdominal wall is made up of the iliacus muscles covering the iliac bones of the bony pelvis. The complex anatomy of the posterior abdominal wall is of great importance during surgery on retroperitoneal organs and retroperitoneal tumours. In this respect, the muscles of the posterior abdominal wall are covered by the endoabdominal fascia, which is given various names depending on the underlying muscles:

- Psoas fascia or sheath covering the psoas major muscles – attached medially to the lumbar vertebrae and below to the pelvic brim.
- Quadratus lumborum fascia – attached to the transverse processes of the lumbar vertebrae and continuous laterally with the anterior layer of the thoracolumbar fascia.
- Thoracolumbar fascia – splits to enclose the deep muscles of the back and is thick and strong in the lumbar region, where it extends from the costal margin to iliac crests and is attached laterally to the internal oblique and transversus abdominis muscles (Figure 21.5).

The retroperitoneal space is bounded above by the diaphragm and below by the pelvic brim but is of course continuous with the retroperitoneal space of the pelvis. The space contains the aorta, vena cava, cisterna chyli, para-aortic

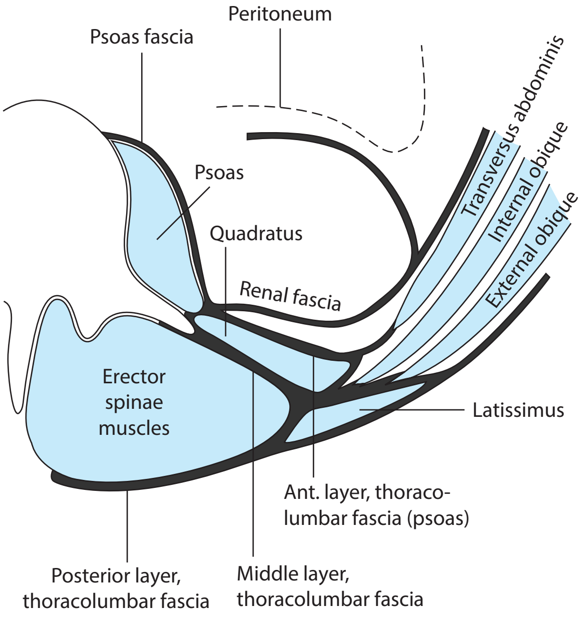

Figure 21.5 Thoracolumbar fascia. This splits to enclose the deep muscles of the back and is thick and strong in the lumbar region, where it extends from the costal margin to iliac crests and is attached laterally to the internal oblique and transversus abdominis muscles.

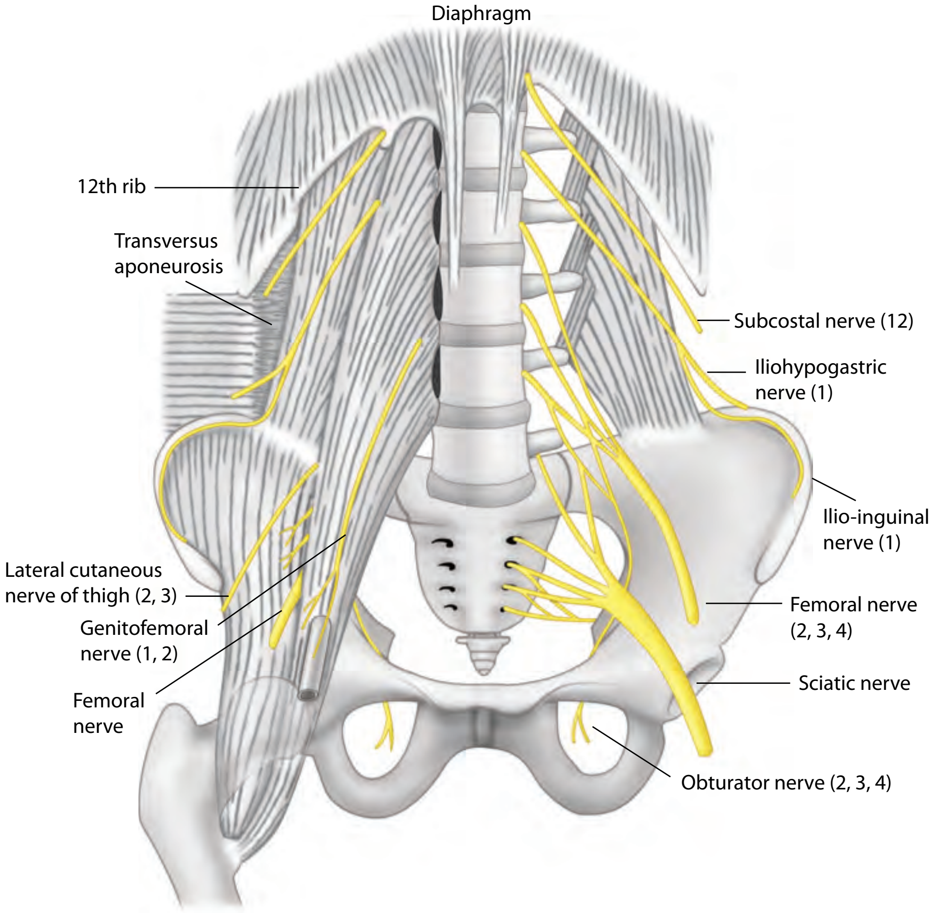

Figure 21.4 The anatomical features of the posterior abdominal wall.

glands and vessels, the kidneys and ureters, the adrenal glands, the second and third parts of the duodenum, the lower end of the bile duct, pancreas, the various nerve plexuses and the lumbar sympathetic chain.

The somatic nerves of the posterior abdominal wall are the:

- subcostal nerves
- lumbar nerves
- lumbar plexus – located in the posterior part of the psoas major (L1–4).

In turn, the lumbar plexus gives rise to the following nerves (on either side):

- *Obturator* nerve (L2–4): exits from the medial border of the psoas and descends medially through the pelvis to reach the thigh, where it supplies the adductor muscles.
- *Femoral* nerve (L2–4): exits from the lateral border of the psoas major, supplies the iliacus and then exits the abdomen deep to the inguinal ligament lateral to the femoral artery. Supplies hip flexor muscles and knee extensors.
- *Lumbosacral trunk*: crosses the sacral wing to enter the pelvis to form the sacral plexus together with the S1–4 nerves.
- *Genitofemoral* nerve (L1, L2): exits from the anterior surface of the psoas major but stays deep to the psoas fascia and lower down (lateral to the common iliac arteries) it divides into its femoral and genital branches.
- *Ilioinguinal and iliohypogastric* nerves (both from L1): descend in front of the quadratus lumborum, penetrate the transversus abdominis near the anterior superior iliac spine and then travel through the internal and external oblique muscles (to which they give branches) to the skin of the groin and pubic region. Only the ilioinguinal nerve courses through the inguinal canal on its way to the skin.
- *Lateral femoral cutaneous* nerve (L2, L3): runs downwards and laterally across the iliacus muscle and exits the abdomen below the inguinal ligament and close to the anterior superior iliac spine. It supplies the skin of the anterolateral aspect of the thigh.

The autonomic nerves consist of:

- vagal branches
- abdominopelvic splanchnic nerves – thoracic (T5–12) and lumbar (L1–3)
- prevertebral sympathetic ganglia
- abdominal autonomic plexuses.

The lumbar splanchnic nerves (three or four in number) enter three nerve plexuses (intermesenteric, inferior mesenteric and superior hypogastric), which supply presynaptic fibres to the prevertebral ganglia and plexuses, situated close to the major branches of the aorta (coeliac, superior mesenteric, aortorenal and inferior mesenteric). The postsynaptic fibres from these prevertebral ganglia form periarterial plexuses that supply the various organs.

The parasympathetic supply to the various plexuses is derived from the vagi and the pelvic splanchnic nerves, which originate directly from the ventral rami of S2–4. The location of the abdominal nerve plexuses is as follows:

- *Coeliac* (solar): surrounds the coeliac trunk.
- *Superior mesenteric*: around the origin of the superior mesenteric artery.
- *Inferior mesenteric*: surrounds the corresponding artery as it arises from the lower aorta.
- *Intermesenteric:* on the anterior surface of the aorta between the superior and inferior mesenteric arteries.
- *Superior hypogastric:* continuous with the intermesenteric and inferior mesenteric plexi and located over the bifurcation of the aorta. It gives rise to the *hypogastric nerves/plexi,* which continue towards the pelvic floor lateral to the rectum, urinary bladder and uterine cervix. These nerves/plexuses must be preserved in males during rectal and prostatic pelvic surgery because they are responsible through their parasympathetic fibres (S2–4) for erection and ejaculation.

Trauma to the space from blunt or penetrating injury is common, particularly in high-speed vehicle accidents. Damage to the contained structures leads to haemorrhage and haematoma formation (see Chapter 14). Haemorrhage into the retroperitoneal space may also occur spontaneously from a leaking abdominal aneurysm, and in patients with bleeding disorders and those taking anticoagulants.

Pelvic floor

This is largely made of the levator ani muscle, which slopes downwards from the lateral pelvic walls, pubic bones, ischial spines and coccygeus towards the centre of the pelvis. Together with the coccygeus muscles posteriorly, the levator ani muscle forms the pelvic diaphragm through the centre of which pass the rectum and urethra in both sexes, separated by the vagina in the female. The levator ani, which has a separate nerve supply (S3, S4), has three components: the pubococcygeus (stretching from the pubis to the coccyx), the puborectalis (which forms a sling around the anorectal junction) and the ileococcygeus (which forms the posterior part). Aside from forming the floor of the pelvis and providing support for the rectum, bladder and uterus, the levator ani plays an important part in the voluntary control of micturition and defaecation.

The pelvic diaphragm is covered by fascia on both its upper and lower surfaces. The ischiorectal fossa is the space between the sloping inferior surface of the pelvic diaphragm and the ischial tuberosity. It is normally packed by fatty tissue and is traversed by the inferior rectal vessels (Figure 21.6). The important nerves associated with the pelvic floor are the pelvic splanchnic (S2–4), nerves to the levator

External anal sphincter

Figure 21.6 The pelvic diaphragm is covered by fascia on both its upper and lower surfaces. The ischiorectal fossa is the space between the sloping inferior surface of the pelvic diaphragm and the ischial tuberosity. It is normally packed by fatty tissue and is traversed by the inferior rectal vessels.

ani and coccygeus muscles and the pudendal nerve. The pudendal nerve (S2–4) exits the pelvis through the greater sciatic foramen to enter the pudendal canal on the medial side of the ischial tuberosity. Although it is the chief sensory nerve to the external genitalia in both sexes, it supplies muscular branches to the external anal and urethral sphincters and to the perineal muscles.

The umbilicus

The umbilicus normally lies in the plane of the disc between the third and fourth lumbar vertebrae, although clearly this varies with sex, age and degree of obesity. When examined from the deep surface, four fibrous cords are seen radiating from it, and these represent structures which in fetal life traverse the umbilical cord: the umbilical vein, right and left umbilical arteries and the urachus. The additional structure to pass through the cord in embryonic development is the vitellointestinal duct with the accompanying vitelline veins. Not surprisingly, subclinical defects in the umbilical cicatrix are common and these give rise to paraumbilical hernias, usually in obese females.

Omphalitis

Infection of the umbilicus is fortunately a rare complication of the neonate. Faulty technique in dealing with the umbilical cord at birth leads to infection by *Staphylococcus aureus* or haemolytic streptococcal organisms with local suppuration and cellulitis of the adjacent abdominal wall. Treatment with appropriate antibiotics and local drainage for bacteraemia is common. There is an association between umbilical sepsis and portal vein thrombosis with the development of portal hypertension in these children.

In the adult, infection of the umbilicus is a more chronic condition with a seropurulent, often foul smelling, discharge and the development of granulation tissue. In the majority of patients, the fault lies in a lack of hygiene, but occasionally small foreign bodies are present and these include an ‘umbilical stone’, a concretion due to desquamated dead superficial epidermal cells. Pilonidal cysts can also occur, albeit rarely in the umbilical pit.

Congenital abnormalities

Patent urachal remnant

A persistent discharge of urine from the umbilicus results from a completely patent urachus. This complication may be delayed into childhood or early adult life, but, in these circumstances, there is almost always an underlying urinary obstruction that has forced open the near-obliterated urachal remnant. It is important that prior to excision of the urachal remnant, which can be preformed laparoscopically, the bladder should be shown to be free from any form of obstruction, e.g. posterior urethral valves.

Two other urachal abnormalities may be delayed into adult life: urachal sinus and urachal cysts. In the former, an intermittent umbilical discharge is the prominent symptom; in the latter, the development of a very tender infected swelling in an infraumbilical position leads to exploration and demonstration of an infected urachal cyst. In both instances excision is indicated but repair of the bladder is not usually required.

Vitellointestinal duct remnant

The persistence of this remnant may show as a faecal fistula at the umbilicus, a bud or polyp of intestinal mucosa at the umbilicus, a cyst lying deep to the umbilicus between the abdominal wall and the ileum, a deep umbilical sinus, or a Meckel’s diverticulum with or without a fibrous band attached to the posterior aspect of the umbilicus and responsible for intestinal obstruction by volvulus or band obstruction (Figure 21.7).

The umbilical sinus, polyp or cyst require excision. The completely patent vitellointestinal duct may be complicated by partial or complete prolapse of the ileum through the umbilicus and requires early correction before this complication occurs. Meckel’s diverticulum is discussed elsewhere (see Chapter 29).

Abdominal wall defects

A failure of the umbilical defect to close leads to the development of omphalocele or an umbilical hernia. Major defects in the development of the abdominal wall are associated with exstrophy of the bladder and other forms of developmental abnormality including intestinal malrotation. The prune belly syndrome (PBS) is a rare genetic disorder affecting about one in 40 000 births, predominantly male infants (97%). PBS is a disorder of the urinary system, characterized by wrinkled abdominal wall skin associated with congenital absence/hypoplasia of abdominal muscles (hence also known as abdominal muscle deficiency syndrome and various other names), major urological abnormalities and cryptorchidism. The abdominal contents are covered only with skin, peritoneum and an intervening hypoplastic muscular layer. The urological abnormalities include a long dilated prostatic urethra associated with prostatic hypoplasia; a large, vertically oriented thick-walled bladder; a urachal remnant from the dome of the bladder; tortuous and dilated ureters; varying amounts of hydronephrosis; and renal dysplasia.

Rectus sheath haematoma

Rectus sheath haematoma (RSH) is rare, although its incidence appears to be rising. It is caused by rupture of the superior or inferior epigastric arteries or their branches. RSH is either sporadic, when there is usually a predisposing cause, or traumatic insult (blunt and stab injuries) and following abdominal surgery (iatrogenic). There has been a significant increase in the incidence of iatrogenic RSH with the advent of laparoscopic surgery owing to failure to take note of the surface marking of the superior and inferior epigastric arteries and veins during blind placement of abdominal ports. This iatrogenic complication is entirely preventable.

Clinical features

RSH is two to three times commoner in females. The median age at presentation is 45 years and the incidence rises with advancing age. The commonest predisposing cause in sporadic cases is anticoagulation therapy. The haematoma is usually located behind the rectus muscle as both arteries enter the muscular compartment posteriorly. Sporadic RSH usually arises as a result of vigorous contractions of the rectus

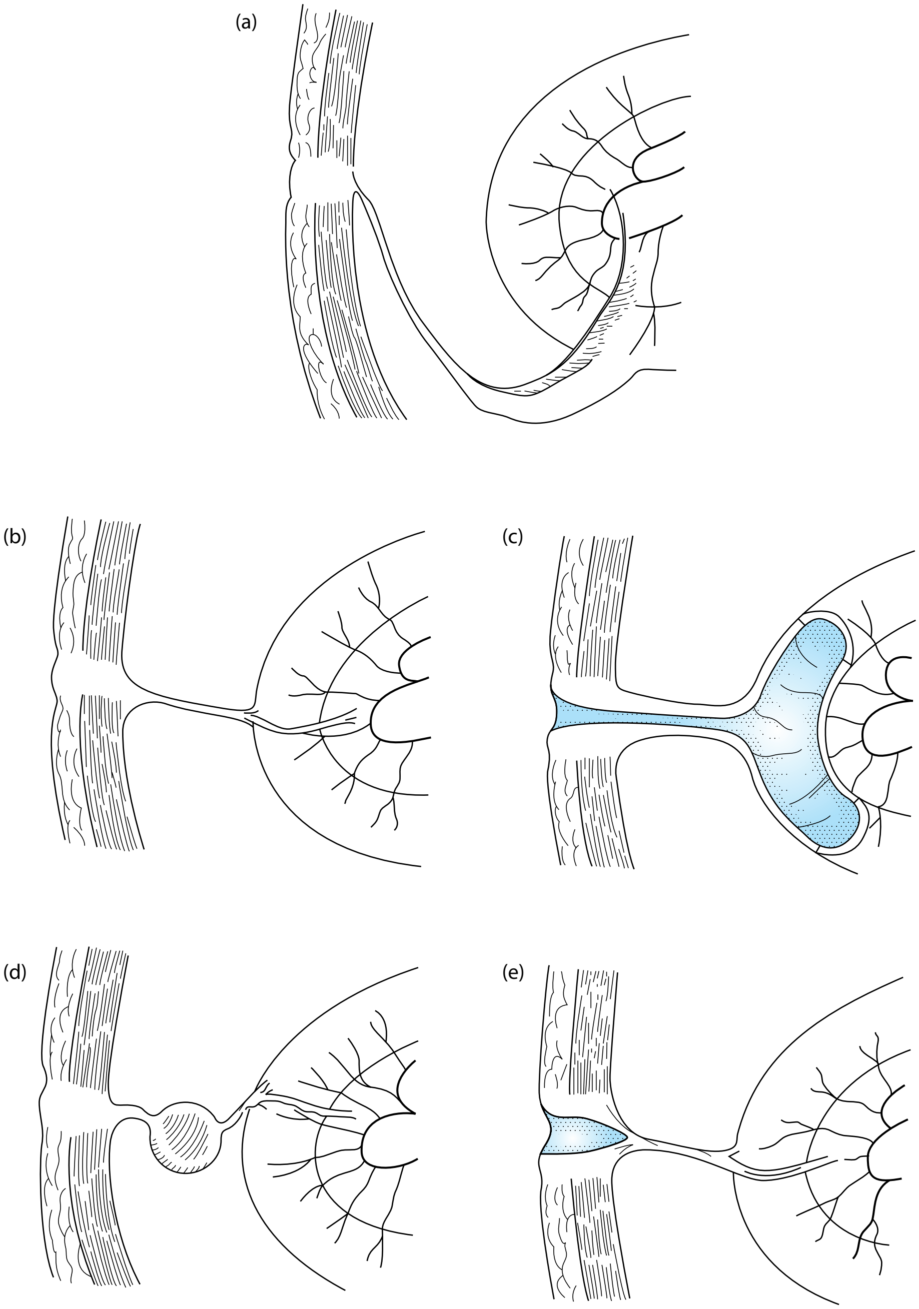

Figure 21.7 The vitellointestinal duct may connect with the umbilicus as: (a) a fibrous cord extending from a Meckel's diverticulum; (b) a simple fibrous cord to a loop of ileum; (c) an umbilical intestinal fistula; (d) a fibrous cord with cyst; (e) an umbilical sinus.

muscles from strenuous vigorous exercise, severe coughing, vomiting and straining at stool. The history in the sporadic variety is usually that of strenuous exercise, strain or paroxysm of coughing followed by severe abdominal pain accompanied with nausea, anorexia and vomiting. On examination an acutely tender rectus muscle swelling can be felt in the abdominal wall. A mild pyrexia and leucocytosis may occur. Sixty per cent of RSHs are situated on the right side and >80% in the lower quadrants. Haematomas above the arcuate line are caused by damage to the superior epigastric artery or its perforating branches, whereas the inferior epigastric vessels are involved in cases below the arcuate line. Haematomas below the arcuate tend to be more extensive and bleed more as the rectus abdominis muscle is only supported posteriorly by the transversalis fascia and the parietal peritoneum. These RSHs often cross the midline and become bilobar. RSH near the peritoneum can result in peritoneal irritation with abdominal rigidity and gastrointestinal symptoms. Classically, three eponymous signs are described for the diagnosis of RSH:

1 Fothergill sign: determines whether an abdominal mass is within the abdominal wall or intra-abdominal: voluntary contraction of the recti muscles fixes the mass and makes it

more painful/tender. The test is difficult to elicit conclusively in obese or pregnant females.

2 Carnett sign: also differentiates between abdominal wall as distinct from intra-abdominal pathology. Pain or tenderness is elicited when the supine patient lifts his or her head or shoulders from bed.

3 Cullen sign: periumbilical ecchymosis associated with retroperitoneal or abdominal wall haemorrhage – in RCH bruising appears after 2–5 days and often extends into the flanks.

The mass is usually palpable, painful, firm, non-pulsatile and does not move with respiration. In obese patients, the mass may be difficult to palpate because of the posterior location of the haematoma behind the rectus. Signs of local peritoneal irritation with rebound tenderness and guarding may be present, especially with large RSHs which cross the midline situated in the subumbilical region. Rarely, a haematoma may rupture into the peritoneal cavity causing haemoperitoneum.

The diagnosis of RSH is confirmed by an ultrasound scan of the abdominal wall (Figure 21.8). Ultrasonography is used as a first-line diagnostic test for RSH and also to monitor the condition in cases treated conservatively.

However, CT or MRI provide better definition of the pathology and especially on the need for conservative or active surgical treatment in sporadic patients. Three types of RSH are identified by CT in terms of severity of the disease:

- *Type I.* Unilateral intramuscular haematoma with increase in size of the muscle but without any dissection of fascial planes. Patients present with mild-to-moderate abdominal pain. Type I haematomas resolve spontaneously.
- *Type II.* Intramuscular, often bilateral, haematoma but with blood extravasation between muscle and the transversalis fascia. May be accompanied by a fall in haematocrit: the patient requires close observation and may need blood transfusions but the condition is treated conservatively in the first instance.
- *Type III.* Large haematoma which extends outside the muscle to the transversalis fascia and transversus muscle, the peritoneum and the prevesical space. May be accompanied by haemoperitoneum: the patient is often hypovolaemic and requires blood transfusion. Reversal of anticoagulation is needed for patients on anticoagulation; patients require urgent surgical treatment, especially if they are unstable.

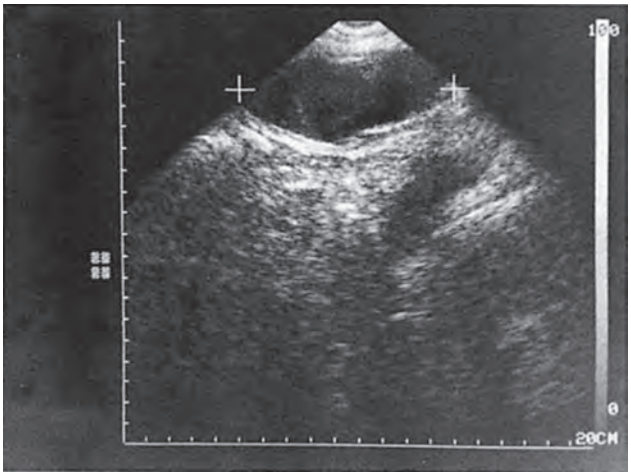

Figure 21.8 Ultrasound of the lower abdominal wall of a patient on dicoumarin therapy, who developed severe abdominal pain after a coughing spasm. The area next to the '+' shows a haematoma confined by rectus sheath.

Conservative and non-surgical treatment

In some centres CT staging is used for triage with sporadic type I being treated conservatively with analgesia and bed rest as an outpatient. Types II and III require hospital admission for close observation and possible active treatment by surgery or radiological intervention. The serious cases are those in the CT type III category on anticoagulation therapy and account for most of the reported fatal cases. Anticoagulation therapy should be stopped immediately on diagnosis and reversal to normal clotting and prothrombin time (PT) achieved. Patients on heparin are reversed with protamine sulphate, whereas patients on oral anticoagulants are commenced on vitamin K analogues but may need fresh frozen plasma if they continue to bleed as the return to a normal PT may take several days. The patients are monitored closely for evidence of hypovolaemia, enlargement of RSH and signs of peritonism.

Radiological intervention with arterial transcatheter Gelfoam/coil embolization is used in some centres to achieve haemostasis and decrease the need for blood transfusion. It can also be used as an alternative to surgery in frail patients not responding to conservative management.

Surgical treatment

Surgical treatment is advisable for failed conservative treatment of sporadic RSH and in all cases caused by trauma or surgery. In sporadic cases the incision is placed on the summit of the haematoma. Surgical treatment includes complete evacuation of the clot, ligation of bleeding vessels and repair of the rectus sheath. Most surgeons opt not to insert drains if the haemostasis is complete. In patients with stab wounds, laparoscopy is the quickest way to determine breach of the parietal peritoneum and intra-abdominal bleeding, which would require full exploration. If the peritoneum is intact, the haematoma is treated as in the sporadic cases. Cases following blunt trauma require CT assessment before surgery to exclude associated intra-abdominal injuries.

Disorders of the peritoneum

Primary peritonitis

In surgical practice, peritonitis is usually *secondary* to gastrointestinal perforation/injury/anastomotic dehiscence or a gangrenous/infected hollow visceral organ. Bacterial peritonitis can, however, be primary, i.e. develops in the absence of surgery/trauma or any primary intra-abdominal focus of infection. This is usually encountered in patients with chronic disease in whom the term *spontaneous bacterial peritonitis* (SPB) is used as opposed to the rarer *primary bacterial peritonitis*, which is reserved for the disease occurring in previously normal individuals (usually women and children).

A fourth category of peritonitis is recognized – *tertiary peritonitis* (TP). This occurs in intensive care patients and is defined as the persistence or recurrence of intra-abdominal infection following apparently adequate therapy of primary or secondary peritonitis. In one reported series tertiary peritonitis developed in 74% of patients admitted with intra-abdominal infection to a surgical intensive care unit (ICU). Patients who develop TP have a significantly longer ICU stay and more advanced organ dysfunction, reflected in higher ICU mortality (64% versus 33%), than patients with uncomplicated secondary peritonitis. The most common infecting organisms in patients with TP are *Enterococcus, Candida, Staphylococcus epidermidis* and *Enterobacter.* The infectious foci are rarely amenable to percutaneous drainage and these patients do not benefit from laparotomy as the infection is diffuse and poorly localized. In common with nosocomial pneumonia in critically ill patients, TP appears to be more a reflection than a cause of an adverse outcome.

Primary bacterial peritonitis

By definition, primary bacterial peritonitis occurs in healthy individuals and the infecting organism is of the Gram-positive type, most commonly *Streptococcus pneumoniae* and group A streptococci. The disease is encountered in children, adolescents and adult women, in whom it may follow childbirth, chest and urinary tract infection. In most instances, the infection is haematogenous.

Infants and children who develop primary pneumococcal peritonitis usually present with acute abdominal pain, vomiting and fever, and abdominal signs indicative of peritoneal inflammation. Diagnosis is made on clinical grounds helped by abdominal radiographs and ultrasound examination. The blood cultures may be positive in these patients. Treatment is with intravenous antibiotics in the first instance. Awareness of the condition is important as primary peritonitis is a rare condition in children, and thus it will be overlooked unless it is considered in the differential diagnosis of children presenting with an acute abdomen.

The disease in adults is confined to women, and, although the infection is commonly pneumococcal, instances of gonococcal peritonitis have been reported. The typical patients are usually young adolescent girls or women of childbearing age. Some cases are reported in association with acute (non-perforated) appendicitis. Primary peritonitis caused by *S. pneumoniae* may follow childbirth. The patients become pyrexial and develop abdominal pain, diarrhoea and clinical signs of peritonitis. In addition to antibiotic therapy, laparotomy is usually necessary to remove pus and for abdominal lavage. Culture of vaginal swabs is usually positive for pneumococcus in patients who develop the condition after childbirth. The prognosis of primary peritonitis with early diagnosis and treatment (antibiotics and abdominal lavage) is good with recovery of the vast majority of patients.

Management

In many of these patients, the differentiation between primary and secondary bacterial peritonitis is difficult, if not impossible. In practice all are explored surgically and the condition is diagnosed because of the absence of a primary focus, although the surgeon must be aware of the mild (non-perforated) appendicitis associated with a seropurulent peritonitis usually in young females. These are now considered as instances of 'primary peritonitis'. At operation, adequate samples of the peritoneal fluid are taken for culture, the appendix is removed if it appears mildly inflamed and abdominal lavage is undertaken before closure. As the infection is most commonly due to *S. pneumoniae,* the initial antibiotic should consist of amoxicillin/clavulanic acid.

Spontaneous bacterial peritonitis

This carries a worse prognosis and has a definite mortality from septic shock and multiorgan system failure. It is an infection of intraperitoneal fluid (ascites or peritoneal dialysate). In general patients with a low ascitic protein concentration ($<1.0\,g/dL$) irrespective of the nature of the underlying disease (liver or renal) are prone to SBP. The groups of patients who are prone to develop SBP include:

- cirrhotic patients with ascites, Wilson disease, chronic active hepatitis
- renal failure in patients on chronic peritoneal dialysis
- patients with the nephrotic syndrome
- immunocompromised patients.

The common factor in these patients is reduced resistance to bacterial infection. The infecting organisms are often Gram-negative.

Clinical features of spontaneous bacterial peritonitis due to liver and renal disease

About 30% of patients with SBP have no symptoms or signs directly referable to the abdomen, and, therefore, a high index of suspicion must be kept especially in susceptible groups. Early diagnosis is imperative, as otherwise the mortality is high, ranging from 50% to 80%. In other patients, the disease develops insidiously and localizing signs of peritonitis are present but often minimal. The most common manifestations include abdominal pain, fever, rebound tenderness and diminished or absent bowel sounds. The full-blown picture is accompanied by septic shock and is invariably fatal. Once suspected, a 100 mL specimen of ascitic fluid is taken for culture and Gram staining of the deposit after centrifugation. The fluid is also examined for polymorphonuclear count (PMN) and pH. A PMN count >250 mL and a pH <7.37 are diagnostic and indicate the need for antibiotic therapy, even if the culture of the ascitic fluid is negative. A blood culture should also be taken and is positive in 70% of cases.

Spontaneous bacterial peritonitis in cirrhotic patients with ascites

In this instance there is bacterial infection of ascitic fluid in the absence of any intra-abdominal, surgically treatable source of infection. The reported incidence of SBP in cirrhotics with ascites varies from 18% to 25%. Most of the infections are aerobic and 50–60% of the reported cases have been caused by *Escherichia coli*. The aetiology is thought to involve:

- bacterial translocation from the gut to mesenteric lymph nodes
- depressed activity of the reticuloendothelial phagocytic system
- decreased antimicrobial capacity of ascitic fluid – low levels of C3, opsonins and fibronectin.

Diagnosis is based on clinical suspicion and analysis of ascitic fluid (white cell count and culture in blood culture bottles). Treatment is with a third-generation cephalosporin.

This achieves a cure rate >80%. Cytological cure is obtained in 65% of patients who are culture positive and sensitive to ceftriaxone after 48 hours of treatment and 95% are cured of their infection after 5 days of treatment. Even so many patients (up to 30%) die during hospitalization despite documented cure of their SBP from complications related to their end-stage liver disease (renal failure, gastrointestinal bleed, cerebral oedema). Infection-related mortality does occur, and is related to the onset of bacteraemia (often from *Pseudomonas* spp.).

Prophylactic selective intestinal decontamination with oral norfloxacin is recommended for the prevention of SBP in cirrhotic patients who are at high risk for developing SBP. These include:

- hospitalized cirrhotic patients with gastrointestinal haemorrhage
- patients with low ascitic fluid total protein (<1 g/dL)
- patients with a high bilirubin level and/or low platelet count.

The long-term prognosis of SBP patients is poor, and these patients should be considered for liver transplantation.

Spontaneous bacterial peritonitis in patients on continuous ambulatory peritoneal dialysis

As in cirrhotic patients, SPB in patients on continuous ambulatory peritoneal dialysis (CAPD) can be culture positive or negative. The infection may be caused by either Gram-positive cocci or Gram-negative bacilli. SPB in this patient group can also arise as a consequence of catheter-related infections (subcutaneous tunnel or catheter exit site). The risk factors for catheter exit-site infection documented in a prospective randomized trial by univariate analysis and multiple logistic regression analysis are:

- younger age (<50 years)
- low serum albumin level (<35 g/L)
- number of previously placed peritoneal dialysis catheters
- short cuff–exit distance (<2 cm)
- *S. aureus* nasal carriage.

The standard primary treatment of CAPD SBP is with intraperitoneal netilmicin combined with intermittent intraperitoneal vancomycin.

However, in a larger randomized clinical trial, oral levofloxacin in combination with intermittent intraperitoneal vancomycin was found to be equally effective. This regimen is simpler to administer and less costly. It is currently recommended as the primary therapy in centres with relatively low exposure and, thus, low background resistance to fluoroquinolones.

The primary cure rate of CAPD SBP averages 75% but varies considerably from centre to centre. Higher cure rates are obtained in patients with culture-negative and Gram-positive infections (75–80%) than in those with Gram-negative infections (55%).

Spontaneous bacterial peritonitis in patients with the nephrotic syndrome

SBP associated with the nephrotic syndrome is largely encountered in children, and is rare in adults. The patients usually have active nephrosis and present with diffuse abdominal pain, ascites, fever and rigors. The infection is caused by either Gram-positive or -negative pathogens, but culture-negative cases have been reported. When it is severe and unresponsive to antibiotic therapy, the patients die of septic shock.

Granulomatous peritonitis

The formation of multiple peritoneal granulomas with the development of ascites may rarely occur as a manifestation of sarcoidosis when differentiation from tuberculous peritonitis can be difficult and is based on a positive Kveim test, negative tuberculosis cultures and a lack of response to antituberculous therapy.

Starch peritonitis (starch granuloma syndrome) used to be a more common cause of granulomatous peritonitis in surgical practice and caused substantial morbidity. Talc (magnesium silicate) was the initial lubricant for surgical gloves and its implantation during surgery caused severe granuloma formation, chemical peritonitis and adhesion formation. It was replaced by Bio-Sorb in 1949. This is the epichlorohydrin polymer of cornstarch mixed with 2% magnesium oxide and small amounts of sodium sulphate and sodium chloride. When introduced, it was claimed to be completely absorbed by the peritoneal membrane and was thus free of the disadvantages encountered with talc. Subsequent experience has shown that reactions to Bio-Sorb do occur and include a syndrome of starch peritonitis (starch granuloma syndrome), which has a characteristic and well-recognized clinical picture. The disease starts 2–6 weeks after abdominal surgery with a low-grade fever, anorexia, nausea, vomiting, abdominal distension, cramp-like pain and tenderness. The abdominal distension is due to ileus and to the accumulation of ascitic fluid. Multiple granulomas develop on both the visceral and parietal pneumoperitoneum. The ascitic fluid is usually amber but may be serosanguinous and contains many leucocytes made up largely of lymphocytes and monocytes. The granulomatous nodules consist of collections of lymphocytes, macrophages, polymorphs and eosinophils around starch granules, which have a characteristic Maltese-cross appearance on microscopy (Figure 21.9). There is debate concerning the nature of the reaction. Some ascribe its development to a state of hypersensitivity to cornstarch, which can be demonstrated by skin patch testing in patients who develop the condition. Others argue that it represents a foreign body reaction. This is unlikely in view of the rare occurrence. The diagnosis is made on the clinical picture together with the demonstration of starch granules in the ascitic fluid obtained by an abdominal tap (iodine staining and polarized light microscopy). Surgery is avoided if the diagnosis is certain and treatment is conservative. Rapid resolution is seen with systemic corticosteroid therapy. The complications of starch peritonitis include sinus and fistula formation, adhesion formation and intestinal obstruction.

Bio-Sorb is seldom used in gloves nowadays, but, if it is, the following measure is advisable. After the gloves have been put on by the surgeon, 10 mL of povidone iodine (Betadine) is applied and smeared on the surface of the gloves. The black starch-iodine granules are then washed off by pouring 500 mL of sterile water from a container. In most instances, hydrogel polymers are used nowadays as lubricants for surgical gloves.

Meconium peritonitis

Meconium peritonitis is an unusual and not uncommonly fatal form of neonatal peritonitis. It is caused by antenatal extravasation of meconium into the peritoneal cavity and this results in a serious illness characterized by intraperitoneal calcification, dense inflammatory fibrosis with or without giant pseudocyst formation. In the majority of cases, no obvious cause can be found for the meconium peritonitis. In neonates and infants in whom a cause is found at laparotomy, this is either jejunal or ileal atresia and less commonly perforation of the appendix. The most striking and common findings during surgery are gross inflammatory adhesion bands with matted intestinal loops. Giant pseudocysts or intestinal perforation are present in 50–60% of cases. The surgical treatment depends on the exact operative findings in the individual neonate/infant. Some need adhesiolysis alone. Pseudocysts are partially resected and temporary enterostomy should be done for perforated bowel or when resection is needed with no attempt at primary anastomosis.

Non-surgical pneumoperitoneum

The introduction of as little as 10 mL of air into the peritoneal cavity may be demonstrated by erect films of the abdomen and chest in the right subdiaphragmatic region. Intraperitoneal air introduced during laparotomy is rapidly absorbed in infants (within 12 hours), often takes longer in older children and adults (38–48 hours) but may persist for 3–4 weeks in adults. Studies on operating room air have indicated the presence of deleterious substances including endotoxin. The absorption of this through the serosal surfaces of the exposed bowel and peritoneal membrane has been incriminated, in part, for the postoperative 'stress response' after open surgery.

In surgical practice, pneumoperitoneum detected by an erect abdominal or chest radiograph usually indicates perforation of a hollow viscus and is accompanied by clinical signs of peritoneal irritation indicative of serious intra-abdominal disease necessitating urgent surgical intervention. However, 10% of all cases of pneumoperitoneum are not accompanied by physical abdominal signs or evidence of significant underlying disease. The common causes of this non-surgical pneumoperitoneum are:

- Escape of air from the tracheobronchial tree in patients with chronic obstructive airways disease and in patients on intermittent positive-pressure ventilation.
- Free air after laparotomy, abdominal paracentesis and peritoneal dialysis. About 25% of patients still have demonstrable air under the diaphragm after an abdominal operation.
- Sealed subclinical perforation. This may be spontaneous or after gastrointestinal endoscopy including colonoscopy (iatrogenic subclinical perforation).
- Gynaecological causes – tubal insufflation, pelvic examination, douching, etc.
- Pneumatosis cystoides intestinalis.
- Idiopathic – no ascertainable cause.

Pneumoperitoneum can occur after laparoscopic surgery undertaken with CO_2 insufflation but usually clears rapidly within 12 hours owing to the rapid absorption of this gas. Complete aspiration of CO_2 after a laparoscopic operation is important for two reasons: less severe immediate postoperative CO_2 narcosis and reduction of shoulder pain the day after surgery.

In all cases, pneumoperitoneum is of significance only in the presence of symptoms and signs of peritoneal irritation. Otherwise a conservative approach is indicated. An overdistended viscus (e.g. hepatic flexure), adventitial gas shadows, subdiaphragmatic extraperitoneal fat and basal pulmonary collapse may produce radiological appearance simulating free air in the peritoneal cavity – *pseudopneumoperitoneum*.

Haemoperitoneum

The presence of blood in the peritoneal cavity is a major feature of trauma to the intraperitoneal and retroperitoneal organs (Chapter 21). The recent trend in patients with splenic and liver injuries is for conservative treatment unless the patient remains unstable with continued hypovolaemia despite blood transfusion and administration of clotting factors (fresh frozen plasma and platelet transfusion). Crystalloid intravenous therapy is no loner advised in these patients because of the risk of abdominal compartment syndrome.

Other causes of haemoperitoneum include bleeding from the puncture site following percutaneous liver biopsy or other related interventions, and after hepatic resections. In both cases, there is the added problem of abnormal coagulation that often precludes spontaneous arrest. Thus active intervention without any delay is needed in these patients.

The bleeding from puncture site(s) following percutaneous interventions may be substantial if a major intrahepatic vessel is damaged. The initial step during the operation is the application of a vascular clamp across the foramen of Winslow (Pringle's manoeuvre). This is left for 10–20 minutes, after which the clamp is removed and, if the bleeding does not recur, the puncture hole is injected with fibrin glue. Recurrence of the bleeding after release of the vascular clamp indicates damage to a major intrahepatic vessel. There are the two options. The traditional one is to expose the damaged vessel by extending the puncture wound after reapplication of the vascular clamp to the inflow vessels. This is then suture ligated and the clamp released. A simpler technique (if equipment and expertise are available) is localized thermal ablation using a radiofrequency probe. There is a risk in patients with these iatrogenic puncture injuries of the development of an intrahepatic arterioportal fistula, and, for this reason, they should be followed by high-dose CT-based angiography.

Bleeding after hepatic resection necessitates identification of the bleeding points usually in the cut hepatic parenchyma with individual suture ligation. If there are no obvious bleeding points but generalized ooze, argon beam spray coagulation is the best option. If this does not control the oozing, perihepatic gauze packing is indicated. The packs are removed 24–48 hours later.

Haemoperitoneum may arise spontaneously from:

- rupture of hepatic neoplasm
- rupture of splenic and hepatic aneurysms
- severe necrotizing pancreatitis
- peritoneal carcinomatosis.

In clinical practice, haemoperitoneum is seldom a feature of patients with leaking abdominal aneurysm who are admitted alive to hospital as intraperitoneal rupture of the aorta is immediately fatal. The clinical picture of spontaneous haemoperitoneum varies with the underlying cause. When the blood loss is substantive, e.g. rupture of liver tumour or splenic artery aneurysm, the clinical picture is that of severe hypovolaemia and abdominal distension. The hypovolaemia is resistant to volume replacement and the only hope of survival of these patients is immediate surgery with subdiaphragmatic aortic cross-clamping.

In the absence of significant hypovolaemia, the presence of blood in the peritoneal cavity causes some irritation of the peritoneal lining with the development of abdominal signs which, however, vary in intensity and can be marked especially if the haemorrhagic exudate is due to an inflamed organ, e.g. severe pancreatitis, or contains irritant secretions, e.g. bile. Adynamic ileus is invariably present in these cases. The clinical features of bleeding peritoneal carcinomatosis include increase in the ascites and abdominal girth and a hypochromic microcytic anaemia. The diagnosis is confirmed by an abdominal tap. Treatment in these terminally ill patients is entirely supportive.

Tumours of the peritoneum

Secondary peritoneal carcinomatosis

By far the commonest is secondary peritoneal carcinomatosis usually encountered in patients above the age of 40 years. The most common sites of the primary are stomach, breast, pancreas, colon and ovary. As far as tumours of the pancreas, stomach, colon and ovary are concerned, there is now evidence for a stage when viable tumour cells are shed into the peritoneal cavity, before any visible macroscopic appearance of deposits. This stage is identified by lavage cytology with use of specific immunohistochemical stains. In general, exfoliation of tumour cells occurs when the tumour reaches the serosa. In cancer of the colon, 30% of patients have positive lavage cytology at the time of the resection of the primary. In most instances, positive lavage cytology is accompanied by an unfavourable prognosis.

Clinical features

Early peritoneal disease (small seedling deposits) is asymptomatic and can only be detected by investigations. It may or may not be accompanied by deposits in the liver but in most cases the primary tumour has reached the serosa and secondary deposits in the lymph nodes are invariably present. Advanced peritoneal carcinomatosis is in contrast relatively easy to detect on clinical grounds as it is always accompanied by cachexia, anaemia and often malignant ascites which may be blood stained. It signifies advanced terminal disease with median survival of only a few months. Equally it is considered untreatable and the patient is best managed with hospice or supportive care with the necessary palliative therapy to ensure comfort and absence of pain.

Between these two extremes – early peritoneal disease and advanced terminal carcinomatosis – is a spectrum of involvement for which two staging systems are available, and there is one specific Japanese P score for carcinoma of the stomach. The two staging systems commonly used in other cancers/neoplasms are the Gilly score and the peritoneal cancer index (PCI) devised by Sugarbaker *et al.*

The Gilly staging identifies four progressive stages of disease advancement:

- stage 0: no macroscopic peritoneal disease
- stage I: malignant implants <5 mm in diameter localized in one part of the abdomen
- stage II: diffuse to the whole abdomen
- stage III: malignant implants 5 mm to 2 cm
- stage IV: large malignant nodules (>2 cm).

The PCI, described by Sugarbaker *et al.*, is also determined at the time of surgical exploration. However, it provides an estimate of probability of complete cytoreduction and an accurate assessment of survival after cytoreductive surgery and intraperitoneal chemotherapy. The PCI quantitatively combines the distribution of tumour throughout 13 abdominopelvic regions, each with a lesion size score. The abdomen is divided into nine regions, which are numbered in a clockwise direction with 0 at the umbilicus and 1 the space beneath the right hemidiaphragm. Regions 9–12 divide the small bowel into upper

	Regions	**Lesion size**
0	Central	———
1	Right upper	———
2	Epigastrium	———
3	Left upper	———
4	Left flank	———
5	Left lower	———
6	Pelvis	———
7	Right lower	———
8	Right flank	———
9	Upper jejunum	———
10	Lower jejunum	———

12	Lower ileum	———
	PCI	☐

Lesion size score	
LS 0	No tumour seen
LS 1	Tumour up to 0.5 cm
LS 2	Tumour up to 5.0 cm
LS 3	Tumour >5.0 cm or confluence

Figure 21.10 Peritoneal cancer index (PCI). Two transverse planes and two sagittal planes are used to divide the abdomen into nine regions, which are numbered in a clockwise direction with 0 being the umbilical and 1 defining the space beneath the right hemidiaphragm. Regions 9–12 divide the small bowel into upper and lower. Lesion size score is determined after complete adhesiolysis enabling inspection of all parietal and visceral peritoneal surfaces. Lesion size score refers to the greatest diameter of tumour implants on the peritoneal surfaces. Disease causing matting of abdominal or pelvic structures together is scored as L-3 even if it is a thin confluence of cancerous implants. [Reproduced from Jacquet, Sugarbaker, in Sugarbaker (ed.) *Peritoneal Carcinomatosis: Principles of Management*. Boston, MA: Kluwer Academic publishers, 1996:359–374.]

and lower jejunum and upper and lower ileum (Figure 21.10). The lesion sizes are then summed for all abdominopelvic regions, giving a score of 0–39.

Diagnosis

The only reliable method for detection of seedling peritoneal tumour deposits is by laparoscopy with laparoscopic contact ultrasonography and this is superior to the standard radiological imaging for establishing the diagnosis. However, the development of special MRI with 3.0T machines and multidetector helical CT scanning has improved the detection of small secondary deposits and some reports seem to suggest that they may replace laparoscopy for stagings The MRI technique involves fat suppression during gadolinium-enhanced MRI after the administration of dilute oral barium solution. This double-contrast MRI enables the detection of carcinomatosis, and tumours <1 cm in diameter in 75–80% of cases.

Treatment

There is no curative treatment for advanced disseminated carcinomatosis; these patients are treated entirely palliatively with hospice care. However, because of the favourable results obtained in patients with pseudomyxoma peritonei (PMP) following cytoreduction surgery and intraperitoneal chemotherapy (see below), this form of therapy has been extended to selected patients with peritoneal metastases secondary to colorectal cancer. The preliminary results have been promising in patients:

- with low-volume, low-grade peritoneal metastases
- with perforated cancers
- in whom definitive surgical cytoreduction is complete.

In these patients hyperthermic intraperitoneal chemotherapy with mitomycin C (35 mg/m^2) results in an actuarial 2 year survival of 59%. Obviously further studies are needed before this treatment is advocated routinely.

Pseudomyxoma peritonei

The term PMP is used to describe rare conditions characterized by the intraperitoneal accumulation of mucoid ascites/mucinous plaques involving the peritoneal surfaces that may or may not contain epithelial and other cells. There has been considerable confusion regarding both the pathology and aetiology of PMP in the past but this is now largely resolved. There are two main clinicopathological types of PMP:

1. *Disseminated peritoneal adenomucinosis* (DPAM): benign peritoneal lesions that consist mainly of extracellular mucin containing few benign mucinous epithelial cells without cytological atypia or mitotic activity. An appendiceal mucinous adenoma (cystadenoma) is present in 50–55%. The condition may also complicate mucocele of the appendix.
2. *Peritoneal mucinous carcinomatosis* (PMCA): malignant peritoneal lesions composed of abundant mucinous epithelium with cytological features of carcinoma.

PMCAs are further classified into:

- PMCA consistent with origin from an appendiceal or intestinal mucinous adenocarcinoma.
- PMCA with features intermediate between DPAM and PMCA or with discordant features despite the presence of at least focal areas of carcinoma in the peritoneal lesions, whether or not the primary site demonstrates an unequivocal carcinoma.

This classification of PMP is important because of its prognostic significance. Thus, with treatment, the age-adjusted 5 year survival rate for patients with DPAM exceeds 80%, as opposed to 38% for patients with PMCA with intermediate or discordant features, and 7% for patients with PMCA.

Pathology

There is some debate on the exact aetiology, as PMP has been reported in association with a variety of neoplasms: appendix, ovary and, rarely, pancreas, colon and urachus.

The immunophenotype (cytokeratin 7 negative; cytokeratin 20 and carcinoembryonic antigen positive) of the lesions of PMP is indicative of a gastrointestinal origin in the vast majority of cases. On very rare occasions, the disease involves the retroperitoneal space either alone or in association with intraperitoneal disease (retroperitoneal PMP). The possibility that some cases of PMP arise from primary transformation of the peritoneal mesothelium into neoplastic mucin-secreting tissue (mucinous metaplasia) has been raised although chromosomal analysis of these tumours does not support this hypothesis. Nonetheless, PMP has to be regarded as a heterogeneous lesion and usually develops from appendiceal (benign or malignant) or ovarian lesions (benign).

PMCA is best considered as a diffuse carcinoma derived from gastrointestinal (usually appendiceal) mucinous cystadenocarcinomas. The cancer cells/mucinous plaques are found at predetermined sites within the abdomen and pelvis and the primary tumour may be small and inconspicuous. The subdiaphragmatic space on both sides, the greater omentum and the pelvis are the sites of maximum disease. Involvement of the intestine is late. Women often have concomitant ovarian mucinous tumours that suggest primary ovarian neoplasia. However, morphological, immunohistochemical and molecular studies in these cases usually indicate that the ovarian tumours are secondary and the PMCA is of intestinal origin. These observations question the existence of a borderline group of mucinous ovarian tumours as a cause for this condition. Thus ovarian tumours exhibiting borderline features should be included in the benign group and designated as atypical proliferative mucinous tumours. Pulmonary parenchymal metastases, although rare, have been reported in patients with PMCA.

In contrast, DPAM represents the benign form of the disease. In these patients the peritoneal implants are usually derived from the extrusion of epithelial cells from an adenoma of the appendix. It is thought that the mucin deposition occurs in accordance with fluid flow and gravitational forces within the peritoneal cavity. The small bowel is not usually involved. Instances of DPAM have been reported in association with mucocele of the appendix (obstructive dilatation of the appendiceal lumen owing to abnormal accumulation of mucus). Mucocele of the appendix has a characteristic CT appearance consisting of spherical or elongated cystic lesions, attached to the wall of the caecum, and may exhibit mural calcification.

Contrary to early reports, cytological examination of the mucin pool/plaques always reveals cells but these vary in count and type (epithelial cells, mesothelial or mesothelial-like cells, histiocytes and fibroblast-like or spindle cells). The epithelial cells may be columnar with mucinous features and may have benign or malignant cytological features. In general, high epithelial cell counts and cytologically malignant cell types are associated with a poor prognosis.

Clinical features

PMP is a rare condition, being reported in approximately two per 10 000 laparotomies. The majority of patients are middle-aged or older patients. Often the primary tumour is slow growing and rarely metastasizes or invades adjacent viscera. In addition to progressive abdominal distension, the condition may present as an acute abdomen with intestinal obstruction. Instances of presentation with spontaneous external fistula in patients with PMP arising from a mucinous carcinoma of the appendix are recorded. PMP has also been reported in association with splenic mucinous epithelial cyst. These may present with splenomegaly before the development of the disease, i.e. presenting feature of PMP, or be detected after the diagnosis or with recurrence of PMP.

When suspected, confirmation of the disease is obtained by fat-suppressed, gadolinium-enhanced, breath-hold MRI after administration of dilute oral barium solution. This carries a higher diagnostic yield than non-enhanced MRI or CT scanning. The characteristic MRI features include thick-walled cysts and septa. Laparoscopy carries the highest diagnostic yield and provides an assessment of the extent of the disease and its pathological type (on biopsy).

Treatment

The treatment is multimodal and consists of:

- aggressive surgical debulking
- intraoperative or postoperative intraperitoneal chemotherapy or systemic combination chemotherapy.

Surgical treatment (usually by laparotomy) entails aggressive surgical evacuation, and resection of the primary and diseased peritoneum. Removal of the appendix is advocated in all cases even if it does not appear to be the site of the primary disease.

Currently most centres favour intraperitoneal chemotherapy with alkylating agents, or 5-fluorouracil (5-FU) and mitomycin C or cisplatin. One report has indicated that hyperthermic (40–42°C) intraperitoneal chemotherapy improves the response rates. Others rely on systemic combination chemotherapy including cisplatin. Radiotherapy is generally regarded as being ineffective in PMP. Long-term survival without recurrence of the disease is well documented in patients with DPAM. By contrast, patients with a high-grade malignant process (PCAM) usually die of the disease within 8 years, but the generally held view is that treatment (if the condition of the patient permits) is the same. In these malignant cases the debulking can be a difficult and time-consuming operation. Others avoid aggressive therapy in view of the high morbidity rates without prospects for significant improvement in survival. This seems to be an unduly pessimistic view. Good results, especially for intermediate PCMAs, can be obtained. They depend on early diagnosis and treatment before large volumes of disease and multiple surgical procedures lead to small bowel entrapment by tumour.

There have been reports of the laparoscopic management of PMP secondary to adenocarcinoma of the appendix. This approach permits thorough exploration of the abdomen, irrigation and aspiration of the thick mucinous material and the instillation of mucolytic agents (5% dextrose solution). Appendicectomy or right hemicolectomy is performed with minimal disturbance of the anterior abdominal wall. The intraperitoneal catheters for chemotherapy are placed through the port sites.

Peritoneal mesothelioma

Mesothelioma is a relatively rare malignant neoplasm arising from the serosal lining of the pleural, peritoneal and pericardial cavities. In many countries there has been a rising incidence of the disease since 1950 owing to exposure to asbestos predominantly in males. Age-specific incidence rates are highest for the older age groups. There is a long latency period between exposure to diagnosis, and this averages 20–30 years. Several studies have shown that these asbestos-related tumours are characterized by balanced chromosomal rearrangements. Asbestos-related mesotheliomas occur most commonly in the pleura, but instances of peritoneal mesotheliomas due to asbestos exposure are well documented and asbestos bodies (mainly amosite) have been documented in the peritoneal cavity, the most common sites being the mesentery and omentum, usually in patients with heavy-fibre burdens in lung tissue.

Peritoneal mesotheliomas can develop, albeit rarely, in the absence of exposure to asbestos. Perhaps the most important is malignant mesothelioma after radiation therapy for Hodgkin disease. In these patients, the mesothelioma arises in the field of prior radiotherapy. There is a rare primary variant that occurs in young females, and instances of mesotheliomas have been reported in patients with familial Mediterranean peritonitis.

Pathology

Malignant mesotheliomas are pleural, pericardial or peritoneal neoplasms usually associated with asbestos exposure. Since mesothelial cells are biphasic, they may give rise to epithelial and sarcomatous malignant mesotheliomas. In addition, benign 'atypical proliferations of mesothelial cells' may occur. The separation of mesothelial hyperplasia from early malignant mesothelioma can be very difficult on histological examination. These lesions are termed 'atypical mesothelial hyperplasia'. Immunostaining for epithelial membrane antigen and the quantification of silver-stained nucleolar organizer regions can be useful in differentiating benign from malignant histological sections of pleural and peritoneal biopsies. There have been recent reports of simian virus 40 DNA large T antigen sequences in both pleural and peritoneal epithelial malignant mesotheliomas but not in sarcomatous lesions. Malignant mesothelioma tends to be a diffuse lesion and, when associated with asbestos exposure, is classified as an industrial disease. Pathological confirmation of asbestos aetiology is necessary for these patients to obtain compensation.

Benign mesotheliomas comprise two macroscopic types: fibrous and multicystic. The fibrous type forms well-encapsulated solid tumours composed of spindle-shaped cells. The multicystic variety has a marked tendency for local recurrence after resection. Both types are associated with long survival after surgical resection.

In females, the histological distinction between epithelial peritoneal mesothelioma and ovarian papillary serous carcinoma diffusely involving the peritoneum may be difficult even with immunohistochemistry and usually requires examination of the ultrastructural features by electron microscopy. To compound a difficult problem further, rare instances of primary mesothelioma in young women have been documented and some of these are associated with highly elevated serum levels of cancer antigen 125. This makes the differentiation even more difficult since this is the typical marker for epithelial serous tumours from the ovary.

Clinical features

Currently only 2.2 cases of malignant mesotheliomas per million population per year are diagnosed. The incidence of the disease continues to increase because of the long latency period, despite the fact that exposure to asbestos in industry has virtually ceased since 1970. Malignant mesotheliomas are encountered mainly in men. The mean age at first diagnosis of malignant mesotheliomas is approximately 59 years; women on average are 4 years younger at presentation. The most frequent initial symptoms of malignant mesotheliomas include fatigue, abdominal pain, anorexia, marked weight loss and abdominal distension caused by intractable ascites. Clinical presentation as fever of unknown origin is exceptional, but, when it occurs, it signifies a very aggressive tumour with a bad prognosis. Both benign and malignant disease may present with an abdominal mass or intestinal obstruction or gastric outlet obstruction. More uncommon presentations include dysphagia secondary to pseudoachalasia, chronic pancreatitis and regional lymphadenopathy. Overall, the mean survival time ranges from about 3 months to 8 years. Prolonged survival is only encountered with benign mesotheliomas.

The current standard non-invasive imaging modality for staging of malignant mesothelioma is CT. However, CT does not determine resectability. Laparoscopy using a multiport technique with diaphragmatic, peritoneal and abdominal wall biopsies provides more accurate staging. The ascitic fluid is examined for malignant cells.

Treatment

This entails surgical exploration with excision (benign lesions) or tumour debulking followed by intraperitoneal chemotherapy. Details of the intraperitoneal chemotherapy vary. Good results have been reported with continuous hyperthermic peritoneal perfusion with cisplatin-based regimens. In phase II studies, this combination results in a median progression-free survival of 26 months, and an overall 2 year survival of 80% (for all mesotheliomas including the multicystic variants). The morbidity is acceptable (24%). Retreatment after initial response can result in a second long-term response.

Some advocate two-stage peritoneal chemotherapy for patients with primary peritoneal mesothelioma. In stage I, patients undergo cytoreductive surgery and placement of an intraperitoneal infusion catheter, through which intraperitoneal chemotherapy is administered for 4 months. In stage II, a second laparotomy with debulking of residual disease and placement of perfusion intraperitoneal catheters is carried out. High-dose intraperitoneal hyperthermic (40–42°C) chemotherapy using a disposable perfusion circuit is then administered. The reported experience with this two-stage treatment is limited and currently there is no evidence that it gives superior results.

Malignant mesotheliomas are generally regarded as being unresponsive to systemic chemotherapy. However, dramatic regression of the disease has been reported following systemic chemotherapy with gemcitabine. The activity of gemcitabine in malignant mesothelioma has been confirmed by phase II studies. There is also evidence suggesting better response rates when gemcitabine is combined with cisplatin. Other regimens that have shown activity are based on doxorubicin and cisplatin.

Special forms of intestinal obstruction

Postoperative intestinal obstruction

It is often incorrectly assumed that a persistent intestinal obstruction (beyond 3–4 days) after abdominal surgery is due to a protracted adynamic ileus. While there are some specific operations in which this is the case, e.g. intestinal intubation with a Baker's tube or complex remedial reconstructive surgery on the gastrointestinal tract, in the majority of patients in whom the obstruction is delayed a mechanical cause is likely to be present. Early obstruction (during the first 5 days) is usually due to non-strangulating causes, e.g. anastomotic oedema, adhesive fibrinous matting with distension and kinking of the intestinal loops. As the obstruction is often incomplete, active surgical intervention is rarely necessary and the majority settle with conservative management. By contrast, later postoperative obstructions (occurring at or persisting beyond 7 days of surgery) are usually caused by organized bands or abscesses and may be strangulating in nature. Laparotomy is therefore necessary for these late or prolonged postoperative intestinal obstructions.

Bolus obstruction

Intraluminal bolus obstruction, usually of the small intestine, may be caused by tricho- and phytobezoars, gallstones or a mass of worms (*Ascaris lumbricoides*). The last is usually encountered in children and is often precipitated by antihelminthic therapy.

Phytobezoars

These are firm masses of undigested fruit or vegetable fibres that can cause gastric or small bowel obstruction. The predisposing factors include:

- ingestion of large amounts of high-fibre foods
- inadequate mastication
- previous gastric surgery producing hypo- or anacidity and loss of the antral pump mechanism.

Often the phytobezoars that form after gastric surgery consist of orange pith.

Patients with gastric bezoars present with epigastric pain, loss of appetite and weight, and episodes of distension and vomiting. The condition is usually diagnosed at endoscopy. Intestinal bezoars present with mechanical small bowel obstruction. Gastric bezoars are multiple in 17% of cases and intestinal bezoars in 4%.

Gastric bezoars may be treated conservatively by cellulase enzymatic digestion (300 mL of 0.5% cellulase solution instilled 4 hourly via a nasogastric tube for 2 days). Alternatively piecemeal removal may be carried out endoscopically but this may be difficult. Laparotomy is needed for patients presenting with small bowel obstruction. Sometimes it is possible to knead the bolus into the caecum. When this is not successful, a gastrotomy is performed.

Intestinal pseudo-obstruction

The term 'pseudo-obstruction' is used to describe obstruction of the small or large intestine in the absence of a mechanical cause or acute intra-abdominal disease. The term covers a variety of syndromes which result from damage to the myenteric plexus (neuropathy) or smooth muscle abnormality (myopathy), or both. Small intestinal and colonic pseudo-obstruction are best discussed separately.

Small intestinal pseudo-obstruction

This condition may be primary (idiopathic) or secondary. Familial *hollow visceral myopathy,* which is included in the primary category, is a particularly severe disorder which involves the smooth musculature of the oesophagus, entire gastrointestinal tract including the colon and often the urinary bladder. The secondary variety results from a neuropathy/myopathy induced by certain systemic disorders or drug misuse (excess phenothiazine administration, laxative abuse). The disorders most commonly associated with the development of secondary small intestinal pseudo-obstruction are:

- diabetes mellitus
- scleroderma
- progressive systemic sclerosis
- acute intermittent porphyria
- hypothyroidism
- Chagas disease.

It has also been reported as a complication of sclerotherapy for oesophageal varices. When the underlying abnormality is a neuropathy (e.g. diabetes mellitus), the pattern of intestinal motor activity is abnormal with derangements of the myoelectrical migratory complexes, absence of any normal activity or disorganized non-propulsive hypermotility. By contrast, in myopathic conditions (e.g. hypothyroidism), the pattern of motor activity is normal but the intensity of the contractile activity is reduced.

The clinical picture is that of recurrent episodes of subacute intestinal obstruction with colicky abdominal pain, vomiting and distension. The treatment entails correction of any underlying disorder whenever this is possible (e.g. hypothyroidism). Intestinal prokinetics, e.g. metoclopramide and domperidone or cisapride, are sometimes beneficial, especially the last. Cisapride acts by increasing the local concentration of acetylcholine in the intestinal smooth musculature but this drug has been withdrawn from clinical practice because of severe side effects. The synthetic peptide ceruletide, which has to be administered intravenously or intramuscularly, is also beneficial, particularly during acute episodes. Intravenous erythromycin may be effective in some patients. Replacement therapy is necessary in patients with hypothyroidism.

Colonic pseudo-obstruction

Two types are recognized: acute and chronic. The acute condition was first described by Ogilvie in 1948 and is sometimes referred to as *Ogilvie syndrome*. It consists of a selective dilatation of the caecum and proximal colon with a sharp cut-off usually at the splenic flexure, and less frequently the hepatic flexure and sigmoid, suggestive of mechanical obstruction. It is best considered as a localized form of adynamic ileus, which usually develops in patients with major pre-existing, non-intestinal conditions requiring hospitalization, e.g. major surgery, severe trauma, sepsis, myocardial infarction, severe renal and respiratory disease. The aetiology remains unknown although administration of drugs that impair colonic motility and air swallowing are thought to be contributory factors. The defect appears to be in the smooth muscle or in one of the intestinal control mechanisms, and slow wave activity (electrical control activity) has been reported to be absent in these patients.

The clinical picture is dominated by abdominal distension often without vomiting. The patient complains of increasing discomfort and may develop cramp-like abdominal pain. Radiography shows features of colonic obstruction with caecal distension (7.5–22.0 cm). Caecal perforation is a well-recognized complication and is likely to occur if the radiological size of the caecum exceeds 12 cm.

The standard treatment is by colonoscopic decompression, which is successful in the majority of patients. Recurrence of the condition is encountered in 20% of patients. These are treated by further colonoscopy when a Baker's intestinal tube is inserted transanally into the caecum, or the colonoscope left *in situ* for 2 hours, thereby maintaining decompression. Surgical intervention with tube caecostomy is undertaken when colonoscopic treatment fails.

Chronic colonic pseudo-obstruction may be primary or secondary. They latter may result from a motility disorder, diabetes mellitus, hypothyroidism, malignancy, psychosis or drug and laxative abuse. This is covered elsewhere (Chapter 30).

Intussusception

Intussusception is a telescoping of a segment of intestine into an adjacent one (Figure 21.11). The condition is encountered most commonly in childhood with a peak incidence at 4 months. Intussusception may, however, be encountered in the adult, in which case a precipitating lesion that initiates the intussusception (the lead point) is usually present, e.g. intestinal polyp or submucous lipoma. By contrast, in infants and children some 70–95% are classed as idiopathic (no lead point) and an associated illness, such as urinary tract infection or gastroenteritis, is encountered in 30%. It is often assumed that hyperplasia of the lymphoid patches in the terminal ileum secondary to common disease in infancy may be involved in the initiation of idiopathic intussusception in this age group. A definite seasonal incidence is observed in infants and children with clear peaks in the spring and summer. This is suggestive of viral infections being the cause of the intestinal lymphoid hyperplasia.

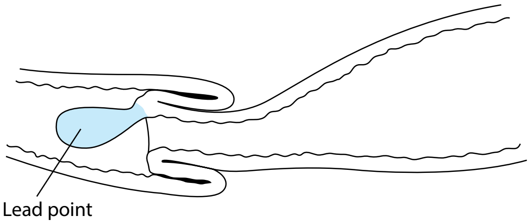

Figure 21.11 Components of an intussusception.

Intussusception is anatomically defined as ileoileal, ileocaecal and ileocolic depending on the site and extent of the telescoping observed by the time of diagnosis. The condition is a strangulating type of intestinal obstruction and, if treatment is delayed, ischaemic necrosis of the involved bowel segments and peritonitis are inevitable.

The clinical features include the sudden onset of vomiting, cramp-like abdominal pain and rectal bleeding. An abdominal mass is palpable in 55–60% of cases. Children with intussusception associated with a lead point (Meckel's diverticulum, polyp, duplication, Henoch–Schönlein purpura, suture line, appendix, tumour) are usually older than the idiopathic cases.

In the absence of peritonitis and intestinal obstruction, the initial treatment is by hydrostatic barium enema, which is successful in 50% and is followed by a recurrence rate of 6%. Intussusception caused by a lead point is not likely to reduce with a hydrostatic barium enema and usually requires surgical intervention. Operative treatment is necessary when the hydrostatic reduction is incomplete, uncertain or contraindicated (peritonitis, intestinal obstruction). Operative reduction is usually possible, although the viability of the bowel may be compromised after reduction and resection is therefore necessary. In adults, it has to be assumed that a lead point is present and its nature determined by subsequent investigations after recovery, unless of course the lesion is palpable through the bowel wall after reduction.

Volvulus

Volvulus is a twist or rotation of a loop of intestine about its mesenteric attachments. It is therefore a sudden obstruction of the closed loop variety if the rotation is complete (360°) and ischaemia or total vascular occlusion may be present by the time of diagnosis.

The condition may involve the stomach (Chapter 23), small and large intestine. Two intestinal varieties are described: primary and secondary. Primary volvulus results from malrotation of the gut or congenital excessive mobility from loose fixation or long mesenteric attachments (volvulus of the mid-gut in the neonate). The more common secondary volvulus is due to rotation of a loop of small intestine around an adhesions/band, an ileostomy or colostomy. Caecal and sigmoid volvulus are considered elsewhere (Chapter 30).

Intraperitoneal adhesions

Adhesions following abdominal and pelvic surgery are important in view of their morbidity and frequent hospital readmissions. They occur after elective surgery and following peritonitis from any cause. The morbidity spectrum of intraperitoneal adhesions includes:

- chronic pain
- acute and subacute intestinal obstruction

- secondary female infertility
- increased operating time for subsequent operations
- risk (20%) of iatrogenic bowel injuries during subsequent operations.

Pathology of adhesions

The causes of intraperitoneal adhesions are:

- open abdominal or pelvic surgery
- individual susceptibility
- ischaemic areas: anastomotic sites, reperitonealization of raw areas
- foreign bodies: talc, starch granules, gauze lint, cellulose, etc.
- peritonitis from any cause
- inflammatory bowel disease: Crohn' disease
- radiation enteritis
- sclerosing peritonitis: usually drug induced, e.g. certain beta-blockers.

The most common category is postoperative adhesions. There is undoubtedly an individual susceptibility as some patients are prone to adhesions and others not, even after major operations, but the genetics and molecular biological basis for this predisposition to adhesion formation are not known. Talc is no longer a problem. Surgical gloves either incorporate a hydrogel polymer or are powdered with epichlorohydrinated cornstarch. Gauze lint is still important and there is evidence that it is responsible for 25% of cases of intraperitoneal granuloma formation caused by implanted foreign bodies. There is some evidence that some postoperative adhesions develop on a background of ischaemia in the region of surgically constructed anastomoses and following attempts at reperitonealization of raw areas. These should be left unsutured, when they are rapidly filled with an inflammatory exudate and thereafter covered by a new serosa derived from free-floating peritoneal macrophages.

The exact pathogenesis of intra-abdominal adhesions is not fully understood but trauma and exposure of the peritoneum and the subsequent biochemical and cellular response to repair this injury are involved. Fibrin deposition is the initiating step as this is essential for mesothelial repair. Normally there is a fine balance between resurfacing of denuded areas by mesothelial cells and fibrinolysis that removes the initial fibrin structural framework. Disturbance of this fine balance between mesothelial repair and fibrinolysis by ischaemia and other factors is thought to be responsible for adhesion formation after abdominal surgery. As the fibrinolytic activity is compromised, the fibrin matrix persists, becomes invaded by fibroblasts and gradually matures into fibrous bands, usually within 5–7 days. Adhesions may be parietal (between viscera and abdominal walls and diaphragm) or visceral (between bowel loops and solid organs). Usually both are present in the individual case.

Another factor that is thought to be important in the development of adhesions is disruption of the naturally occurring surface active phospholipid (SAPL) barrier, which normally keeps the peritoneal membrane lubricated and separates the visceral from the parietal peritoneum. The component lipids of this SAPL barrier, which protects other surfaces such as the alveolar membrane, are dipalmitoylphosphatidylcholine (DPPC) and unsaturated phosphatidylglycerol (PG). Three-dimensional studies of the molecular configuration have shown that the SAPL barrier is composed of multiple layers (lamellar bodies). The efficacy of SAPL lamellar bodies is due to their ability to bind to the mesothelial epithelium within the microvilli to form molecular structures that keep the surface well lubricated and dewetted. The protective and lubricating properties of the SAPL barrier are compromised during surgery and may account for the development of adhesions.

There is no established classification of adhesions. They can be filmy, dense or string-like, and of variable spread within the peritoneal cavity, but are usually centred on the operative site and the parietal access wound. From the symptomatic and pathological viewpoint, parietal adhesions (those binding the intra-abdominal contents to the parieties) are more important than interloop/visceral adhesions.

Adhesions after elective surgery

Although estimates of the incidence of adhesions vary (40–97%), all the reports indicate that the problem is substantial and results in both a significant morbidity and major added healthcare costs. In the USA over 400 000 operations were performed for lysis of adhesions in 1993 and the total costs for treating patients with complications and symptoms caused by adhesions has been estimated at $1.2 billion annually. In one retrospective cohort study based on validated data of patients undergoing open abdominal or pelvic surgery (29 760) from the Scottish National Health Service database in 1986, followed up for 10 years, 34.6% were readmitted a mean of 2.1 times during the study period for a disorder directly or possibly related to adhesions, or for abdominal or pelvic surgery that could be potentially complicated by adhesions. Six per cent of all readmission during the study period were directly due to adhesions and the majority of these (97%) required an operation during the readmission. Most of the adhesion-related events are encountered during the first year after surgery (22% of all operative adhesiolysis performed in the first 12 months) but the incidence of adhesion-related morbidity and readmissions did not decline during the 10 year period (Figure 21.12).

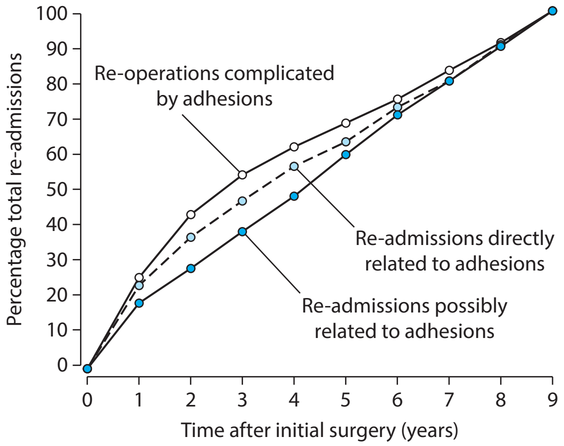

Figure 21.12 Adhesion-related hospital readmissions after abdominal and pelvic surgery: a retrospective cohort study. (Reproduced by kind permission from Ellis, *Lancet* 1999;**353**:1476–1480.)

Complications of adhesions requiring readmission to hospital are much more frequent after surgery on the small bowel and colon than after pelvic gynaecological surgery involving the female reproductive organs. Small bowel obstruction developed in 25% of patients after total colectomy with ileoanal pouch reconstruction in one large reported series of 1005 patients. Approximately 70% of all hospital admissions for small bowel obstruction are due to adhesions.

Clinical features

Patients with intraperitoneal adhesions may develop chronic symptoms or present acutely with intestinal obstruction.

Chronic adhesion syndromes

The most common is abdominal pain with or without nausea in the absence of abdominal signs, except perhaps minimal tenderness. The pain distribution is variable and is not necessarily beneath the abdominal wall scar. These are the most difficult patients to evaluate and they usually undergo a series of investigations, often repeated before coming to either laparotomy or laparoscopy. The outcome in terms of pain relief after adhesiolysis is uncertain; some patients obtain pain relief (possibly a placebo effect) but usually the pain recurs. In other patients the pain is episodic and colicky in nature, accompanied by nausea, audible excessive bowel sounds and abdominal distension lasting for variable periods. These attacks terminate in diarrhoea, which relieves both the pain and the abdominal distension. In these patients the symptoms are due to recurrent attacks of subacute small bowel obstruction and, indeed, these patients may develop acute obstruction at any time. These patients often lose weight from malabsorption due to bacterial overgrowth. This group undoubtedly benefits from surgery (see below).

Acute adhesive intestinal obstruction

This is the most common reason for emergency admission/readmission to hospital. The obstruction is almost always in the small bowel although the level of obstruction varies. Colonic obstruction due to adhesions is rare and other causes should be considered. The severity of vomiting and the extent of abdominal distension vary with the level of the obstruction. The condition is readily diagnosed by the clinical symptoms and signs and abdominal plain films (erect and supine). The possibility of strangulation should be suspected if the pain is constant, there is obvious tenderness on palpation and a marked leucocytosis. Early recourse to surgical intervention may prevent infarction of the intestine.

Treatment of adhesion-related complications

Prophylactic

In the first instance good surgical technique is important. In this context, the specific points include:

- delicate handling of tissues and organs
- avoidance of spillage of visceral contents during surgery
- minimizing operative blood loss
- protection of exposed viscera from drying
- avoidance of closure of parietal peritoneal defects – this induces ischaemia at the suture line
- washing the operative region and peritoneal cavity with isotonic saline at the end of the operation.

There is good evidence that laparoscopic surgery is followed by a significantly reduced incidence of postoperative adhesions and this effect is probably related to maintenance of the 'milieu intérieur' of the coelomic cavity during the operation, although other factors may be involved.

Even with the best operative techniques, elective surgery on the small intestine and colon and emergency surgery for acute peritonitis is a significant risk factor and there is an increasing argument for specific prophylaxis after these operations. A variety of drugs [anticoagulants, dextrans of various molecular sizes, antihistamines, non-steroidal anti-inflammatory drugs (NSAIDs), povidone, streptokinase etc.] have been investigated as antiadhesion agents but none have been shown to be effective as chemoprophylactic agents against adhesion formation.

There is to date only one proven prophylactic treatment that should be considered in these patients. This consists of a bioresorbable membrane based on sodium hyaluronate (Seprafilm) which is placed on the front of the intestinal loops/greater omentum separating them from the parietal wound. The use of this membrane has been shown to be entirely safe (no detectable adverse effects) and in a prospective randomized trial of patients undergoing colectomy and ileal pouch anal anastomosis significantly reduced the incidence of adhesions (15% versus 58%).

Based on the role of the SAPL barrier in peritoneal lubrication and its disruption by open surgery, a synthetic mixture of surface-active phospholipids (DPPC and PG – proprietary name ALEC) has been used in experimental studies and shown to reduce adhesions by 70%. The product is available in powder form (identical to surfactant used in neonatal respiratory problems) and is jet sprinkled into the peritoneal cavity at the end of the procedure. Clinical studies are ongoing in patients undergoing emergency colonic operations with ALEC but to date there are no published results.

Another antiadhesion agent of interest is a 4% icodextrin solution (Adept) used extensively in peritoneal dialysis. As these patients do not form peritoneal adhesions, icodextrin has been studied experimentally and in one clinical trial against Ringer's solution in gynaecological laparoscopic surgery. In both instances it reduced the incidence, severity and extent of adhesions. However, its efficacy in general surgical practice remains unproven. It has several advantages. These include proven non-toxicity, low cost and ease of administration, i.e. 1 litre of the solution is instilled in the peritoneal cavity at the end of the operation. Icodextrin solution is contraindicated in patients with known allergy to starch-based polymers and in patients with maltose or isomaltose intolerance.

Treatment of patients with symptomatic/complicated adhesions

Patients with chronic symptoms

The patients with a clinical picture of subacute small bowel obstruction should undergo surgical adhesiolysis. This may be undertaken by the open approach or laparoscopically depending on local expertise. Following adhesiolysis, insertion of Seprafilm between the contents and the parieties is advocated. The insertion of Seprafilm may prove difficult if the operation is conducted by the laparoscopic approach. The decision for adhesiolysis is difficult in patients with chronic symptoms in the absence of definitive abdominal signs. If the surgeon decides to intervene, the laparoscopic approach is preferable to the open approach in these patients, as the likelihood is that the symptoms will recur after a variable period and the patient will then be insistent on further surgery. The author had a patient referred for remedial surgery to reconstruct the abdominal wall who, by the age of 49 years, had had 38 operations. The alternative to Seprafilm is Adept solution, particularly if the operation is conducted laparoscopically.

Patient with acute small bowel obstruction

In the absence of signs and symptoms of strangulation, these patients are managed conservatively with nasogastric decompression and fluid and electrolyte replacement in the first instance. This conservative management is usually successful but if there is no improvement within 12–24 hours of admission, emergency laparotomy and adhesiolysis is undertaken. These operations should be performed under prophylactic antibiotic cover, and, if for any reason the bowel is injured during the operation or resection of an intestinal segment is performed, a full 5 day antibiotic course to cover Gram-negative organisms (anaerobes and aerobes) is necessary. The laparoscopic approach is used by some surgeons in these patients but is technically difficult in view of the distended oedematous intestinal loops and may carry a higher risk of iatrogenic bowel injury than the open conventional approach. In some instances, because of dense adhesions, the bowel may be injured during the mobilization. Inadvertent enterotomy during adhesiolysis occurs in 15–20% and increases the postoperative morbidity and urgent relaparotomy rate. These patients are also more likely to require intensive care support and parenteral nutrition and have significantly longer postoperative stay in hospital. The risk factors for inadvertent enterotomy during adhesiolysis are:

- obesity
- three or more previous laparotomies
- adhesiolysis in lower abdomen and pelvis
- old age.

If the inadvertent enterotomy is ragged and extensive, it is better to resect this injured segment; otherwise, it is oversewn. The insertion of Seprafilm between the intestinal loops/omentum and the parietal wound is advisable in all patients undergoing adhesiolysis for intestinal obstruction (irrespective of iatrogenic bowel injury). Patients with features of strangulating obstruction at or soon after admission (especially those with constant pain and marked leucocytosis) require immediate surgery following resuscitation.

Patients with recurrent episodes of small bowel obstruction

These patients pose real problems in surgical management, as the relative efficacy of the various surgical operations used for this condition has never been adequately assessed by prospective randomized studies. The operations available include:

- adhesiolysis alone
- adhesiolysis with Seprafilm
- Noble intestinal plication
- Child–Phillips placation
- Baker intestinal intubation.

To date there is no evidence of any clear superiority of one procedure and there are no data on the efficacy of Seprafilm in reducing the obstructive episodes after adhesiolysis, but this seems a sensible addition to adhesiolysis especially as its use does not incur any adverse effects.

The Noble intestinal plication (Figure 21.13) involves suturing the small intestinal loops with serosal sutures so that the small bowel coils become fixed in gentle curves when adhesions reform. The procedure is rarely performed nowadays because it is time-consuming and carries an appreciable morbidity (perforation, fistula, peritonitis). Furthermore, patients complain of chronic abdominal pain and remain subject to recurrent attacks of intestinal obstruction.

In the Child–Phillips operation of transmesenteric plication (Figure 21.14) after adhesiolysis, the small intestine and mesentery are placed in an orderly fashion. Thereafter, the intestinal

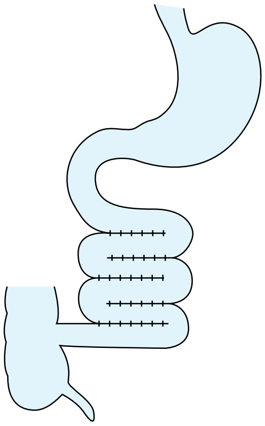

Figure 21.13 Noble's plication operation. The small intestinal loops are sutured together in smooth curves by means of seromuscular sutures.

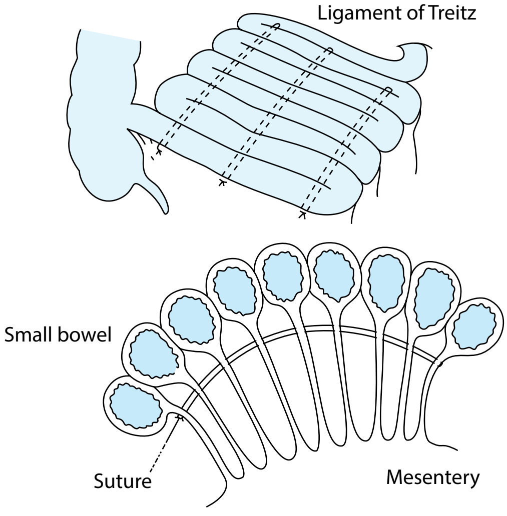

Figure 21.14 The Child–Phillips operation of transmesenteric plication for recurrent small intestinal obstruction due to adhesions.

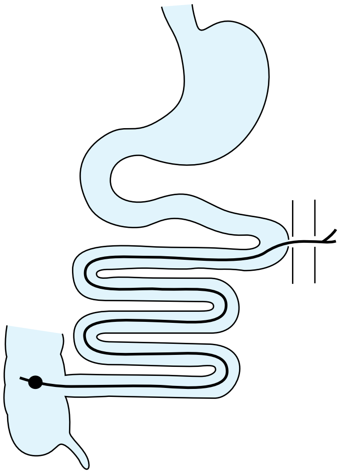

Figure 21.15 Intestinal intubation for recurrent small bowel obstruction using a Baker's tube inserted via a Witzel jejunostomy.

coils are fixed in position by means of transmesenteric sutures or some 3–5 mm away from the mesenteric border of the intestine, avoiding the terminal branches of the mesenteric arcade. The results of a number of retrospective reports with this procedure for recurrent small bowel obstruction due to adhesions have been good in terms of relative freedom from further episodes of intestinal obstruction.

The intraluminal tube or long intestinal 'stent' tube was first proposed by White as a simple method of achieving gentle curves rather than allowing the bowel to develop acute angulations when adhesions reform. Baker introduced the jejunostomy tube and advocated its insertion through either a purse-string suture in the upper jejunum or a Witzel jejunostomy (Figure 21.15). The tube has an inflatable balloon near its tip, which facilitates passage down the small intestine into the caecum.

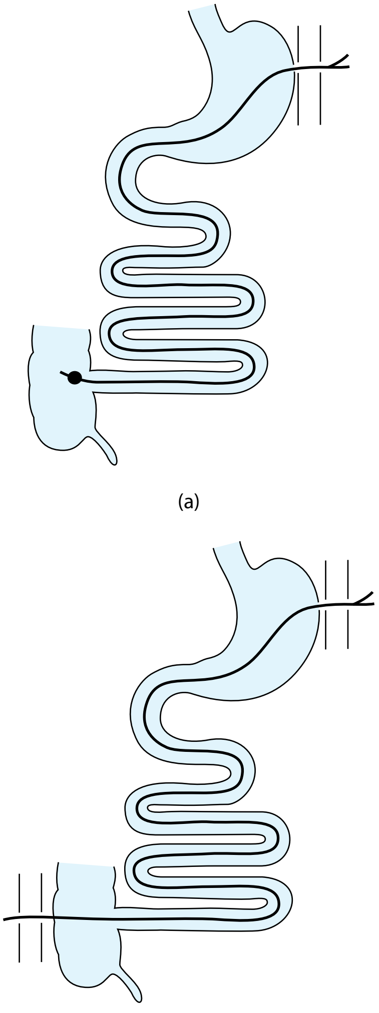
Modifications of the technique include gastrostomy stent plication with and without tube exit-caecostomy (Figure 21.16). The latter is unnecessary and increases the risk of infection. One disadvantage of the intestinal intubation method is the long period of ileus after the operation. Reports on the efficacy of intestinal intubation in preventing recurrent intestinal obstruction have been conflicting. Some have found the procedure beneficial and have extended its use as a prophylactic measure in the treatment of patients with generalized peritonitis and following major abdominal surgical procedures. Other reports indicate that intestinal intubation is inferior to adhesiolysis alone.

Desmoid tumours (aggressive fibromatosis)

The pathological disorder underlying the development of these lesions is *aggressive fibromatosis*. Desmoid tumours are considered as locally aggressive but non-metastasizing tumours. This is not strictly true as instances of peritoneal dissemination are documented but are uncommon. These tumours exhibit a marked tendency to recur after surgical excision, lead to considerable morbidity and not uncommonly contribute to death of the patients. Aggressive neurofibromatosis may arise sporadically or in association with familial adenomatous polyposis (FAP) and Gardner syndrome.

Pathology

Aggressive fibromatosis (myofibromatosis in children) is a fibroproliferative disorder of fascial and musculoaponeurotic structures that most commonly affects the trunk and extremities but variants can affect the intra-abdominal mesenteries and the parietal pleura. Instances of desmoids developing in the breasts are well documented but rare. The pathological process consists of a monoclonal proliferation of spindle (fibrocyte like) cells that are locally invasive with a tendency to recurrence but very rarely metastasize, although instances of peritoneal dissemination have been reported in patients with mesenteric desmoids. Some tumours arise sporadically but a subgroup is associated with FAP. -Catenin mutations and -catenin dysregulation have been documented in both sporadic aggressive fibromatosis and that occurring in association



(a)

(b)

Figure 21.16 (a) Gastrostomy with long intestinal tube plication for recurrent small bowel obstruction. (b) Modification of the technique with gastrotomy and tube exit-caecostomy. This technique is not generally recommended as the exit-caecostomy is considered unnecessary and increases the risk of infection.

with FAP, itself caused by germ-line mutations in the adenomatous polyposis coli (*APC*) gene. In desmoid tumours, one of the two mutations usually occurs distal to the second β-catenin binding/degradation repeat of the gene (3' to codon 1399). Catenin and catenin-binding genes are known to be associated with neoplastic processes. Independent predictors of increased risk of developing desmoid are (1) germ-line mutation distal to codon 1399, (2) family history of gastrointestinal disease and (3) a strong family history of desmoid tumours.

In genetically normal individuals (sporadic cases), at least two somatic mutations must occur in both alleles of the *APC* gene (which normally acts as a tumour suppressor gene). In FAP syndrome patients, one *APC* germ-line gene is already mutated and, therefore, only one new somatic mutation is required in the opposite *APC* gene for a desmoid to develop. It is known that the *APC* gene is involved in the regulation of the cellular level of β-catenin, which has a cell membrane function (member of the adherens junctions) and binds transcription factors in the nucleus, thereby activating transcription (mediator in Wingless signalling). Cellular β-catenin protein level is elevated in all desmoid tumours (sporadic and those associated with FAP). The demonstration of mutations in two mediators in the Wnt-APC-β-catenin pathway implicates β-catenin stabilization as the key factor in the pathogenesis of aggressive fibromatosis. It appears that truncating *APC* gene mutations (337 bp insertion of an *AluI* sequence into codon 1526 of the *APC* gene) give aggressive fibromatosis cells a proliferative advantage through elevated cellular levels of β-catenin protein. What is interesting is the observation that the higher level of β-catenin protein compared with surrounding normal tissues is associated with normal levels of β-catenin mRNA. This suggests that the elevated β-catenin is due to degradation at a lower rate than normal tissues.

Desmoid tumours are oestrogen receptor and progesterone receptor negative. Despite this, antioestrogens (tamoxifen and toremifene) and NSAIDs (sulindac and diclofenac) have been shown to induce objective response rates in both adult patients and children with unresectable or recurrent desmoid tumours and the effect of the combination is synergistic, i.e. increased efficacy compared with either agent alone. Most desmoid tumours express the proliferating cell nuclear antigen, although this has not been shown to influence outcome.

Clinical features

Desmoid tumours are rare with a reported incidence of two to four per million population. They can occur at any age from childhood to old age but there is an established female preponderance and the majority of sporadic cases occur in women of childbearing age, in whom they usually appear during or after pregnancy. Infantile/juvenile tumours tend to be very aggressive and involve proliferation of fibrous and muscle layers (myofibromatosis). The mesenteric variant constitutes about 10% of all desmoid tumours and accounts for 50–70% of lesions developing in patients with FAP. Although the trunk and extremities are the most common sites of external desmoids, lesions can occur anywhere – neck, chest, hands, etc.

Table 21.1 Staging system for intra-abdominal desmoid tumours in familial adenomatous polyposis

Stage	Description
I	Asymptomatic, <10 cm maximum diameter, and not growing
II	Mildly symptomatic, <10 cm maximum diameter, and not growing
III	Moderately symptomatic or bowel/ureteric obstruction, or 10–20 cm, or slowly growing
IV	Severely symptomatic, or >20 cm, or rapidly growing

Mildly symptomatic, sensation of mass, pain, but no restrictions.
Moderately symptomatic, sensation of mass, pain; restrictive but not hospitalized.
Severely symptomatic, sensation of mass, pain; restrictive and hospitalized.

The problem with clinical management of desmoid lesions relates to their rarity and the many different therapies available. Standardization is needed so that prospective studies can be planned. In 2005, Church *et al.* proposed a staging system for intra-abdominal desmoid tumours in FAP, based on tumour size and behaviour. This has since been used in sporadic cases as well. The system proposed is simple but useful (Table 21.1).

The majority of tumours developing in patients with FAP do so after surgery and 50–70% are intra-abdominal (mesenteric variant) and 30–50% external in the abdominal wall. Mesenteric desmoids have a significantly worse prognosis than abdominal wall tumours and cause recurrent intestinal or ureteric obstruction, which often contributes to the death of the patient. By contrast abdominal wall desmoids do not cause death or significant morbidity, although recurrence is common after excision.

CT or MRI are used for diagnosis and to determine the extent of the tumour and its relationship/involvement of adjacent structures, to detect recurrence after surgery and to assess response to non-surgical treatment, especially radiotherapy.

Treatment

In view of the rarity of the condition the treatment is not standardized. There treatment modalities are:

- surgical excision
- radiotherapy
- combined antioestrogen and anti-inflammatory drug therapy
- chemotherapy
- newer modalities: isolated limb perfusion and immunotherapy with interferon.

Surgical excision

This remains the most effective, although recurrence rates are high (average 30% at 5 years), recurrence-free survival is good (80–75%) at 5 years for primary extremity and trunk desmoid tumours. Local recurrence after surgical excision is not related to any specific prognostic factors (age, sex, depth and size of tumour, and positive resection margins). Thus attempts at wide excision resulting in unnecessary morbidity may not prevent local recurrence. Surgical excision of these lesions should remove macroscopic disease with preservation of function and structure when possible, as residual microscopic disease does not significantly compromise the 5 year disease-free or overall survival. Conservative surgery is especially indicated in children, in whom it should be accompanied by adjuvant therapy (see below). In limb lesions, amputation should be reserved only for patients in whom the disease or repeated resections have resulted in a non-functional or chronically painful extremity.

Radiotherapy

Radiation is an effective modality for desmoid tumours, either alone or as an adjuvant to resection. The main indication for radiotherapy is unresectable disease. Postoperative radiation is not recommended for patients with negative resection margins. Patients with positive margins should receive 50 Gy of postoperative radiation. Unresectable tumours are irradiated with a dose of approximately 56 Gy with a 75% expectation of local control. The radiation dose correlates with the incidence of complications. Thus doses of 56 Gy or less produce a 5% complication rate at 15 years compared with 30% with higher doses.

In 30% of juvenile patients with aggressive fibromatosis primary complete resection is not feasible. In this age group, radiotherapy as primary treatment is indicated only if complete tumour resection is not feasible without mutilation. In general, radiotherapy should be used as a last resort in children with skeletal immaturity because of the risk of growth disturbance, contracture and secondary malignancy.

Medical therapy

The most common medical treatment used is combined antioestrogen (usually tamoxifen) and NSAID (sulindac) therapy, which can be used at any age but is indicated in patients with unresectable disease/recurrence after radiotherapy, especially children, in whom it is recommended prior to resort to chemotherapy. Reasonable response rates (up to 30%) and disease control are well documented. More recently, the tyrosine kinase inhibitor imatinib has been used with promising results in some patients whose tumours express one of imatinib's molecular targets, platelet-derived growth factor receptor. Early results with antifibrotic agents (pirfenidone) appear promising but the reported experience is very limited.

Chemotherapy

Chemotherapy is used in patients with unresectable tumours, and in those with tumours that do not respond to tamoxifen and/or sulindac. Low-dose chemotherapy with methotrexate and vinblastine produce high response rates, particularly in children. The combination of methotrexate and vinorelbine produces similar response rates but with less nerve damage. Liposomal doxorubicin appears to be more effective (because of increased tumour uptake) than doxorubicin. Low-dose chemotherapy is often given for a year, then stopped for assessment of response by CT or MRI; it requires several months for detection of improvement.

High-dose chemotherapy treatment is more active but is accompanied by increased toxicity; for this reason, it is administered for a shorter duration, usually 6 months in patients unresponsive to other therapies or with very rapidly growing symptomatic tumours. The most commonly used regimen is doxorubicin combined with dacarbazine.

Newer modalities

Isolated limb perfusion with tumour necrosis factor and melphalan has been used with some success as a limb preservation treatment in patients with recurrent desmoids and significant symptoms who would otherwise require mutilating surgery for control of the disease. However, the reported experience, though promising (40% regression rate), is limited. Also interferon-induced remission in aggressive fibromatosis of the lower extremity has been reported. Other new therapies include intralesional sclerosant therapy with acetic acid or absolute alcohol and radiofrequency thermal ablation, but the long-term benefit of both is not known.

Disorders of the retroperitoneum

Retroperitoneal fibrotic disorders

There is a group of fibrotic disorders of the pneumoperitoneum that are closely related and considered to be distinct from aggressive fibromatosis (desmoids). They include:

- secondary retroperitoneal fibrosis: drug-induced, extravasation of urine, desmoplastic response to a variety of tumours
- idiopathic retroperitoneal fibrosis (Ormond disease)
- inflammatory aortic aneurysm
- sclerosing mesenteritis
- multifocal retroperitoneal fibrosclerosis.

All are rare. The secondary type accounts for about 30% of cases. The drug-induced type is associated with the administration of methysergide for migraine but other drugs (methyldopa, phenacetin, etc.) have been implicated.

Idiopathic retroperitoneal fibrosis (Ormond disease)

The condition accounts for 70% of cases and results in the development of a flat, grey–white plaque of tissue that is found in the lower lumbar region and then spreads laterally and upwards to encase the common iliac vessels, vena cava and the aorta. Rarely, it may extend upwards above the renal arteries and become contiguous with a similar process in the mediastinum, or forwards into the small bowel mesentery or mesocolon. It may very rarely also involve the bile duct, duodenum and pancreas. The histological picture varies from an active one which shows inflammatory cells and small blood vessels surrounding bundles of collagen fibres, to a more mature process that is relatively avascular and acellular with patches of calcification.

The aetiology of idiopathic retroperitoneal fibrosis is unknown. It has been attributed in the past to lymphatic and venous obstruction and lymphangitis. Leakage of blood or urine from trauma into the retroperitoneal space causing fibrosis is classed as secondary retroperitoneal fibrosis. The majority of idiopathic cases are regarded as part of an obscure collagen disorder. A possible genetic predisposition for idiopathic retroperitoneal fibrosis is suggested by the presence of the human leucocyte antigen B27 immunophenotype in 44% of cases. The association in some patients with inflammatory aortic aneurysm is now established (see below). In these patients it appears that the fibrosis is caused by a chronic inflammatory or autoimmune response to antigens leaking into the retroperitoneum from atheromatous plaques in the aorta or common iliac arteries.

The average age at presentation is 50–55 years but the disease is documented in young individuals and elderly patients (aged 44–71 years). There is a male predominance in reported cases. Clinical presentation may be insidious with a variable picture but the most common presentation is with hypertension, obstructive uropathy (single or bilateral) and renal failure. A nagging, ill-defined, low back pain is common and there may be evidence of venous obstruction as shown by swelling of the scrotum and legs. Uncommonly, the patient may present with claudication. Examination reveals anaemia, leucocytosis and an increased sedimentation rate. Biochemical investigation may show a degree of renal failure. The intravenous urogram reveals a characteristic picture consisting of hydronephrosis and medial displacement of the ureters with gross irregularity.

Patients in renal failure will require cystoscopy and ureteric stenting to relieve the obstructive uropathy and permit recovery of the renal function. If stenting is unsuccessful, percutaneous nephrostomy is necessary to improve renal function before definitive treatment. This consists of surgical ureterolysis. The operation is carried out by a transabdominal approach, and the freed ureter(s) are separated from the fibrous tissue by vascularized omental interposition and placed intra- or extraperitoneally. This operation gives the best results (even without subsequent corticosteroid therapy) with complete resolution of the symptoms and long-term successful alleviation of ureteric obstruction in 100% of patients.

Many drugs have been shown to effective in idiopathic retroperitoneal fibrosis. These include corticosteroid, azathioprine, cyclophosphamide, methotrexate, tamoxifen and mycophenolate mofetil. Tamoxifen and corticosteroids seem to be the most effective combination and are indicated in patients with continuous activity of the disease and to prevent recurrence after surgery.

Inflammatory aneurysm

Inflammatory aneurysm (aortitis) accounts for 4% of abdominal aneurysms and has an established association with retroperitoneal fibrosis. Following surgical treatment of the aneurysm, the inflammatory fibrosis resolves completely in only 23%, improves in 35% but remains static in the remainder and can then lead to involvement of the ureter(s) or intestine. The characteristic perivascular distribution of idiopathic retroperitoneal fibrosis is in support of the hypothesis that the disease is an immune-mediated response to leaking antigens from severe atherosclerosis. It is recommended that patients with inflammatory aneurysms should be followed up and receive medical therapy with corticosteroids and tamoxifen if the fibrosis does not resolve, or progresses.

Sclerosing mesenteritis

This is a very rare idiopathic benign mesenteric lesion and only a few cases have been reported. It is characterized by fat necrosis, fibrosis and chronic inflammation and has been recently reported in HIV-positive patients. It presents with recurrent abdominal pain and weight loss and tends to form masses that involve the pancreas and the small bowel mesentery. The condition responds to tamoxifen and corticosteroids.

Multifocal idiopathic fibrosclerosis

Multifocal idiopathic fibrosclerosis is a rare syndrome characterized by exuberant fibrosis involving many organs/systems – mediastinal fibrosis, retroperitoneal fibrosis, orbital pseudotumour, Riedel's thyroiditis and sclerosing cholangitis. Patients may also have Dupuytren's contractures, lymphoid hyperplasia, Peyronie disease, vasculitis, testicular fibrosis and pachymeningitis.

Retroperitoneal swellings

The term retroperitoneal tumour is usually confined to lesions arising from tissues (muscles, fat, fibrous tissue, lymph nodes, nerves and developmental remnants) of this compartment but excluding origin from the retroperitoneal organs (pancreas, kidneys and ureters and adrenal glands). Retroperitoneal swellings may be cystic or solid, benign or malignant.

Benign cystic lesions

The cystic swellings are usually benign and the majority are discovered accidentally. They include:

- cystic lesions arising from developmental (Wolffian) remnants of the urogenital tract; these are situated near one or other kidney
- mesenteric cysts (intra- and retroperitoneal)
- teratomatous and dermoid cysts
- abdominal cystic lymphangiomas (lymphogenous cysts)
- parasitic cysts.

Abdominal lymphangiomas

Lymphangiomas are benign lesions of vascular origin that show lymphatic differentiation. The vast majority (95%) occur in the neck and axillary regions with the remainder being located in the abdomen and retroperitoneum, lung and mediastinum. On ultrasound scanning, lymphangiomas appear as multilocular cystic masses that are anechoic but may contain echogenic debris. Intravenous contrast-enhanced CT may show enhancement of the cyst wall and any septa. On MRI, the signal pattern resembles that of fluid: low signal intensity on T_1 weighted imaging and high signal intensity on T_2 weighted images, although haemorrhage or infection in the cystic lesions may alter both the CT attenuation and MRI signal pattern giving a more solid appearance.

In one of the largest series of 107 abdominal lymphomas Levy *et al.* reported the following distribution of abdominal cystic lymphangioma:

- mesenteric, 54%
- retroperitoneal, 10%
- splenic, 8%
- colonic, 7%
- small bowel, 7%

- pancreatic, 5%
- rare site: hepatic, biliary, renal, adrenal, bladder, ovary.

Retroperitoneal lymphangiomas tend to form large elongated lesions. Large mesenteric lymphangiomas may simulate ascites but can be differentiated from it by the presence of septa, compression on adjacent small bowel loops and absence of free fluid in the paracolic gutters and subhepatic spaces.

Lymphangiomas may also involve the gastrointestinal tract: oesophagus, stomach and especially the small intestine and colorectum. Most intestinal lymphangiomas form mural masses usually found incidentally at endoscopy or on radiological studies. The aetiology of intestinal lymphangiomas is variously attributed to intramural lymphatic obstruction, disturbed endothelial permeability, inflammation, congenital absence of lymphatics and ageing of the bowel wall. Barium contrast studies show smoothly marginated mural masses that deform on external abdominal compression. Endoscopic sonography and CT show evidence of cystic mass in the intestinal wall.

Clinical features

Abdominal cystic lymphangiomas are rare and usually present in infants and children, mean age 5 years (range 3 months–8 years) and indeed some are diagnosed on the prenatal ultrasound examination. They may, however, present in adult patients. The majority (90%) of childhood lesions are intraperitoneal (mesentery and gastrointestinal tract) but some (10%) are located in the retroperitoneal space. The symptomatology varies but the most common presentation is with abdominal pain. A palpable tumour is found in 30% of patients. In children, abdominal lymphangiomas may present with complications such as intestinal obstruction (including volvulus), infection and sudden increased pain and swelling caused by intracystic haemorrhage. The diagnosis is established by abdominal ultrasonography, CT and MRI.

In adults, symptoms of abdominal cystic lymphangiomas have usually been present for several months to years, and the documented sites include the pancreas, spleen and retroperitoneum. Thus, compared with children, a significantly higher proportion involve retroperitoneal structures and acute presentation is rare.

Treatment

Treatment is with surgical excision whenever possible and is indicated only for symptomatic or complicated disease. Resection has to be complete to prevent recurrence.

The treatment of colonic symptomatic intestinal lymphangiomas is by colonoscopic endoscopic deroofing of the cysts or polypectomy if pedunculated and small to intermediate in size, but large lesions usually require colonic resection.

Generalized lymphangiomatosis

The diffuse condition of generalized lymphangiomatosis is a rare congenital disorder which consists of multifocal lymphagiomatous lesions. It usually presents in childhood and involves multiple organs including the lung, liver, spleen, bone and skin. Phangiomatosis (generalized lymphangiomatosis) is caused by maldevelopment of the lymphatic systems during the intrauterine period. The condition is most commonly diagnosed in children (65%) and has an equal sex incidence. Cross-sectional imaging with CT and MRI is important for the diagnosis because of the widespread nature of the condition. There are some isolated reports of an association with other mesenchymal dysplasias, such as *Maffucci syndrome* and diaphyseal aclasis. Generalized lymphangiomatosis covers a large spectrum of abnormalities and affects multiple organs. Cases with localized lesions carry a better prognosis but the prognosis of generalized lymphangiomatosis also depends on the extent of the disease. Skeletal involvement is often present when the bones most frequently involved are the tibia, humerus, ilium, skull, mandible, vertebrae and small bones of the hands. The bony lesions are osteolytic with multiple septae and these lesions can cause complications: pathological fracture, joint deformity and severe pain. Some patients have extensive mediastinal, pleural and peritoneal involvement with cystic fluid collections. The prognosis is bad in patients with combined mediastinal and bone lesions. Splenic lymphangiomatosis shows characteristic findings on CT imaging: enlarged spleen containing multiple well-circumscribed cystic lesions that usually show no contrast enhancement. Although rare, subcutaneous nodules, are well documented in the literature.

Treatment

Treatment of generalized lymphangiomatosis is usually conservative. Surgical intervention is indicated only for complications such as pathological fractures and symptomatic/complicated disease. Bisphosphonate medication is used to prevent bone loss in skeletal lymphangiomatosis. Abdominal complications are treated by laparotomy with resection of the diseased organ involved in the complication.

Solid tumours

The majority of solid retroperitoneal tumours are malignant. The benign tumours, which constitute 20%, include:

- lipomas
- neurofibromas, neurilemmomas
- leiomyomas
- extra-adrenal chromaffinomas (phaeochromocytomas) – may be malignant
- retroperitoneal mucinous cystadenomas
- haemangiopericytoma.

The *Costello syndrome* is characterized by mental retardation and the occurrence of benign tumours (usually papillomata) but instances of children with the Costello syndrome who develop retroperitoneal embryonal rhabdomyosarcoma are documented. Adult retroperitoneal tumours of nervous origin account for 20% of the retroperitoneal tumours in this age group. The majority are males (sex ratio 10:3). The main symptom is the abdominal pain (84.6% of all cases) and all the tumours usually reach a large size by the time of presentation. Benign solid lesions such as retroperitoneal neurilemmomas show up as well-demarcated round or oval masses on CT. They may exhibit heterogeneous contrast enhancement, no enhancement indicative of cyst formation and tumour calcification.

Paragangliomas are tumours of embryological origin from the neural crest and can be found in any location along the aorta and/or in association to the sympathetic chain. These tumours can be non-functioning or secreting [catecholamines – usually norepinephrine (noradrenaline)] and the secretory state influences the clinical presentation. These secreting neuroendocrine tumours are responsible for 0.1–0.5% cases of hypertension. Only 20% of paragangliomas are catecholamine secreting, and cause a syndrome similar to that of phaeochromocytoma. Paraganglionomas may be multiple and malignant. The malignant types recur locally after excision and spread by the bloodstream predominantly to bones and lungs. Immunohistochemical staining of paraganglionomas may exhibit type I cells (chromogranin A and neurone-specific enolase), which have no prognostic significance, or type II cells (S100 protein), the presence of which is associated with a good prognosis. Some paraganglionomas are familial (hereditary paraganglioma) and are associated with germ-line mutations in the von Hippel–Lindau disease tumour suppressor gene and the *ret* proto-oncogene.

Both benign (mucinous cystadenomas) and malignant (mucinous cystadenocarcinomas) can occur as primary tumours of the retroperitoneum. The immunological staining characteristics of malignant lesions indicate that these tumours have patterns similar to ovarian mucinous tumours. This genotypic similarity with ovarian mucinous tumours may indicate similar mechanisms in their histogenesis.

Haemangiopericytomas are rare vascular benign tumours derived from pericytes and can develop in the retroperitoneal space where they usually present as very bulky but otherwise clinically silent tumours. Tumours as large as 30 cm have been documented. Treatment is by surgical excision.

Although not strictly a primary retroperitoneal tumour as angiomyolipoma (a mesenchymal tumour) usually originates from the kidney, it is considered here for a number of reasons. In the first instance, its pleomorphic appearance and involvement of regional lymph nodes may simulate malignancy, although the lesion is benign. Second, angiomyolipomas are very common (approximately 40%) in patients with tuberous sclerosis and are then usually small, bilateral and asymptomatic.

The important clinical feature of angiomyolipomas is spontaneous rupture and retroperitoneal haemorrhage and this usually occurs with larger tumours. Although the tumour has specific ultrasonographic and CT appearances, histological examination is necessary for establishing the diagnosis. The management varies with size. Thus small asymptomatic lesions should be followed up with sequential CT scans and removed by enucleation or partial nephrectomy only if they reach a size >4.0 cm. Emergency surgery is needed for patients with massive bleeding, when it is usually very difficult to preserve the kidney.

Overtly malignant retroperitoneal tumours are of diverse origin:

- lymphomas
- congenital neuroblastoma
- soft-tissue sarcomas: fibrosarcoma, liposarcoma, rhabdomyosarcoma, neurofibrosarcoma and other malignant nerve cell tumours
- neoplasms arising from the urogenital ridge.

Congenital neuroblastoma

Congenital neuroblastoma is an embryonal malignancy of the sympathetic nervous system arising from neuroblasts. By definition, *congenital neuroblastoma* is defined as a neuroblastoma diagnosed within a month of birth, and is of types: (1) *fetal* and (2) *neonatal* neuroblastoma. The vast majority of fetal neuroblastomas (90%) originate in the adrenal glands. They are identified by fetal ultrasound examination usually in the third trimester (36 weeks' gestation). In most cases the tumour undergoes maturation and regression, and prognosis for the fetal type is excellent with conservative management. The prenatal detection necessitates delivery in a perinatal centre so that neonatal surgery, if needed, can be performed.

Neonatal neuroblastomas have a much better prognosis than those presenting in older children with cure rates of 90%. The adrenal glands are the site of origin in only 45% of neonatal neuroblastomas and in 60% of infants metastases, most frequently to the liver, are present at the time of diagnosis and cause massive hepatomegaly with respiratory impairment. In contrast 70–80% of children older than 18 months present with widespread metastatic disease, usually to the lymph nodes, liver, bone and bone marrow and <50% can be cured, even with aggressive treatment.

The cause of neuroblastoma is unknown. The vast majority of tumours arise sporadically without any family history. A small minority (1%) have a family history of neuroblastoma and these patients usually present at an earlier age or with multiple primary tumours. Neuroblastoma can occur in association with other disorders linked to abnormal development of neural crest tissues, e.g. Hirschsprung disease and central congenital hypoventilation syndrome. These cases have a germ-line mutation in *PHOX2B*, a homeobox gene that acts as a regulator for the development of the autonomic nervous system.

Pathology

The tumour is composed of undifferentiated neuroblasts, which histologically appear as small, round, blue cell tumours. A peculiar arrangement of dense nests of cells in a fibrovascular matrix –'pseudorosettes' – is seen in 15–50% of tumours – these are neuroblasts surrounding eosinophilic neuritic processes. These neuroblast tumour cells are small and uniform cells with scanty cytoplasm and hyperchromatic nuclei. Formation of neuritic processes is a pathognomonic feature of neuroblastoma cells. Immunohistochemical staining with neuron-specific enolase, chromogranin, synaptophysin and S-100 stains are usually positive. Electron microscopy is used to detect ultrastructural features of the tumour: neurofilaments, neurotubules, synaptic vessels and dense core granules.

Chromosomal and molecular markers

The most important biological marker is *MYCN,* an oncogene that is overexpressed in approximately 25% of neuroblastomas through the amplification of the distal arm of chromosome 2. Patients whose tumours exhibit *MYCN* amplification have aggressive rapidly growing disease and a poor prognosis. In contrast, expression of the *H-ras* oncogene correlates with a better prognosis and lower stage of the disease at presentation. Deletion of the short arm of chromosome 1 is the most common chromosomal abnormality present in neuroblastoma and, when present, confers a poor prognosis. DNA index is another useful parameter that correlates with therapeutic response in infants with neuroblastoma: tumours which exhibit hyperdiploidy (DNA index >1) have a good therapeutic response to chemotherapy with cyclophosphamide and doxorubicin, whereas infants with tumours exhibiting a DNA index of 1 are less responsive, requiring more aggressive combination chemotherapy.

The neurotrophin receptor gene products *TrkA*, *TrkB* and *TrkC*, are tyrosine kinases that code for receptors of members of the nerve growth factor family. In infants <12 months, a high expression of *TrkA* correlates with a good prognosis. In contrast, *TrkB*, which is more commonly expressed in tumours with *MYCN* amplification, is associated with poor prognosis. Other biological markers associated with poor prognosis include increased levels of telomerase RNA and lack of expression of glycoprotein CD44 on the tumour cell surface. P-glycoprotein and multidrug resistance protein are two proteins expressed in neuroblastoma that confer multidrug resistance in some cancers.

Histopathological classification (Shimada)

This is based on (1) the degree of neuroblast differentiation, (2) extent of Schwannian stroma (stroma rich or stroma poor), (3) cellular proliferation (mitosis–karyorrhexis index; MKI), (4) nodular pattern and (5) age. It has been confirmed to be very useful in differentiating patients into those with favourable histology indicative of good prognosis and those with unfavourable histology indicative of aggressive disease.

Favourable groups include:

- patients of any age with stroma-rich tumours without a nodular pattern
- patients <18 months with stroma-poor tumours, MKI <200/5000 (200 karyorrhectic cells per 5000 cells scanned) and differentiated or undifferentiated neuroblasts
- patients <60 months with stroma-poor tumours, MKI <100/5000 and well-differentiated tumour cells.

Unfavourable groups include:

- patients of any age with stroma-rich tumours and a nodular pattern
- patients of any age with stroma-poor tumours, undifferentiated/differentiated neuroblasts, MKI >200/5000
- patients >18 months with stroma-poor tumours, undifferentiated neuroblasts, MKI >100/5000
- patients >18 months with stroma-poor tumours, differentiated neuroblasts, MKI of 100–200/5000
- patients >60 months with stroma-poor tumours, differentiated neuroblasts, MKI <100.

Clinical features

Neuroblastoma constitutes 6–10% of all childhood cancers, and 15% of cancer deaths in children. The highest incidence is in the first year of life, and some cases are congenital. Although the age range is broad, including older children and even adults, only 10% of neuroblastomas occur in individuals >5 years old. A large European study reported that <2% of 4000 neuroblastoma patients were over 18 years old. International reports indicate high incidence rates in the rich Western countries (Europe and North America), and lower incidence in low-income/developing countries (Africa, Asia and Latin America). Males have a slightly higher incidence of neuroblastoma than females (male to female ratio 1.2:1). The age distribution at the time of diagnosis is: 40% of patients are <1 year, 35% are aged between 1 and 2 years and 25% are >2 years when diagnosed. According to SEER, incidence decreases every consecutive year up to age 10 years, after which the disease is rare.

The majority (90%) of neuroblastomas are secretory with elevated levels of catecholamines or their metabolites (dopamine, homovanillic acid or vanillylmandelic acid) being present in the blood or urine or blood. The common symptoms include abdominal pain, vomiting, weight loss, anorexia, fatigue and bone pain. Chronic diarrhoea is a rare presenting symptom secondary to autonomous secretion of vasoactive intestinal peptide by the tumour. Overall, 50% of patients present with advanced stage disease with osseous and bone marrow deposits. Thus, the most common presentation is with bone pain and a limp. Some patients may develop unexplained fever, irritability and periorbital ecchymosis secondary to metastatic disease to the orbits. Pathological fractures are commonplace in patients with bony metastases.

In 70% of patients, the primary tumour is intra-abdominal and hence an asymptomatic abdominal mass, usually discovered by the parents, is a common early manifestation. In time the mass becomes symptomatic, with the symptoms depending on the proximity of the tumour to vital structures. Tumours arising from the paraspinal sympathetic ganglia can grow through the spinal foramina into the spinal canal and impinge on the spinal cord producing a spectrum of neurological manifestations ranging from weakness and limping to paralysis and even bladder/bowel dysfunction. In a small proportion of infants <6 months, neuroblastoma presents with a small primary tumour and metastatic disease to the liver, skin and bone marrow (stage 4S). In neonates, the skin lesions may be confused with congenital rubella. When the skin involvement is extensive, the term ‘blueberry muffin baby’ is used to describe the striking appearance. Rarely (2%) patients present with opsoclonus and myoclonus – a paraneoplastic syndrome characterized by the presence of myoclonic jerking and random eye movements. These patients often have localized disease and a good long-term prognosis. The neurological abnormalities may, however, persist.

Clinical staging (International Neuroblastoma Staging System)

This is as follows:

- Stage 1: localized tumour with complete gross excision, microscopic residual disease, or both. Histologically negative ipsilateral lymph nodes (nodes attached to the primary may be positive for tumour).

- Stage 2A: localized tumour with incomplete gross resection. Representative ipsilateral non-adherent lymph nodes microscopically negative for tumour.
- Stage 2B: localized tumour, complete gross excision, or both with positive ipsilateral non-adherent lymph nodes. Enlarged contralateral lymph nodes, which are histologically negative.
- Stage 3: unresectable unilateral tumour infiltrating across the midline, regional lymph node involvement, or both. Alternatively, localized unilateral tumour with contralateral regional lymph node involvement.
- Stage 4: any primary tumour with dissemination to distant lymph nodes, bone, bone marrow, liver, skin and/or other organs (except as defined for stage 4S).
- Stage 4S: localized primary tumour (as for stages 1, 2A or 2B) with dissemination limited to the skin, liver and/or bone marrow (<10% involvement). Limited to infants.

More recently the International Neuroblastoma Task Force has proposed the International Neuroblastoma Risk Group (INRG) classification system as retrospective studies have revealed high survival rates of children in the 12–18 month old age group previously categorized as high risk. In this group of children the tumour does not have amplification of the *myc* gene.

The new INRG risk assignment will classify neuroblastoma at diagnosis based on a new International Neuroblastoma Risk Group Staging System (INRGSS) is as follows:

- Stage L1: localized disease without image-defined risk factors.
- Stage L2: localized disease with image-defined risk factors.
- Stage M: metastatic disease.
- Stage MS: metastatic disease 'special', in which MS is equivalent to stage 4S.

The risk stratification is based on the new INRGSS staging system: age (dichotomized at 18 months), tumour grade, N-*myc* amplification, unbalanced 11q aberration and ploidy into four pretreatment risk groups: very low, low, intermediate and high risk.

Treatment

Most centres now follow the INRG treatment strategies with different treatment regimens for (1) low-risk, (2) intermediate-risk and (3) high-risk groups.

Treatment strategy for low-risk patients

Patients with localized resectable tumours (stage 1) have excellent event-free survival (EFS) rates with surgical excision of tumour only. Adjuvant chemotherapy is not indicated in these patients but is used if patients develop recurrent disease. The overall survival rate is high (>95%). Similar management is indicated in patients with stage 2A/2B disease if they fall in a low-risk category and have non-amplified *myc* tumours, regardless of age, histology or ploidy. However, patients with stage 2A/2B disease with *myc*-amplified tumours are considered high risk regardless of age and histology. Most patients with 4S disease (non-*myc*-amplified tumours, favourable histology, hyperdiploid tumours in infants <12 months) are also considered a low-risk group as most experience spontaneous regression. Thus, management consists of observation or surgery alone. Chemotherapy is used to control life-threatening situations such as respiratory distress from a large liver.

Treatment strategy for intermediate-risk group

Surgery and multiagent chemotherapy are used for intermediate-risk patients. Intermediate-risk patients include (1) children <18 months with stage 3 or 4 disease and favourable biology (non-*myc*-amplified tumours, regardless of histology and DNA index). These patients are treated with the four cytotoxic agents active against neuroblastoma (cyclophosphamide, doxorubicin, carboplatin, etoposide) using four cycles, six cycles or eight cycles, depending on histology and DNA index and response to treatment. In these patients, surgery can be performed either at the time of diagnosis or after combination chemotherapy. Radiotherapy is considered for residual disease after chemotherapy and surgery. However, this remains controversial.

Treatment strategy for high-risk group

These patients seem to require aggressive treatment with multiagent chemotherapy, surgery and radiotherapy, followed by consolidation with high-dose chemotherapy and peripheral blood stem cell rescue. Current protocols involve four phases of therapy: *induction, local control, myeloablative consolidation* and *treatment of minimal residual disease*. *Induction therapy* consists of multiagent chemotherapy with alkylating agents, platinum, and anthracyclines and topoisomerase II inhibitors. *Local control* is by surgical resection of primary tumour and radiotherapy to the primary tumour site. Primary tumours often become resectable after induction chemotherapy. *Myeloablative consolidation therapy* has been shown to improve EFS in high-risk patients and is administered using etoposide, carboplatin and melphalan. Most centres now recommend the use of peripheral blood stem cell support over bone marrow during myeloablative consolidation therapy. *Treatment of minimal residual disease* with biological agents improves survival. To date, most experience has been with 13-*cis*-retinoic acid. But, increasingly, other biological agents are being added to 13-*cis*-retinoic acid, e.g. CCG-389, interleukin 2, granulocyte macrophage colony-stimulating factor and the chimeric anti-GD2 (gangliosidase) antibody.

Surgical treatment

Surgery has an important role but forms part of multidisciplinary treatment. Surgical resection is curative in patients with localized disease. For patients with regional or metastatic disease it is often used for second-look surgery after chemotherapy, when residual disease is resected or debulked as completely as possible without sacrificing major organ function.

Prognosis

Between 20% and 30% of high-risk cases do not respond adequately to induction high-dose chemotherapy. Most long-term survivors are patients with low- or intermediate-risk disease. Even so many survivors have long-term adverse effects from the treatment. Thus, survivors of intermediate- and high-risk disease often have hearing loss, growth reduction, thyroid function disorders and learning difficulties in addition to a greater risk of secondary cancers in high-risk disease patients.

Retroperitoneal sarcomas

Retroperitoneal sarcomas constitute only 10–20% of all sarcomas and have an overall incidence of 0.3–0.4% per 100 000 of the population with a peak incidence in the fifth decade of life. The most frequent cell types are liposarcoma, leiomyosarcoma and malignant fibrous histiocytoma (MFH). Recently, however, retroperitoneal MFH has been disputed as a separate entity by immunohistochemistry studies, which have indicated that most retroperitoneal MFHs are dedifferentiated liposarcomas. Despite advances in molecular oncology, the aetiology in most soft-tissue sarcomas remains elusive. At the time of presentation, these tumours are usually large owing to their slow, relatively asymptomatic, growth over a period of many months (Figure 21.17). Local recurrence is very common (33–86%) after surgical resection and local failure is usually the cause of death as distant metastases are rare (up to 30%) in reported series.

Pathology

Retroperitoneal liposarcomas constitute the commonest type of retroperitoneal sarcomas and carry a worse prognosis than liposarcomas of the trunk and extremities largely because of the late and advanced stage at presentation. Liposarcomas are mesenchymal neoplasms containing both atypical adipocytes and lipoblasts in an adipose tissue stroma. They exhibit variable biological aggression in terms of local invasion and metastatic risk depending on the degree of differentiation. Irrespective of site of origin, liposarcomas are classified into four main histological subtypes: (1) well differentiated, (2) myxoid, (3) round cell (low risk) and (4) dedifferentiated (high risk/grade). The dedifferentiated type carries a bad prognosis in terms of recurrence and survival. The mitotic index of retroperitoneal sarcomas reflects the grade as follows:

- sarcomas with no or one mitosis per 10 high-power fields (HPFs) (low risk)
- sarcomas with one to nine mitoses per 10 HPFs (intermediate risk/grade)
- sarcomas with more than nine mitoses per 10 HPFs (high risk/grade).

Some liposarcomas exhibit on histology peculiar meningothelial-like whorls and metaplastic bone in the whorls or immediate vicinity The meningothelial-like whorls represent a mesenchymal proliferation that may undergo myofibroblastic or osteoblastic differentiation in liposarcoma. The meningothelial whorls are thought to represent an early sign of dedifferentiation of liposarcomas. CT has been shown to reliably distinguish between well-differentiated and dedifferentiated retroperitoneal liposarcomas based on percentage fat content, focal nodular/water density, ground glass opacities and hypervascularity. Dedifferentiated tumours are more likely to be infiltrative and hypervascular with areas of necrosis. The CT-based radiological diagnosis of a well-differentiated lesion is 100% accurate, and avoids the need for preoperative biopsy in these patients.

Leiomyosarcomas are also more aggressive when found in the retroperitoneum. On histology, these tumours consists of cells with cigar-shaped nuclei, and stain positive for actin on immunohistochemistry. Leiomyosarcomas arise either from large vascular structures or from non-vascular tissues, with patients with primary vascular lesions exhibiting a worse prognosis in terms of overall median and metastasis-free survival (2.1 years and 0.25 years, respectively) than those with leiomyosarcomas of non-vascular origin (7 years and 9.6 years, respectively).

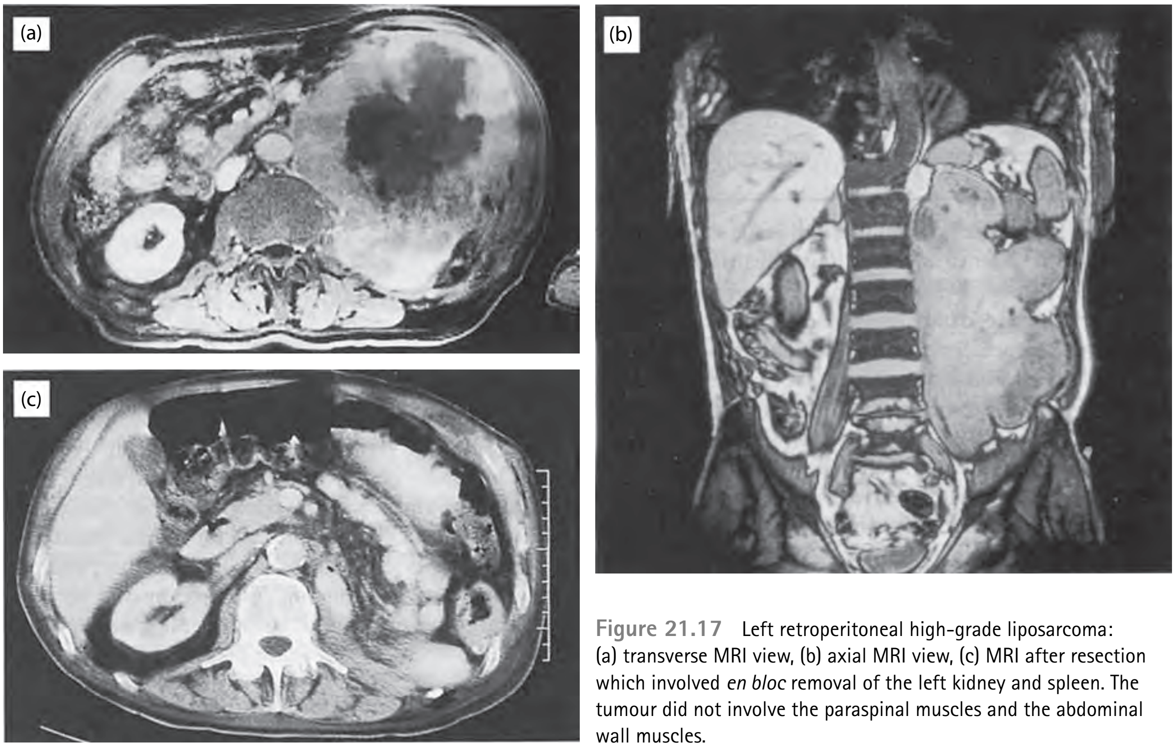


Figure 21.17 Left retroperitoneal high-grade liposarcoma: (a) transverse MRI view, (b) axial MRI view, (c) MRI after resection which involved *en bloc* removal of the left kidney and spleen. The tumour did not involve the paraspinal muscles and the abdominal wall muscles.

Clinical features

Patients with retroperitoneal sarcomas usually present late when the lesion has grown significantly in size, as in the early stages these tumours are totally asymptomatic. The symptoms are non-specific, and include abdominal pain and fullness from pressure symptoms. Other symptoms include back pain, abdominal fullness, anorexia, vomiting fatigue and weight loss. In most instances, however, presentation is with a palpable abdominal mass. If the mass is pelvic and the patient female, there is a real risk of misdiagnosis of gynaecological (usually) ovarian malignancy. This leads to laparotomy and inappropriate transperitoneal biopsy instead of referral to a soft-tissue sarcoma centre. In advanced cases, there may be evidence of caval compression with lower limb oedema, varicocele, ascites and dilated abdominal wall veins. Helical CT is most commonly used for establishing the diagnosis, with intravenous contrast MRI being reserved for the detection of vascular invasion and suspicious small lesions in the liver. Positron emission tomography/18-fludeoxyglucose, if available, is useful for tumour grading (low, intermediate, high) and for the detection of recurrence after excision.

A retroperitoneal core needle biopsy is performed under ultrasound guidance in tumours that appear dedifferentiated on CT. These tests have largely replaced other investigations, although an intravenous urogram is advisable as part of the work-up to exclude ureteric involvement and to assess the function of both kidneys (in case one needs to be removed with the tumour).

Treatment

There is no separate staging system for retroperitoneal sarcomas, although the American Joint Committee Staging System for extremity soft-tissue sarcomas is used in some centres, but its appropriateness for retroperitoneal sarcomas is doubtful. The treatment of retroperitoneal sarcomas, although essentially surgical, is complex and these patients are best managed in tertiary referral soft-tissue sarcoma centres by multidisciplinary teams that have the necessary surgical expertise in dealing with these rare tumours. Distant metastases and infiltration of non-resectable vascular or neural structures preclude resection.

Surgical treatment

The scope of surgical treatment is complete *en bloc* surgical excision with no residual tumour (R0 resection). Although there is agreement on this objective, surgical strategies vary. The orthodox radical *en bloc* resection including macroscopically involved adjacent organs is technically demanding and it often proves difficult even in experienced hands to obtain adequate tumour-free margins. Invasion of the retroperitoneal muscles can pose major problems even in experienced hands. Thus, complete radical resection is possible in only 30% of cases. The resectability rate in published series with the orthodox *en bloc* resection ranges from 38% to 100% but the radical (complete) resection rates are lower.

For these reasons, some centres in France advocate *compartmental resection* on the grounds that an R0 resection can only be achieved by this approach rather then resection *en bloc* with the tumour of macroscopically involved organs. These surgeons report improved survival with the more radical compartmental resection. However, the potential for postoperative morbidity is high and limits the applicability of this approach to all patients with retroperitoneal sarcomas. The problem with compartmental resection is that it entails resection of uninvolved organs to obtain negative margins.

In cases with vascular invasion or in situations when the tumour arises from a major vascular structure such as the inferior vena cava (IVC), combined resection with vascular reconstruction has been described and is safe when performed at a centre with expertise in these complex procedures. Management of the IVC after resection of a leiomyosarcoma is an area of debate regarding the need for reconstruction. Ligation of the IVC without reconstruction is generally well tolerated with a surprisingly low incidence of transient lower extremity oedema or other sequelae, although patients may develop postoperative acute renal failure. In its favour, ligation avoids the long-term complications of grafting, i.e. infection and pulmonary embolism.

Chemotherapy

The role of neoadjuvant chemotherapy is not well defined in view of the rarity of retroperitoneal sarcomas. Neoadjuvant chemotherapy may reduce the extent and complexity of the resection in tumours that respond to systemic therapy, and one retrospective series reported that this is achieved in 13% of patients with a resultant higher resection with negative margins, reduced local recurrence and higher overall survival than non-responders. In other major sarcoma centres preoperative chemotherapy is used selectively for large intermediate- to high-grade lesions with combination doxorubicin/ifosfamide. However, in the absence of data from prospective clinical trials, the reported retrospective case series do not support the universal use of neoadjuvant chemotherapy for all retroperitoneal sarcomas. Instead, neoadjuvant chemotherapy is restricted to biopsy-proven large, intermediate- to high-grade tumours.

Several prospective randomized trials on adjuvant chemotherapy have demonstrated decreased local recurrence rates in patients who received adjuvant regimens. A Cochrane review of 14 trials on adjuvant chemotherapy concluded that local recurrence and disease-free survival were positively affected by adjuvant therapy, but the effect on overall survival was uncertain owing to lack of data. Chemotherapy may also benefit patients with advanced disease in terms of metastasis-free and overall survival.

Radiotherapy

Although commonly used in both neoadjuvant and adjuvant settings, there is no level I evidence for the efficacy of radiotherapy in retroperitoneal sarcomas. However, in most sarcoma centres, preoperative radiotherapy is used in selected cases, usually for intermediate- to high-grade lesions, often as part of neoadjuvant chemoirradiation.

Radiotherapy (external and brachytherapy) is administered in some centres following resection and neoadjuvant radiotherapy.

Prognosis

Prognosis is influenced by four factors: (1) histological grade, (2) completeness of the surgical excision (R0, no residual disease), (3) mitotic activity and (4) multifocal disease. The reported 5 year survival rate after radical resection for cure varies from 62% to 92% in well-differentiated tumours, as distinct from 16–48% in undifferentiated sarcomas. The mitotic activity is a major criterion. The 5 year survival rate is inversely proportional to the mitotic activity of retroperitoneal sarcomas and is worst for sarcomas with more than nine mitoses per 10 HPFs (high risk). The third prognostic criterion is multifocal disease or sarcomatosis (seven or more lesions), which carries a bad prognosis (30% 5 year survival) compared with patients with unifocal disease (60% 5 year survival). The diagnosis of sarcomatosis is made when detailed examination reveals seven or more lesions.

Hernias

Internal hernias

Internal hernias are a rare but important cause of intestinal obstruction (0.2–0.9% of all cases) because they are often undiagnosed before emergency laparotomy; not uncommonly, they lead to infarction necessitating bowel resection (of varying extent), and this contributes to the high morbidity and mortality rates. Internal hernias are often classified as developmental (congenital) or acquired. In the congenital types, except in instances of gross mid-gut malrotation, the presentation occurs over a wide age range, but the majority of patients are in the fifth decade. By definition, developmental internal hernias cause obstructive symptoms in the absence of any previous surgical intervention.

Acquired internal hernias occur in patients who have undergone abdominal surgery, most commonly of the upper gastrointestinal tract, e.g. after gastric bypass surgery for morbid obesity or following Roux-en-Y diversion (especially if this is antecolic). They are well documented after right hemicolectomy (both open and laparoscopic), after laparoscopic extraperitoneal hernia repair (through unrecognized defects in the peritoneum), vascular operations, e.g. intraperitoneal femorofemoral bypass grafting, and after pelvic lymphadenectomy when loops of small intestinal become trapped beneath one or other iliac arteries. A particular group of acquired internal hernias occurs, albeit rarely, in relation to transplantation of the kidneys and liver. These are sometimes referred to as paratransplantation internal hernias and can have serious consequences. Following renal transplantation the internal hernia is caused by entrapment of bowel or omentum through a defect in the peritoneum covering the transplanted kidney. Internal herniation with volvulus of the small intestine is a potentially fatal complication after liver transplantation. The herniation occurs around the Roux-en-Y loop used for the biliary reconstruction. The mortality of this condition (from graft or bowel necrosis) is 50%. In view of the high mortality of peritonitis in transplant patients, early surgical treatment is indicated in all these patients who develop intestinal obstruction after surgery.

Pathological anatomy

This provides a more useful classification and better understanding of the underlying pathology. Thus, internal hernias fall into two groups: *true hernias* and *internal prolapses.*

True hernias

These have a hernial sac. The orifice involved may be:

- normal, e.g. Winslow's foramen
- paranormal, i.e. peritoneal fossae – paraduodenal, ileocaecal, inter- and mesosigmoidal, paracolic, supravesical.

Internal prolapse

These do not have a sac. The prolapse may occur through:

- an abnormal orifice in a mesentery or an omentum (transmesenteric, transmesocolonic, transomental)
- an anomalous orifice – congenital defects in a ligament (falciform, gastrosplenic, broad ligaments) or a mesentery (mesentery of Meckel's diverticulum)
- surgical defects or entrapment by surgically altered internal anatomy, e.g. anastomoses, stomas.

Paraduodenal hernias (right and left in close relation to the fourth part) constitute the commonest true internal hernias and account for 30–53% of cases. They are caused by incomplete rotation of the mid-gut such that the small intestine becomes entrapped behind the colon and mesocolon. The most valuable investigation for paraduodenal hernia is a small bowel enema, which usually shows clumping of the small intestine with incomplete rotation of the caecum and ascending colon. Other true internal hernias worthy of specific mention are hernia through the foramen of Winslow (epiploic foramen) and paracaecal hernia. Herniation through the epiploic foramen accounts for 8% of internal hernias. Most commonly the caecum and ascending colon are involved, and, in some cases, re-enter the main peritoneal cavity through an additional congenital defect of the lesser omentum. In patients with chronic symptoms, a barium enema may be diagnostic because it shows the caecum lying posterior and medial to the stomach. Paracaecal hernia presents with both subacute and acute low small bowel obstruction.

Internal hernia (prolapse) arises as a complication of gastrointestinal surgery in 0.3–1.0% of cases. The majority occur after upper gastrointestinal surgery (Billroth II gastrectomy with antecolic gastrojejunostomy and enteroanastomosis, Roux-en-Y reconstruction or diversion, etc.) and less commonly after colon surgery (right hemicolectomy, colostomy). Presentation with intestinal obstruction may occur early or several years after (up to 25) the intervention.

Malrotation of the mid-gut usually presents acutely in the neonatal period but affected individuals may not develop symptoms until much later (2–23 years). The most common symptoms include vomiting (68%), colicky abdominal pain (55%) and diarrhoea (9%). The diagnosis is made by barium meal and follow-through, or, preferably, a small bowel enema. A significant number of these late presenting patients (40%) are found to have either a volvulus or internal hernia at operation.

Clinical features

The reported incidence of all internal hernias varies between 0.2% and 0.9% of autopsies, 0.3–2.0% of parietal hernias and 0.01% of laparotomies. Overall the condition is more common in males (male to female ratio 3:2). The age distribution varies widely but peak symptomatic incidence is in the fifth decade (mean age of 45–50 years). Some (10–15%) are discovered as an incidental finding during laparotomy for another condition. Most commonly, these are paraduodenal hernias.

The symptoms of internal hernia irrespective of type are entirely non-specific and very few cases are diagnosed in the elective situation, with the vast majority (90%) presenting with acute intestinal obstruction, which is often strangulating with evidence of established peritonitis caused by infarcted bowel (30–60%). In a minority of patients recurrent attacks of colicky pain and abdominal distension are followed by imaging tests (contrast radiology, CT scanning, abdominal ultrasound), and these may provide a preoperative diagnosis. More rarely still, a mass is found on physical examination of the abdomen in a patient with subacute obstructive symptoms. Acute intestinal obstruction with strangulation occurring in a patient without an external hernia or previous abdominal surgical intervention should suggest the possibility of a congenital internal hernia, especially if the patient gives a history of chronic intermittent abdominal pain and a palpable abdominal mass is found on examination.

Treatment

The essence of good management is early intervention (laparotomy) as this is the only means of preventing necrosis of the bowel. The surgical treatment consists of reduction of the hernial contents, resection of the necrosed bowel, usually with primary anastomosis, and correction of the anatomical defect that caused the herniation in the first instance. The operative reduction of the hernia and the surgical repair must be conducted with extreme care to avoid injury to the major mesenteric vessels juxtaposed to or surrounding the hernial orifice. The hospital stay, morbidity and mortality (up to 30% in large series) depend on the presence/absence of bowel infarction. In the rare instances when an internal hernia is discovered after investigation of chronic symptoms, elective surgery is needed because of the pathogenic potential of this condition.

Diaphragmatic hernias

Strictly speaking diaphragmatic hernias should include hiatal hernias but, by convention, these are included with gastro-oesophageal reflux disease (see Chapter 22). Diaphragmatic hernias excluding this category fall into three groups:

1. congenital diaphragmatic hernia
2. traumatic diaphragmatic hernia – secondary to undiagnosed rupture of the diaphragm
3. herniations through congenital small defects – through the foramen of Morgagni (anterior) and foramen of Bochdalek (posterior).

Congenital diaphragmatic hernia

This is a serious congenital anomaly, which is always associated with pulmonary hypoplasia and other abnormalities (35%), particularly of the central nervous system and the skeleton. The condition is diagnosed in the majority (80%) by prenatal ultrasound, when the question of termination arises. With emergency neonatal surgery (reconstruction of the diaphragm with prosthetic mesh) and extracorporeal membrane oxygenation for cases with severe pulmonary impairment, the survival of infants born alive with congenital diaphragmatic hernia averages only 60% and more than half (60%) of these have persistent disorders that include respiratory problems, developmental delay, poor growth and gastro-oesophageal reflux. Despite advances in neonatology there is still a high mortality and morbidity associated with congenital diaphragmatic hernia.

Rupture of the diaphragm and traumatic diaphragmatic hernia

The primary event is rupture of the diaphragm owing to severe blunt trauma, most commonly from motor vehicle accidents. The rupture, which is twice as common on the left side and is rarely bilateral (5%), may be diagnosed immediately or missed when a traumatic hernia is diagnosed because of symptoms or complications. Rupture of the diaphragm is more common in males (male to female ratio 4:1) and occurs over a wide age range. Associated injuries are present in the majority of patients (90%) with rupture of the diaphragm. These include rib fractures, splenic, hepatic, pulmonary and bowel injuries. Helical CT with sagittal and coronal reformatted images is the best imaging test for the diagnosis of diaphragmatic rupture after blunt trauma. Findings consistent with diaphragmatic injury include waist-like constriction of abdominal viscera (collar sign), intrathoracic herniation of abdominal contents and diaphragmatic discontinuity. Helical CT reformatted images detect 78% of left-sided and 50% of right-sided diaphragmatic injuries.

The injury is always a major one with a reported mean injury severity score (ISS) of 30–35. The immediate mortality ranges from 15% to 20%. Predictors of death include old age, high ISS, severe hypovolaemic shock and bilateral injuries. Emergency repair of a ruptured diaphragm can be carried out through a laparotomy, thoracotomy or the thoracoabdominal approach, depending on the nature of the associated injuries.

Traumatic diaphragmatic hernia may be diagnosed months to several years (average 5 years) after the injury. The patient may have non-specific symptoms (vague chest pain, shortness of breath, palpitations) or presents acutely with clinical signs of intestinal obstruction/strangulation of a hollow organ. In line with its aetiology traumatic diaphragmatic hernia is more common on the left. The chest radiograph is often suggestive and diagnosis is usually confirmed by barium studies of the gastrointestinal tract. The most common herniated abdominal organs in traumatic diaphragmatic hernias are the stomach and colon. The repair involves closure of the defect by a prosthetic mesh and this can be performed through a thoracotomy or laparotomy or laparoscopically.

Iatrogenic diaphragmatic hernia

This is due to damage to the diaphragm during surgery, particularly laparoscopic antireflux surgery. The injury is often caused by high-frequency electrosurgery and the resulting defect, which is small, leads to herniation, usually of the stomach over the succeeding months. The most common complaint is pain in the left upper quadrant and left shoulder. The condition is diagnosed by a barium meal and is often missed by flexible endoscopy.

Morgagni and Bochdalek hernias

Hernias through the foramina of Morgagni (right and left) are rare congenital hernias that may present in infancy, childhood and adult life. They are situated anteriorly in the immediate retrosternal position. In children Morgagni hernias are usually asymptomatic but they may be associated with mild respiratory distress or cause gastrointestinal symptoms and rarely incarceration of bowel, which may be of the partial Richter type. In adults, they may present with vague symptoms or intestinal obstruction or gastric volvulus. The foramina of Bochdalek are congenital posterior diaphragmatic defects resulting from persistence of the pleuroperitoneal canal on one or both sides. Bochdalek hernias are rare and present in adult and elderly patients with digestive symptoms and less frequently with obstruction. Both hernias do not have a sac and are thus instances of internal prolapses.

Incisional hernias

Incisional hernias after abdominal surgery are common but with a varied reported incidence depending on case mix (2–20%). Strictly speaking, the term ventral hernia should be restricted to incisional hernia arising in abdominal midline operative wounds, but often the two names are used synonymously. There are several factors that contribute to the aetiology of incisional hernias, the most important being adequacy of abdominal wound closure in the first instance and the occurrence of wound infection and subclinical wound dehiscence in the postoperative period. There is no evidence that abdominal wound closure with synthetic monofilament biodegradable sutures carries a higher incidence of incisional hernia than closure with non-absorbable sutures. There are however a number of recognized risk factors, which include:

- wound infection: most important aetiological factor
- postoperative abdominal distension: pressure on wound
- obesity, especially morbid obesity: very strong risk factor
- chronic obstructive airways disease
- emergency surgery: independent risk factor
- reoperation for a postoperative complication: independent risk factor
- type of incision: more frequent after vertical than transverse/oblique incisions
- steroid dependence: less important than morbid obesity
- underlying disease: diabetes
- creation of a stoma (colostomy, ileostomy, urinary conduit): parastomal hernias
- age >70 years
- no prophylactic antibiotic cover during primary operation: increased incidence.

Wound infection is the most significant independent factor for incisional ventral hernia. In patients who develop postoperative wound infection, the reported risk of incisional hernia averages 25%. Many reports indicate that transverse/oblique incisions are accompanied by a lower rate of incisional hernias than vertical midline incisions. There is some evidence that, apart from technical faults and risk factors, incisional hernia may arise in patients with an underlying collagen metabolic disorder, known to play an important role in the development of inguinal hernia. Studies have shown a decreased ratio of collagen I/III owing to a concomitant increase in collagen III in patients with incisional and recurrent incisional hernias. This appears to reduce the mechanical strength of connective tissues and may explain the high incidence of recurrence in patients undergoing fascial repair procedures.

Clinical features

Aside from the obvious disfigurement, they cause pain and discomfort and may strangulate, although the risk of this complication is low. The diagnosis is obvious and is made on clinical examination, when tensing of the muscles of the anterior abdominal wall (elevation of head from pillow or lower limbs from bed) accentuates the bulge. The vast majority of incisional hernias are reducible when the patient lies down in the supine position.

Treatment

This has to be individualized. Thus, if the patient has minimal symptoms and especially if elderly or suffers from significant comorbid disease, conservative management with an abdominal support is advisable. Many patients, however, have symptoms and dislike the bulge, and for this reason insist on repair. There are many techniques of surgical repair of incisional hernias:

- primary repair
- primary repair with relaxing incisions
- primary repair with onlay mesh reinforcement
- onlay mesh only
- inlay mesh placement
- retrorectus mesh placement
- intraperitoneal mesh placement.

There is now sufficient reported evidence that primary fascial repair techniques have an unacceptably high incidence of recurrence (up to 50%) and these operations have largely been abandoned in most centres. By contrast, tension-free repair by a synthetic mesh is accompanied by a much lower recurrence rate (2–10%) and is the technique that is in general use.

Mesh materials

Absorbable meshes are only used in cases when mesh infection is a significant risk and primary closure is not possible. Polyester mesh appears in some studies to be associated with higher rates of mesh infection and enterocutaneous fistula formation. However, fluorinated polyester mesh that can be gel impregnated for antibiotic bonding immediately before use has been shown experimentally to induce minimal adherence to bowel and this material exhibits minimal contraction and hardening with time.

Polypropylene has greatest tissue ingrowth of all non-absorbable mesh materials. Polytetrafluoroethylene (PTFE) (Gore-Tex) has the lowest bowel adherence rate and related complications. The Gore Dualmesh Plus, which incorporates antimicrobial agents (silver and chlorhexidine), carries the lowest mesh infection rates in most reported studies but is expensive. One experimental study involving infection of graft materials with *S. aureus* and meticillin-resistant *S. aureus* (MRSA) organisms showed that Gore Dualmesh Plus biomaterial was the only mesh material used in the study able to kill both *S. aureus* and MRSA.

The most commonly used are polypropylene meshes, which may be monofilament (Marlex), double filament (Prolene) or multifilament (Surgipro, Atrium, etc.). The absorbable meshes available are polyglactin 910 (Vicryl) and polyglycolic acid (Dexon). Whatever material is used, it is important that the mesh overlaps the size of the defect by a significant margin, and it should lie loosely rather than be stretched over the defect. Tension-free mesh repair can be undertaken laparoscopically with good results.

The types of repair techniques for incisional ventral hernia are:

- *Primary repair*: this consists in freshening and approximating the two edges of the defect. It is no longer practised in view of high recurrence (>50%) owing to tension on the repair. Some procedures (Keel repair) use relaxing incisions to reduce tension but still incur an appreciable recurrence.
- *Primary closure with mesh reinforcement*: an onlay is sutured over the primary repair to the anterior rectus sheath as reinforcement. However, the hernia repair suture line remains under tension. In addition, the mesh increases the infection risk without any material benefit in terms of recurrence.
- *Inlay mesh repair*: after excision of the hernial sac, the fascial margins of the defect are sutured to a mesh [polypropylene or expanded PTFE (ePTFE)]. Polypropylene is used when omentum can be placed between intestine and mesh; otherwise, ePTFE is preferred. This method is difficult to perform laparoscopically and is usually carried out by the open approach.
- *Retrorectus mesh repair (Rives–Stoppa technique)*: in this technique the hernia sac is used to separate the mesh from the intra-abdominal contents. Above the umbilicus, the dissection to create the necessary space for the mesh is performed above the posterior rectus fascia and under the rectus muscles; below the umbilicus, dissection is in the preperitoneal space. A suitably sized mesh is placed in the dissected place and fixed to the muscle layer superficial to the mesh. This repair is safe and effective with a reported low recurrence and morbidity rates.
- *Intraperitoneal underlay mesh repair*: this technique can be performed by either the open or laparoscopic approach, which is increasingly favoured nowadays.

Complications of tension-free mesh repairs

The risks of tension-free repair of incisional hernias include:

- wound infection
- infection of the mesh
- seroma formation
- wound sinus
- enterocutaneous fistula formation
- recurrence.

Although wound infection is common (4–17%), actual incidence rates of mesh infection are not known but most such instances resolve with antibiotic treatment, although persistent serious infections necessitating removal of the mesh are well documented. This is a major problem. The management is staged with temporary skin cover until infection is eradicated, followed by abdominal wall reconstruction by muscle transfer flaps. Seroma formation is also common but its incidence varies (0–22%) with the size of the defect and hence the mesh. Most surgeons insert tunnelled Redivac suction drains to the site to prevent this complication. There is no evidence that these tunnelled small-calibre suction drains increase the incidence of postoperative wound/mesh infection. However, the efficacy of these suction drains in reducing the incidence of seroma formation remains unproven. Wound sinus is reported in 4–18% of cases. It usually heals with conservative management or minor intervention to remove the offending suture. Enterocutaneous fistula has been reported but appears to be a rare complication. Its exact aetiology is not known but adherence of the bowel to the mesh appears to initiate the process. In a large retrospective report on 136 cases, the patient-related factors considered important on statistical evaluation in relation to recurrence following tension-free mesh repair with polypropylene were:

- age >70 years
- hernia >6 cm
- no prophylactic antibiotic cover
- recurrent hernia
- wound infection.

It is important to stress that the recurrent hernia is usually larger than the initial one and hernial defects >10 cm may require autogenous reconstruction of the abdominal wall by muscle flaps.

Massive midline wall defects

These include large central incisional hernias (usually recurrent) and pose major problems in management. In one reported series of 22 patients, the defects varied in size from 14 to 24 cm and the causes included:

- removal of infected synthetic mesh material (32%)
- recurrent incisional hernia (18%)
- removal of split-thickness skin graft and dense abdominal wall cicatrix (18%)
- parastomal hernia (9%)
- primary incisional hernia (9%)
- trauma/enteric/abdominal wall sepsis (9%)
- abdominal wall tumour resection (4.5%).

In view of the size of the defect, conservative management with an abdominal support is unsatisfactory, and, if the patient is fit, surgical treatment is indicated. Reconstruction of these large central abdominal wall defects is a major surgical undertaking that requires specialist plastic surgical expertise. Modern surgical treatment is based on autogenous tissue reconstruction introduced by Ramirez *et al.* The technique utilizes bilateral, innervated, bipedicle, rectus abdominis–transversus abdominis–internal oblique muscle flaps that are transposed medially to reconstruct the central defect.

The results of the Ramirez autogenous tissue reconstruction are good, with satisfactory healing and no recurrence in 90%. The morbidity considering the magnitude of the operation is reported to be minimal and confined to superficial infection and wound seroma formation. The postoperative mortality averages 4–5%. Although the Ramirez operation is usually used to treat complicated (trauma, surgical excision) or recurrent central abdominal wall defects, it is also used as a primary repair of large central incisional hernias.

Port site wound (incisional) hernias after laparoscopic surgery

The overall reported incidence of incisional hernias through port site wounds is 2–3%. The risk factors include:

- size of port >10 mm
- obesity
- inadequate fascial closure.

The vast majority occur in port wounds >10 mm but instances of herniation have been reported in smaller port wounds (5 mm), especially in the lower abdomen. It has to be remembered that, below the arcuate line, there is no posterior rectus sheath and thus the abdominal wall is intrinsically weaker. The commonest reported site is the umbilical region, probably because this is usually a large port (used to insert the laparoscope and extract specimens). Patients can present with localized pain and a subcutaneous lump, which is tender and has a cough impulse; or acutely with acute intestinal obstruction. This usually involves the small bowel and is of the Richter type. In obese patients, the small hernia can be easily overlooked as a cause of the small bowel obstruction (see below).

Parastomal hernias

A parastomal hernia is an incisional hernia that occurs at the site of a surgically constructed intestinal stoma on the abdominal wall. The basic underlying cause for the development of a parastomal hernia is progressive enlargement of the trephine opening in the abdominal wall, owing to tangential abdominal forces working on the circumference of the opening through which the bowel emerges. This physical consideration accounts for the unsatisfactory results of surgical repair irrespective of its nature.

Parastomal hernias are common and their management is both difficult and controversial. They continue to pose management problems. In one large series of 316 patients with 322 stomas, an overall incidence of 67% stoma-related complications was reported. This included a 31% parastomal herniation rate, stenosis of the stoma in 10% and prolapse in 7% at 10 years after surgery. Parastomal hernias include:

- paracolostomy hernia
- ileostomy hernia
- urinary conduit hernia.

After sigmoid colostomies the crude and actuarial risk of complications are 50% and 58%, respectively, at 13 years with paracolostomy hernia being the highest at 35–40% at 10 years. Paracolostomy hernias are more likely in the elderly and in patients with other abdominal wall hernias. From the published data, the extraperitoneal technique appears to reduce the incidence of paracolostomy hernia. Other technical factors, e.g. mesenteric fixation and siting the stoma through the belly of the rectus abdominis, do not appear to influence the rate of this complication, although there are strong proponents for both measures.

In general, complications are detected much later in patients with a urological stoma than in those with a colostomy. The high incidence of stomal complications requires long-term follow-up of these patients.

Paracolostomy hernia most commonly presents with a bulge, ill-fitting bag and leakage problems, but they may present acutely with intestinal obstruction (usually small bowel), and indeed strangulation. Instances of incarcerated stomach in the hernial sac have been reported. The presumed reduction in the risk of intestinal obstruction with closure of the lateral space has not been confirmed by long-term studies. However, there is a slight reduction in the risk of intestinal obstruction with the extraperitoneal technique.

The stomal complications of ileostomy may occur many years after construction and at 20 years the incidence of stomal complications exceeds 70% in patients operated on for ulcerative colitis, but is lower – though still high (50–60%) – in patients following colectomy for Crohn' disease. The complications in order of frequency are:

- skin problems (34%)
- intestinal problems (23%)
- retraction (17%)
- parastomal herniation (16%)
- prolapse.

Thus, stomal herniation is distinctly less common after terminal ileostomy than after terminal colostomy. Again closure of the lateral space does not diminish the risk of intestinal obstruction and fixation of the mesentery does not reduce the probability of prolapse of the ileostomy. The incidence of parastomal herniation is unaffected by siting the ileostomy through the rectus abdominis as distinct from the oblique muscles.

The incidence of parastomal hernia in patients with ileal conduit diversion is lower than ileostomy after proctocolectomy (4–5%). The most common presentation is with a poorly fitting appliance causing leakage of urine. However, acute presentation with obstruction, anuria and parastomal ileal conduit fistula are well documented.

Treatment of parastomal hernias

The surgical treatment of parastomal hernias presents a continuing challenge and there is no universally effective operation. There are four techniques used in the surgical treatment of parastomal hernias:

1. relocation of the ostomy with repair of the defect (fascial or with mesh)

2 mesh repair of the defect around the ostomy exit site; in this method, the hernia sac (laparocoele) is replaced without being opened and the mesh positioned in the preperitoneal space
3 reduction and mesh repair with two strips of polypropylene mesh through a midline incision
4 special prosthesis consisting of a polypropylene ring mounted in the centre of a polypropylene mesh.

Irrespective of technique, parastomal hernia repair is often unsuccessful (average recurrence rate of 30% at 5 years) and rarely without complication. The general consensus for first-time repair is to relocate the stoma and repair the defect with a tension-free mesh. This, of course, may transfer the problem to the other side. For recurrent parastomal hernias, local repair with prosthetic material (without relocation) is advocated, as it appears to be the best of a bunch of poor alternatives. In either case, fascial repair alone should not be performed owing to an unacceptably high recurrence rate.

There have been other techniques reported but the data on their efficacy are limited. As the basic problem is progressive enlargement with time of the hole by the tangential abdominal forces, a ringed prosthesis technique has been reported, which appears to give good results in the short term. The prosthesis consists of a polypropylene ring of varying internal diameter (20, 25 or 30 mm), mounted in the centre of a polypropylene mesh. Following mobilization the exteriorized bowel is inserted through the ring and the mesh sutured to the parieties. In a series of 14 patients treated with this technique there was only one recurrence during a follow-up period of 5–35 months. Another procedure uses the midline laparotomy approach and, after reduction, two strips of polypropylene are sutured on either side of the bowel to prevent enlargement of the orifice.

Non-incisional abdominal wall hernias

These hernias occupy a good deal of surgical time and account for 10–15% of all surgical operations. The majority of operations (80%) are performed for inguinal hernias, although this figure is even higher in the male population. The remainder are in the region of the umbilicus (8%), incisional (7%) and femoral hernias (5%). Rarer forms of hernias, although very interesting, form only a tiny proportion of the surgical problem.

Diagnosis of abdominal wall hernias

In the vast majority of patients, the diagnosis is made on history and physical examination (location of the bulge and cough impulse) and no other confirmatory tests are needed. However, diagnostic problems may be encountered especially in obese patients and those presenting with acute intestinal obstruction. Water-soluble contrast herniography is an accurate means of identifying inguinal and femoral hernias in cases presenting diagnostic problems. For other hernias, ultrasound and cross-sectional imaging CT or MRI is preferred. These are especially useful in the detection of the rare, e.g. Spigelian or obturator (pelvic floor), hernias.

Epigastric, umbilical and paraumbilical hernias

These hernias are grouped together because herniation occurs through a defect in the linea alba between the xiphisternum and the umbilicus. The paraumbilical hernia is an epigastric hernia situated just above the umbilicus.

Epigastric hernia

This hernia is usually encountered in males above the age of 40 years. About one-quarter of cases are multiple. The defect in the linea alba allows a small pad of extraperitoneal fat to protrude, and, as a result of the increased intra-abdominal pressure, the defect enlarges and then permits a sac of peritoneum, and eventually the sac may admit omentum or even small bowel. Most epigastric hernias are symptomless and are diagnosed incidentally by the patient or doctor. A small nodule, which is more prominent on standing, is palpable in the midline but it is rare for a cough impulse to be elicited. A small number of patients present with vague upper abdominal symptoms that do not fit a dyspeptic pattern and in whom repair of the hernia gives relief. It may be that in these patients a degree of tension on the peritoneal sac has produced the symptoms.

Small epigastric hernias do not require treatment. Those >2.0 cm have the potential of strangulation because of the narrow neck through the linea alba and are best treated surgically. The procedure consists of excision of the sac and repair of the defect by either a simple longitudinal fascial repair or a transverse overlapping of the Mayo type. The results except in the very obese are generally very good.

Adult paraumbilical hernia

These hernias are more common in females (female to male ratio 3:1) and are largely confined to obese patients. The defect lies just above the umbilicus, although deformity of the umbilical button is the earliest manifestation. In adults these are common with an overwhelming female preponderance. In one study of 2100 patients undergoing laparoscopy, paraumbilical fascial defects were found in 18% of patients and only 56% of these had symptomatic or overt umbilical hernias. The hernia may enlarge to the size of an orange but the neck of the sac remains dangerously small so that the risk of strangulation is ever present. The chronicity of the condition leads to firm adhesions forming between the peritoneal sac and its contents so that almost all large hernias are irreducible and should never be treated by the use of an abdominal support or truss. Surgical treatment is best carried out effectively in all patients. The majority of patients, however, present acutely with obstruction/strangulation. The procedure of choice for repair of paraumbilical hernia is that described by W.J. Mayo in 1893. After excision of the sac, the defect is closed by suture, the upper crescent being fixed over the front of the lower half of the defect. The Mayo operation has reported recurrence rates of 2–3%. For large hernias in the elective situation, some now use a prosthetic mesh repair.

Infantile umbilical hernia

The worst defect is exomphalos, which fortunately is a rare condition, occurring in about one in 5000 births and is nowadays diagnosed prenatally. It is frequently associated with other congenital defects and not surprisingly about one-quarter of the babies have malrotation of the intestine.

Simple umbilical hernia is common in infants and young children with the highest reported incidence in African Caribbean babies. In the vast majority of infantile umbilical hernias spontaneous closure occurs (reduction in size by approximately 18% each month) before the age of 4 years and thus management is conservative, especially as complications during this age period are rare. However, large infantile umbilical hernias (neck of the sac >2 cm) are unlikely to close spontaneously and surgical repair is therefore advisable. Irrespective of size, an umbilical hernia that persists beyond 4 years requires surgical repair, as closure then becomes unlikely. It is generally considered important to preserve the umbilical cicatrix after excising the sac and repairing the defect so that the child will not appear different from its fellows.

The most common complication in these children is incarceration with the development of small bowel obstruction. The reported risk of this complication is approximately one in 1500 umbilical hernias. Another very rare complication reported in Nigerian children is spontaneous rupture. This usually occurs in the first year of life and is probably precipitated by raised intra-abdominal pressure from excessive crying. The condition results in partial evisceration and needs urgent intervention.

Adult umbilical hernia

The umbilical hernia that develops in patients with refractory ascites due to chronic liver disease is often overlooked but can assume clinical significance. In the first instance incarceration is well documented as a complication of effective relief of the ascites following diuresis, paracentesis, peritoneovenous shunting and transjugular intrahepatic portosystemic shunt. Second, these patients have marked atrophy of the abdominal muscles and some have, in addition, large high-pressure veins following recanalization of the umbilical vein (caput medusae). Thus repair can be difficult and should always be conducted using prosthetic mesh, preferably of the double-stranded, closely knitted variety. In addition, subcutaneous suction drains should be avoided because of the increased risk of infection of the ascitic fluid. The use of prophylactic antibiotics against Gram-negative bacteria is mandatory.

Groin hernias

Because of the erect posture, the inguinofemoral area is subjected to maximum strain from the intra-abdominal pressure, especially during exertion. This together with the intrinsic weakness that is caused by the inguinal canal in males accounts for the predominance of these hernias in males. The hernia starts as a small pressure-induced diverticulum (hernial sac) that emerges through the deep inguinal and less commonly the femoral ring to enter the respective canal and exits as a lump in the groin that has a cough impulse. The term groin hernia covers inguinal and femoral hernias, which are discussed separately.

Complications of groin hernia

The complications of groin hernias are:

- irreducibility
- obstruction
- strangulation.

The majority of patients who are admitted as emergencies with complicated groin hernias have not previously sought medical attention or been diagnosed with the condition in the outpatient department. This observation implies that most hernias that develop complications do so within a relatively short time in the natural history of the disease. Mortality of obstructed hernias is high in patients with coexisting cardiorespiratory disease, whereas the morbidity rate is influenced by the viability of contents of the hernial sac. In turn, this is directly related to the duration of irreducibility/incarceration or delay in presentation.

The risk factors for complications of groin hernias are:

- Adults:
  - old age
  - duration of hernia: short duration <1 year
  - type of hernia: femoral more than inguinal
  - coexisting medical illness: especially chronic obstructive airways disease.
- Children:
  - very young (infants)
  - gender (male)
  - short duration of hernia
  - side (right).

Inguinal hernia

By far and away, inguinal hernia is the most common external abdominal hernia, accounting for over 90%. Normally, two mechanisms act to prevent herniation through the inguinal canal. With increased intra-abdominal pressure, contraction of the internal oblique and transversus muscles acts upon the section of the transversus aponeurosis that arches convexly upwards over the medial half of the canal. The arch is pulled down and flattened and thus reinforces the posterior inguinal wall. The second mechanism, which may in fact be more important, depends upon the attachment of the strong fascial layer forming the deep inguinal ring. This fascial ring is normally firmly adherent to the posterior surface of the transversus muscle so that contraction of this muscle pulls the ring upwards and laterally.

In essence, an inguinal hernia is the consequence of weakness of the posterior abdominal wall. In the past, stretching of the transversalis fascia was considered to be the most important factor and some fascial repair procedures (Shouldice operation) were based on suture plication of this layer. Some, however, consider the transversalis (endoabdominal) fascia to be the thinnest and least important layer in the prevention of inguinal hernia formation and consider that the strength of the posterior wall of the inguinal canal is due to the muscle fibres and aponeuroses of the internal oblique and transversus abdominis. There is evidence for an increased risk of right inguinal hernia after appendicectomy. This is related to the denervation of the right transversus abdominis muscle fibres. These fibres are responsible for the support of the deep inguinal ring of fascia. Weak fascial support due to an abnormal accumulation of type III collagen has been demonstrated in some patients with direct but not indirect inguinal hernia.

Inguinal hernia exhibits a marked male predominance (male to female ratio 20:1) and from the anatomical standpoint is of two types – indirect (or lateral) and direct (or medial). The sac of an indirect hernia arises from the processus vaginalis. The hernia travels down the inguinal canal from the internal ring and exits as a subcutaneous lump, exhibiting a cough impulse at the external inguinal ring above and medial to the pubic tubercle. The herniation lies inside the spermatic cord (covered by all three spermatic fascial layers). In view of its indirect course, it does not often reduce itself spontaneously when the patient lies down and is more prone to irreducibility than the direct inguinal variety. Indirect inguinal hernia enters the scrotum as it enlarges, whence it qualifies as inguinoscrotal hernia (Figure 21.18). The same pathology occurs in the female.

Persistence of the processus vaginalis forms a peritoneal diverticulum (canal of Nuck). This enters the inguinal canal to form the hernia, which, after exiting from the superficial inguinal ring, enters the labium majus as it enlarges. The direct hernia results from a weakness of the posterior wall of the inguinal canal medial to the internal ring and hence the inferior epigastric vessels; the sac is thus in close proximity to the external ring. Occasionally, the medial wall of the sac of a direct inguinal hernia is composed of the bladder wall. As the hernia enlarges it exits through the superficial inguinal ring behind or above the spermatic cord. Because of the direct path and wide neck, the vast majority of direct hernias are spontaneously reducible when the patient lies down and rarely strangulate. Moreover, even when large, direct hernias do not enter the scrotum; they tend to enlarge in the groin beneath Scarpa's fascia, which obstructs their entry into the scrotum. Patients with major weakness of the posterior inguinal wall may develop combined direct and indirect hernias with the two hernial sacs straddling the inferior epigastric vessels – this is sometimes referred to as a pantaloon hernia.

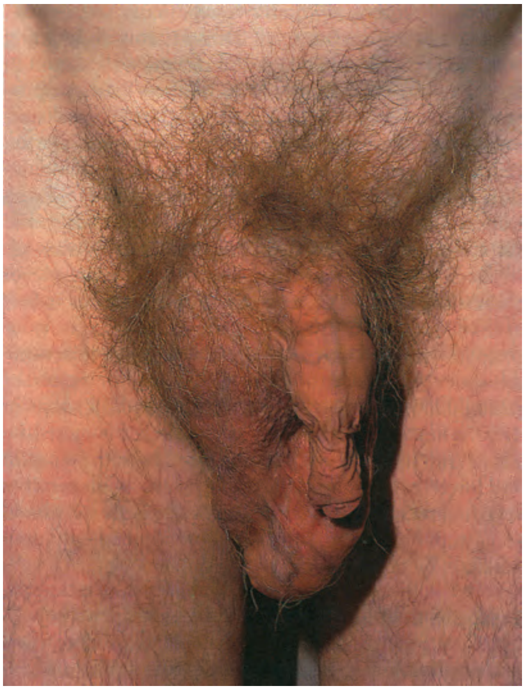

Figure 21.18 Inguinoscrotal hernia.

Clinical features

The complaint common to nearly all patients is the appearance of a lump in the groin. Some patients complain of a dragging sensation or pain in the groin, particularly during the early stages, but many hernias are asymptomatic. There may be a history of a major physical strain or of heavy physical work prior to the development of the hernia. Presumably, increased abdominal pressure can stretch the fascial margins of the deep inguinal ring and open up a preformed peritoneal sac.

The hernia may be best shown with the patient standing or precipitated by coughing and straining. The bulge should be above and medial to the pubic tubercle. In patients with large inguinoscrotal hernias the diagnosis is obvious though a cough impulse may be difficult to elicit. The differential diagnosis of inguinal hernia includes femoral hernia, inguinal lymphadenopathy, ectopic testis, hydrocele of the cord, saphena varix and lipoma of the cord. Endometriosis in a hernial sac may be mistaken for an incarcerated hernia, as may malignant tumours in the groin. Patients with chronic groin pain constitute a difficult diagnostic problem. Most cases of chronic pain in athletes are due to soft-tissue injuries, but, in a small number, an undeclared hernia is the cause.

In the vast majority of cases, the diagnosis of an inguinal hernia is made clinically and a good physical examination can distinguish between the two types of hernia. The old practice of inserting a finger into the inguinal canal to detect the exact position of the cough impulse (tip of the finger in indirect and volar aspect of the finger in direct hernia) is no longer practised because it causes considerable patient discomfort. The best technique is to reduce the hernia with the patient in the supine position, and then apply pressure over the internal ring. This should control the hernia only if it is of the indirect variety. When difficulty arises in establishing the diagnosis because the hernia is small, especially if the patient is obese, water-soluble contrast herniography (50–80 mL injected intraperitoneally) may be used.

Sliding inguinal hernia

Essentially, in a sliding inguinal hernia, part of the sac wall is formed by prolapsed viscus and, for this reason, these hernias are always large (Figure 21.19). The condition can be suspected but not confirmed preoperatively on clinical examination. Usually the diagnosis is established during surgery, although ultrasound and cross-sectional imaging may identify sliding components preoperatively. The most common organ associated with a sliding inguinal hernia is the sigmoid colon, but other organs can be involved. These include the vermiform appendix, urinary bladder, etc. In neonates, large sliding hernias containing Fallopian tubes, ovaries and uterus are well documented and such instances have been reported in middle-aged women.

The more usual sliding hernia involving the colon forms a large inguinal mass and is often irreducible by the time of diagnosis. Sliding inguinal hernia may present acutely with strangulation involving omentum, small bowel, bladder or colon itself.

Inguinal hernias in children

In this age group, 90% of inguinal hernias occur in males, and these often present at about 1 year when the child starts to walk with the vast majority being of the indirect type (patent

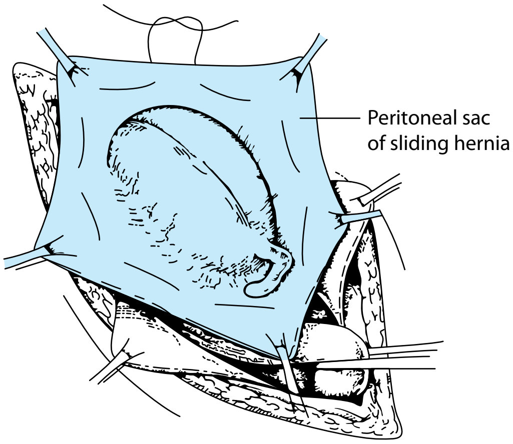

Figure 21.19 A sliding hernia develops when the contents, usually sigmoid colon, descend into the inguinal region. The colon does not lie within the sac but the sac is applied to its surface. The bowel is liable to damage if the sac is fully dissected from the surface and is best managed by a plicating suture after which the bowel can be returned to the abdominal cavity. [Derived from Nyhus LM, London RE (eds). *Hernia*, 2nd edn. Philadelphia, PA: Lippincott, 1978.]

processus vaginalis). Between 10% and 20% of children will develop a hernia on the other side; in about 50%, this peritoneal sac will be present at the time of operation on the presenting side. Attempts to detect these occult hernias have included contrast herniography and laparoscopy. There is no indication for routine exploration of the contralateral side. Direct inguinal hernia is extremely rare in children.

The history of a lump appearing in the groin is usually obtained from the mother, who notices the hernia after a period of straining or coughing by the child. Quite frequently the hernia cannot be demonstrated by the medical examiner and all that can be felt is a silky sensation on palpation of the spermatic cord as the layers of the processus vaginalis move under the examining fingers. Unfortunately, as many of the signs are ignored, there is a tendency for the hernia to become obstructed and strangulated by the time of presentation. This being the case, all children with a strong history should have elective exploration of the affected side. The operation consists of transection and high ligation of the processus vaginalis (herniotomy). Repair of the inguinal canal is not necessary. Differential diagnosis at this age includes undescended testis, hydrocele of the cord and torsion of the testis.

Repair of inguinal hernias

In general, if the patient is fit, an inguinal hernia should be repaired surgically. There are however situations when non-operative management is sensible. This conservative management should only be considered if the hernia is easily reducible and the patient has significant comorbid disease. Small indirect inguinal hernias are controlled by a spring truss, but large indirect and direct hernias require a large pad and firm belt. In all other patients surgical repair should be recommended.

The various repair procedures fall into two categories: fascial repairs (Bassini, Bassini with Tanner's slide, McVay, Ferguson, Shouldice) and tension-free prosthetic mesh repairs, and these may be performed by the anterior open approach or laparoscopically/endoscopically (Box 21.1).

BOX 21.1 Inguinal hernia repair procedures

- Fascial repairs
  - Bassini
  - Bassini with Tanner's slide
  - Shouldice
  - Ferguson
  - McVay
- Tension-free prosthetic mesh repairs
  - Rives–Stoppa
  - Lichtenstein
  - Laparoscopic TEP (Total Extra Peritoneal)
  - Laparoscopic TAPP (Trans-Abdominal PrePeritoneal)

The fascial repairs are the oldest. Their only advantage is the avoidance of prosthetic material, which may become infected, but they carry the highest incidence of recurrence, particularly the Bassini operation since the repair cannot be effected without tension. In practice, infection of the prosthetic mesh, requiring removal, has proved to be a rare occurrence, and this category of hernia repair operation is much more favoured nowadays in view of the uniformly reported good results and low recurrence rates. Open tension-free mesh repairs can be carried out under local anaesthesia as day cases and this reduces the costs considerably.

The laparoscopic approach has a number of advantages that include less postoperative pain, earlier return to full activity and work, and reduced incidence of persistent groin pain at 1 year. The initial higher morbidity (including major vascular, bowel, bladder and nerve injuries) and high recurrence rates reflected inexperience with the technique as surgeons were not familiar with the anatomy of the posterior abdominal wall as visualized from the peritoneal side. The morbidity and recurrence rates of the laparoscopic versus open tension-free repairs are now equivalent. The residual disadvantages are increased hospital (but not total) costs and the need for general or epidural anaesthesia. There is now good evidence that the laparoscopic TEP operation gives the best results in patients with large bilateral and recurrent hernias. The recurrence rate after primary laparoscopic TEP repairs at 3 years is under 1%.

Uniformly excellent results have been reported consistently with the open Lichtenstein repair using polypropylene (Marlex) mesh under local anaesthesia. At 5 years, this procedure in hernia centres has a recurrence rate of 0.1%. Most of the recurrences occur at the pubic tubercle, usually because the mesh used was too small. The tension-free mesh plug repair was introduced in the late 1980s. A preformed mesh plug is used to fill and expand extraperitoneally occluding the defect. In large hernias, the plug is overlaid with an appropriately sized sheet of mesh. The technique is simple and entails minimal dissection, especially in direct hernias. The reported recurrence rates vary from 1% to 3%. In a prospective randomized study comparing open mesh plug repair with laparoscopic TEP, the overall recurrence rate was similar (2.5% for the TEP versus 3% for the mesh–plug hernioplasty). However, patients undergoing the laparoscopic repair required less narcotic analgesic medication and returned to full activity 1 week sooner than the open surgery group. There were no major postoperative complications in either arm in this study but minor morbidity was lower (13%) after laparoscopic TEP than after open mesh plug (23%).

The complications of inguinal hernia repair are:

- urinary retention, especially in males
- wound infection and haematomas
- scrotal swelling
- orchitis and testicular atrophy
- recurrence
- iatrogenic bladder, bowel, nerve and vascular injuries
- chronic groin pain.

Recurrent inguinal hernias

The recurrence rates vary widely, but irrespective of approach, the lowest recurrence rates are encountered after tension-free prosthetic mesh or plug repairs. The majority of recurrence rates occur within the first 2–3 years of the repair. Acceptable recurrence rates should be <3% at 5 years. A Swedish study on a large cohort ($n = 1232$) of patients aged 15–80 years operated upon for inguinal or femoral hernia involving several surgeons/hospitals demonstrated the positive effect of audit (closing the loop) over a 10 year period. The recurrence rate decreased from 18% in 1984–6 to 3% in 1993–4. During this interval, there was a corresponding decline in the reoperation rate for recurrence at 3 years from 10.8% to 2.2%.

The surgical treatment of recurrent inguinal hernias is less effective and the risk of further recurrence is higher than after first time repair. It is now generally agreed that all recurrent inguinal hernias require some form of tension-free prosthetic mesh repair (open or laparoscopic). It is essential that the size of the mesh used is large enough to overlap the defect by a significant margin. The risk of further recurrence depends on the technique and the number of previous repairs. Thus, in a large reported series, patients with a first-time recurrence had recurrence rates of 2% as opposed to 9% in patients who had undergone two or more prior repairs. The morbidity of recurrent hernia repair is higher and includes wound haematoma, scrotal oedema, temporary pain at the wound site, paraesthesiae, injury of the ilioinguinal nerve and femoral hernia, although the overall morbidity can be low with good surgical technique.

Femoral hernias

The pathogenesis of femoral hernias is now thought to be related to the mode of insertion of the fibres of the transversus abdominis and its investing sheath into the superior pubic ramus and develops in two stages. If the insertion of the transversus abdominis fibres on the superior pubic ramus is through a narrow band, a cone-shaped defect overlying the femoral ring (the femoral cone) results. Initially, preperitoneal fat with or without a sac enters this femoral cone as a result of increased abdominal pressure. This is the asymptomatic stage I (internal) femoral hernia that can only be detected if the preperitoneal space is explored during inguinal herniorrhaphy. In time the fatty contents of the femoral cone exit from the narrow distal orifice when a stage II (external) symptomatic hernia results. As the hernia extends downwards, the sac is turned forwards through the cribriform fascia and may then turn upwards to overlie the inguinal ligament, when it may be mistaken for an inguinal hernia. The hernia may, however, remain quite small and be invisible or scarcely palpable in obese patients. Femoral hernia is particularly prone to incarceration and strangulation. By the time of diagnosis 16% of stage II femoral hernias are irreducible and 25–40% present with incarceration/strangulation. Of the emergency group up to 40% will have strangulation of the hernial sac contents (omentum, small bowel, vermiform appendix) requiring excision.

Femoral hernias can occur at any age with peak incidence in the fifth and sixth decades and are significantly commoner in females especially if multiparous (female to male ratio 4:1). The higher incidence on the right side is inexplicable unless the right leg being in use more often than the left in severe exercise is the reason. Femoral hernias are exceedingly rare in children. A small stage II femoral hernia may be difficult to diagnose especially in obese women. The lump may not be easily palpable and the cough impulse difficult to elicit. On other occasions, the nodule, typically below and lateral to the pubic tubercle, may be difficult to differentiate from a lymph node. In such cases, contrast herniography or cross-sectional imaging with CT or MRI can be extremely useful.

Treatment of femoral hernias

All require surgical repair because of risk of obstruction/strangulation. The surgical approach varies with the presentation. In the elective situation, the surgical approach may be from below the inguinal ligament or through the inguinal canal.

Infrainguinal operations

In the classic low approach, the hernial sac is isolated through an incision below the inguinal ligament. The sac is opened and emptied, with care taken to avoid injury to the bladder wall, which may be close to the medial side of the sac. The peritoneum is closed above the neck of the sac and the stump returned to the abdomen. The femoral canal is repaired by interrupted non-absorbable sutures passing from the undersurface of the inguinal ligament to Cooper's ligament behind, or by the insertion of a rolled-up mesh plug. The repair with this cylindrical mesh prosthesis inserted into the femoral canal gives better results than the classic low fascial repair and is favoured nowadays. Alternatively a mesh repair can be effected laparoscopically using the total extraperitoneal approach.

Transinguinal approach

The inguinal canal is opened anteriorly and then the neck of the femoral hernia exposed by incising the posterior inguinal canal wall. The sac is open and the contents are reduced, after which the peritoneum is closed and a tension-free mesh repair is effected of the posterior wall of the inguinal canal, ensuring this is of adequate size and thus overlaps the pubic tubercle.

Obstructed/strangulated femoral hernia

Although both the above can be used in patients with obstructed femoral hernias, the preperitoneal approach of McEvedy is recommended, especially in the presence of strangulation of the contents of the hernial sac because this gives immediate access to the peritoneal cavity. The skin incision may be longitudinal or transverse over the lower abdomen but above the inguinal canal. The musculoaponeurotic layer is divided lateral to the rectus abdominis, and the extraperitoneal space of the lower abdomen is entered. The hernia is usually easily reducible from above but it may not be. In this case the incision is enlarged and the peritoneal cavity entered above the sac.

Other hernias

Richter's or Richter–Littre hernia

In 1700, the French surgeon Alexandre de Littre described a hernia in which only the antimesenteric part of the bowel was inside the hernial sac. Subsequently, in 1777, Richter described 'the intestinal wall hernia', in which the antimesenteric border of the bowel was incarcerated within the hernial sac. For this reason Richter's hernia is sometimes referred as Richter–Littre hernia. Richter's hernia can complicate any small hernia but the most commonly involved is femoral hernia in which a knuckle of the small intestine becomes incarcerated. The patient presents acutely with symptoms and signs of intestinal obstruction. The diagnosis is often delayed as the obstruction may be incomplete or the small hernia may be overlooked particularly in obese patients. There are now well-documented cases of Richter's hernia complicating small unrecognized port site wound hernias after laparoscopic surgery. The diagnosis should be considered in all patients who develop acute intestinal obstruction after laparoscopic surgery and is established by cross-sectional CT imaging.

All patients, irrespective of the nature of Richter's hernia, require urgent intervention after resuscitation; if the partial incarceration of the bowel is necrotic, the affected segment of the small intestine is resected.

Littre's hernia

This is defined as any hernial sac that contains a Meckel's diverticulum and may involve inguinal, umbilical, femoral, ventral and lumbar hernias. Littre's hernia is rare, particularly in children, in whom the umbilical variety is the commonest. It may present with evidence of gastrointestinal bleeding, as an incompletely reducible hernia, or acutely with intestinal obstruction and faecal–hernial fistulas. Obstructed/strangulated Littre's hernia usually presents in adult patients with intestinal obstruction. Preoperative diagnosis is rare with the vast majority being recognized during emergency surgery. The recommended treatment is resection of the Meckel's diverticulum from within the opened hernial sac but extension of the wound is needed when the adjacent loop of small intestine is infarcted, usually as the result of a volvulus.

Obturator (pelvic floor) hernia

Herniation through the obturator foramen is a rare clinical entity occurring most commonly in elderly thin (average body weight 35–40 kg) multiparous women and presenting with acute small bowel obstruction. In one report of a large series one-third of the patients were admitted from homes for elderly people and were either bed-ridden or wheelchair-bound. The vast majority of patients with obstructed obturator hernia are high-risk patients and this together with the delayed diagnosis and intervention accounts for the high morbidity and mortality (15–25%) because of the frequent presence of infarcted bowel (60–75%). The preoperative diagnosis of obturator hernia is difficult since there are no specific clinical features although the Howship–Romberg sign may be positive, but a groin mass is rarely found on physical examination. Recently, pelvic CT has been shown to provide the diagnosis in suspect cases, and may be indicated in elderly patients with mechanical intestinal obstruction of uncertain origin. However, the correct preoperative diagnosis does not appear to influence the outcome, with survival being determined by early surgical intervention.

Repair of the hernial defect is difficult because adjacent tissues are not easily mobilized and thus requires a polypropylene mesh placed in the preperitoneal space and sutured to Cooper's ligament. Recently there have been a few reports on the laparoscopic repair of obturator hernia but the experience is limited. This approach is inadvisable in the presence of infarcted bowel.

Spigelian hernia

This is an interesting hernia that is probably more common than the number of reported cases suggests. The herniation occurs close to the linea semilunaris (Spigelian line). This marks the transition between the muscular and aponeurotic part of the transversus abdominis muscle (Spigelian aponeurosis) at the edge of the rectus abdominis on either side, and extends from the costal margin to the pubic tubercle. The herniation occurs through a defect in the Spigelian aponeurosis between the linea semilunaris and the lateral edge of the rectus (Figure 21.20). As the hernia is covered by the external oblique aponeurosis, it is initially intramural and may not be palpable externally, i.e. the sac lies between the internal and external oblique muscles (85%) but may penetrate through the external oblique layer as it enlarges (15%). The hernial sac may be empty or contain small bowel, omentum and, more rarely, caecum or sigmoid colon. Although very rare, congenital Spigelian hernia has been reported in children and these cases may be associated with an undescended testis or an ipsilateral mediastinal neuroblastoma in which muscle atrophy caused by the neuropathy of the ninth to twelfth intercostal nerves is thought to be responsible for the hernia.

The mean age at diagnosis is 60 years and the hernia can occur on either side with equal frequency. The clinical presentation

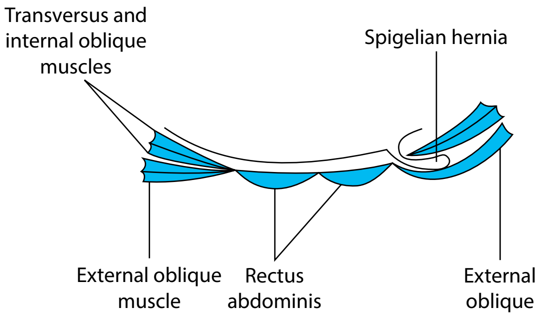

Figure 21.20 Spigelian hernia. The herniation occurs through a defect in the Spigelian aponeurosis between the linea semilunaris and the lateral edge of the rectus.

varies depending on the contents of the hernia sac and the size/type of herniation. Pain is the most common symptom but varies in intensity and nature. On physical examination, the commonest findings are a palpable hernia and a palpable hernial defect. Some patients (20–25%) present acutely with a tender irreducible mass or intestinal obstruction caused by incarceration of a loop of intestine.

Although large easily palpable Spigelian hernias do not pose diagnostic problems, small hernias are often overlooked. Persistent point tenderness along the Spigelian aponeurosis with associated spasm of the abdominal wall should suggest the diagnosis in these cases. Ultrasound scanning or CT will identify these small impalpable hernias.

The treatment of Spigelian hernia is surgical. A grid iron incision is favoured by many surgeons in patients with palpable hernias. In patients with non-palpable hernias the preperitoneal dissection is carried out through a vertical incision, which permits good exposure. The vertical approach is also recommended in patients requiring emergency surgery because of intestinal obstruction as it enables an exploratory laparotomy. Repair can be either fascial or by prosthetic mesh sheet or plug, although as with other hernias tension-free prosthetic repair is favoured nowadays. The repair of uncomplicated Spigelian hernias can be performed laparoscopically. Irrespective of approach, the reported recurrence rates after surgical repair are low.

CHAPTER 22

Disorders of the oesophagus

GEORGE B. HANNA, SAMI M. SHIMI AND SIR ALFRED CUSCHIERI

Anatomy and physiology of the oesophagus

Embryology of the oesophagus

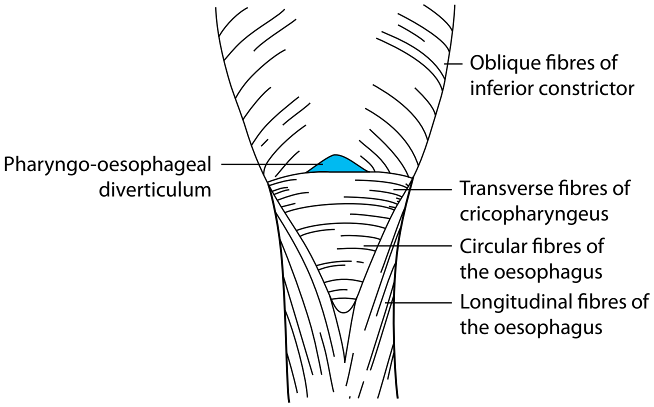
The oesophagus starts to develop in the fourth week of embryonic development from the foregut immediately caudal to the primordial pharynx and extends through the fusiform dilatation in the foregut, this time to become the stomach. The oesophagus is short initially, but it elongates rapidly owing to the growth and descent of the heart and lungs, reaching its final relative length by the seventh week. As the laryngotracheal groove grows from the ventral wall of the primordial pharynx, longitudinal tracheo-oesophageal folds grow and approach each other to fuse and form a septum between the developing trachea and oesophagus. Incomplete fusion of the tracheo-oesophageal folds results in a defective tracheo-oesophageal septum and fistula formation. By the fifth week of development the oesophageal epithelium is two cells thick and is composed of columnar cells, which develop cilia by 10 weeks. The epithelium lining proliferates and partly or completely obliterates the lumen by the eighth week of development and large vacuoles appear in the centre. In succeeding weeks, the vacuoles coalesce and the oesophageal lumen recanalizes but with a multilayered ciliated epithelium. During the fourth month this epithelium finally becomes replaced with the stratified squamous epithelium that characterizes the mature oesophagus. Failure of recanalization of the oesophagus in this period results in oesophageal atresia and possibly oesophageal stenosis. Surrounding the oesophageal epithelium, layers of muscle begin to differentiate from the mesoderm. The inner circle of the muscular layer is recognizable by 5 weeks of gestation and the outer longitudinal layer of muscle begins to take shape by 8 weeks of gestation. The striated muscle in the superior third of the oesophagus is derived from mesenchyme in the caudal pharyngeal arches, whereas the smooth muscle in the inferior third of the oesophagus develops from the surrounding splanchnic mesenchyme. Both types of muscle are innervated by branches of the vagus nerve, which supply the caudal pharyngeal arches. A dorsal mesentery more developed inferiorly connects the oesophagus to the developing aorta and may, on occasion, have smooth muscle remnants in adult life. Vagal trunks run alongside the oesophagus, but as the stomach rotates to the right, the right vagus assumes a posterior position and the left trunk crosses the lower oesophagus to lie anterior to the oesophagogastric junction. The oesophagus attains its final length at the seventh week of gestation, having a length at birth of 8–10 cm.

Anatomy of the oesophagus

The oesophagus is a hollow muscular tube, which is about 25 cm long, and connects the pharynx to the stomach. It commences in the neck, level with the lower border of the cricoid cartilage (sixth cervical vertebra) and descends mainly anterior to the vertebral column traversing the diaphragm at the level of the tenth thoracic vertebra, ending in the abdomen at the cardiac orifice of the stomach, at the level of the eleventh thoracic vertebra. Topographically the oesophagus is generally vertical but has two shallow curves. Immediately below the pharynx it is a midline structure but inclines to the left as far as the root of the neck, gradually returning to the midline near the fifth thoracic vertebra and deviates to the left again at the seventh thoracic vertebra finally turning anteriorly as it traverses the diaphragm. The oesophagus also curves in a coronal plane, to follow the cervical thoracic curvatures of the vertebral column. The surgical relevance of these deviations is that the cervical oesophagus is best approached from the left side of the neck, and the thoracic portion through the right side of the thorax except the lower third (below the thoracic arch), which is more accessible from the left thorax.

The oesophagus is arbitrarily divided into three segments:

- *The cervical part* (5 cm long) is behind the trachea and attached to it by loose areolar tissue. It lies in front of the prevertebral fascia separated from it by loose areolar tissue. The recurrent laryngeal nerves ascend on each side in the groove between the trachea and the oesophagus. The left recurrent laryngeal nerve is positioned closer to the oesophagus than the right one as it ascends along the oesophagus for a larger distance. The cervical oesophagus commences with cricopharyngeus muscle at the inferior portion of the inferior pharyngeal constrictor, clearly identified by its transverse fibres. Just above cricopharyngeus, the transition between the oblique fibres of the inferior constrictor muscle and the transverse fibres of cricopharyngeus creates a point of potential weakness termed Killian's dehiscence, which is the site of origin of a pharyngo-oesophageal (Zenker's) diverticulum (Figure 22.1). Cricopharyngeus muscle fibres blend into the longitudinal and circular muscles of the cervical oesophagus.
- *The thoracic oesophagus* runs in the superior mediastinum between the trachea and the vertebral column, and passes behind and to the right of the aortic arch to descend in the posterior mediastinum along the right side of the descending thoracic aorta as it proceeds behind the pericardium overlying the left atrium. The oesophagus then deviates further to the left and anteriorly, entering the oesophageal diaphragmatic hiatus at the level of the tenth thoracic vertebra. On either side the thoracic oesophagus is bound by the parietal pleura. Clinically, the thoracic oesophagus is divided into three parts. The upper thoracic oesophagus extends from the cricopharyngeus to the level of the carina. The middle thoracic oesophagus extends from the level of the carina to halfway between the carina and the oesophagogastric junction and the lower thoracic oesophagus from halfway between the carina and the oesophagogastric junction to include the lower third of the oesophagus. Oncologically the thoracic oesophagus is divided into the supracarina oesophagus (upper oesophagus) and the infracarina oesophagus (middle and lower oesophagus).
- *The abdominal oesophagus* emerges from the right diaphragmatic crus slightly to the left of the midline at the level of the tenth thoracic vertebra. It forms an inverted cone (1–2 cm in length) which curves sharply to the left and its base continues with the gastric cardiac orifice. It is covered by peritoneum on its front and left side, and the peritoneum reflected from its posterior surface to the diaphragm is part of the gastrophrenic ligament. Behind it is the left crus of the diaphragm.



Oblique fibres of inferior constrictor
Pharyngo-oesophageal diverticulum
Transverse fibres of cricopharyngeus
Circular fibres of the oesophagus
Longitudinal fibres of the oesophagus

Figure 22.1 Diagrammatic representation of the posterior aspect of the upper oesophagus and pharynx showing Killian's dehiscence as the longitudinal fibres of the oesophagus sweep anteriorly. The pharyngo-oesophageal diverticulum emerges between the oblique fibres of the inferior constrictor and the transverse fibres of the cricopharyngeus.

Oesophageal attachments

The oesophagus is loosely bound to adjacent structures by fibroareolar tissue throughout its course except at the upper and lower ends. Superiorly, the longitudinal muscle fibres of the oesophagus are inserted into the cricoid cartilage. The lower attachments consist of serous reflections and the phreno-oesophageal membrane. The subdiaphragmatic pleural reflection is continuous with the mediastinal pleura and is separated from the lower segment of the oesophagus by a condensation of the endothoracic fascia which constitutes the phreno-oesophageal membrane. This important fibroelastic membrane fixes the lower gullet but permits its continuous vertical displacement as occurs with respiration. The phreno-oesophageal membrane consists of a superior and an inferior limb. The latter is inserted into the cardia and the superior limb into the lower 3 cm of the thoracic oesophagus. The fibres of the membrane are disposed in bundles and lamelli and are inserted deeply into the oesophageal walls, some reaching the submucous layer. Approximately 40–60% of the fibres are made of elastin. The membrane has both strength and resilience, which are necessary to cope with the continuous movement of the hiatus during life. The phreno-oesophageal membrane is easily identified during mobilization of the oesophagus during laparoscopic antireflux surgery.

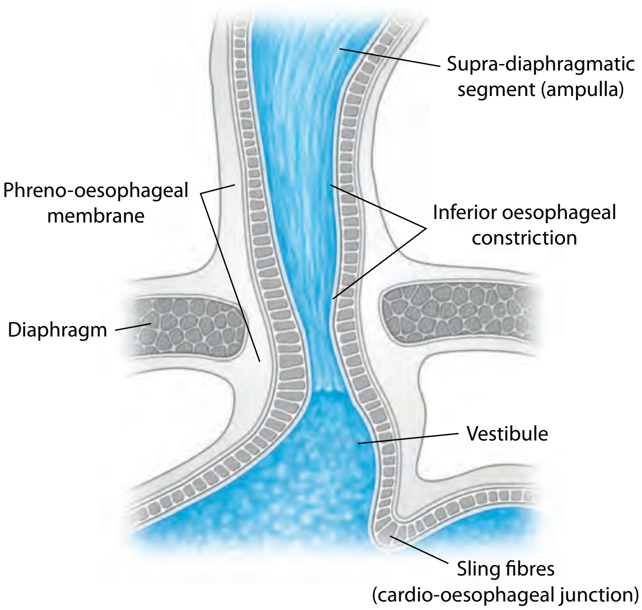
Structure of the oesophagus

The oesophagus consists of four layers. The fibrous adventitia is irregular, and consists of loose, areolar connective tissue containing elastin fibres. The looseness permits considerable movement of the oesophagus during swallowing. The fibres penetrate and surround the fasciculae of muscle in the deeper layers. The muscular layer is composed of an outer thicker longitudinal and inner circular layer. The longitudinal fibres surround the whole length of the oesophagus with a continuous coat except posterosuperiorly where the longitudinal fibres separate and sweep round to the anterior aspect of the oesophagus before their insertion into the posterior aspect of the cricoid cartilage. The V-shaped interval between these fasciculae is filled by cricopharyngeus above and circular muscle fibres below. The potential weak area posteriorly may become the site of acquired pulsion diverticulae (Zenker's above and Laimer's below). A natural constriction occurs at this point due to the presence of the hypopharyngeal fold and the cricopharyngeus muscle. Accessory slips of non-striated muscle sometimes pass between the oesophagus and left pleura or the root of the left principal bronchus, trachea, pericardium or aorta. The circular fibres are continuous with those of cricopharyngeus superiorly and with the oblique gastric muscle fibres inferiorly. The two muscle layers of the upper quarter of the oesophagus are striated. Below this there is a gradual replacement with smooth muscle. Although similar in appearance to striated skeletal muscle it is not under voluntary control but rather under autonomic nervous control. At the lower end of the oesophagus, the circular muscle layer is thickened but a definite anatomical sphincter is not present. The external longitudinal muscle of the oesophagus continues longitudinally along the gastric greater and lesser curvatures. These muscle bundles turn upward toward the fundus, interlacing with fibres of the internal muscle layer. The circular muscle layer of the lowermost portion of the oesophagus becomes semicircular (clasps) and continues down the lesser curvature aspect of the cardia to insert in the submucosal connective tissue on the opposite side. Gastric sling fibres are also semicircular in the opposite direction and at an oblique angle to the posterior attachments of the oesophageal semicircular muscles.

The submucosa is very loose in order to permit dilatation of the oesophagus during swallowing. It loosely connects mucous and muscular layers and contains large blood vessels, nerves and mucous glands. The mucosa is made of non-keratinized squamous epithelium, which is arranged in longitudinal folds especially at the lower end where the oesophageal mucosal folds form a rosette. The mucosal layer consists of the lining epithelium, connective tissue with papilli (lamina propria) and non-striated muscularis mucosa. At the upper oesophagus the muscularis mucosa is absent or sparse and becomes a considerable stratum below this. At intermediate levels its fascicles are mainly longitudinal but become more plexiform towards the gastro-oesophageal junction (GOJ). There are small oesophageal glands of compound racemose mucous type in the submucosa deep to the muscularis mucosa each with a long duct traversing it and the other layers of the mucosa. Glands of the abdominal portion of the oesophagus resemble gastric cardia glands and lie superficial to the muscularis mucosa.

The cardio-oesophageal junction

This consists of the supradiaphragmatic portion, the inferior oesophageal constriction, the vestibule, and the cardia (Figure 22.2). Radiologically the supradiaphragmatic portion consists of an ampulla and the empty segment just distal to it. The ampulla is not an anatomical dilatation and is caused by the primary peristaltic wave (during a contrast examination) acting in conjunction with the negative intrathoracic pressure, which momentarily expands the segment just before the lower oesophageal sphincter (LDS) relaxes. The inferior oesophageal constriction consists of a concentric narrowing of the oesophageal lumen at the level of the diaphragmatic hiatus. On average, it is situated some 2 cm from the cardio-oesophageal junction. It is not synonymous with the LOS although the sphincter region extends to include this area. The longitudinal oesophageal mucosal folds are very prominent inside the inferior constriction but disappear readily when the oesophagus is distended. The intra-abdominal segment of the oesophagus is also known as the vestibule. It is often described as an inverted funnel or cone which inclines to the left before joining the stomach at an angle (cardiac angle or angle of His). When viewed endoscopically from within the stomach it forms a well-marked ridge at the left margin of the gastro-oesophageal junction, which is occasionally referred to as the incisura. The cardia denotes the junction between the oesophagus and stomach. The only reliable and constant anatomical landmark of this is made by the sling or oblique muscle fibres of the stomach but these cannot be identified



Supra-diaphragmatic segment (ampulla)
Phreno-oesophageal membrane
Inferior oesophageal constriction
Diaphragm
Vestibule
Sling fibres (cardio-oesophageal junction)

Figure 22.2 Diagrammatic representation of the anatomy of the lower oesophagus. (From Hennessey and Cuschieri, *Surgery of the Oesophagus*. Oxford, UK: Butterworth Heineman, 1992, with permission.)

endoscopically. Clinically the term cardia is used to describe the junction between the oesophagus and stomach. It contains the squamocolumnar junction, which forms the serrated z-line marking an abrupt change from the tough smooth pale squamous epithelium of oesophagus to the epithelium of the stomach. A zone of junctional epithelium is interposed between the squamous lining of the oesophagus and the gastric mucosa. It is lined by columnar cells which contain simple tubular mucosal glands which are superficial to the muscularis mucosa and hence resistant to acid and peptic digestion.

Vascular supply, venous and lymphatic drainage

The oesophagus receives a segmental arterial supply from several small arterioles throughout its course. These come from the inferior thyroid, common carotid, costocervical and vertebral arteries in the neck, bronchial and direct aortic branches in the thorax, and branches of the left gastric and left inferior phrenic artery at the lower end including the abdominal portion. The arterioles terminate in a fine capillary network before penetrating the oesophageal muscle layer. After penetrating and supplying the oesophageal muscle layer, the arterioles join a capillary plexus in the submucosa. These capillary networks run longitudinally in the submucosa allowing mobilization of segments of the oesophagus without compromise to the blood supply. The venous drainage is to the inferior thyroid and hypopharyngeal veins in the neck, and the azygos, hemiazygos and intercostal veins in the chest except at the lower end which drains into the left gastric vein (Figure 22.3). The lower oesophagus is clinically the most important site of communication between the portal and systemic venous radicles, being the site of occurrence of varices in the majority of patients with portal hypertension. In the lower oesophagus the veins are mainly situated within the lamina propria whereas in the more proximal oesophagus and stomach they reside in the submucous plane. This is held responsible for the propensity of the lower oesophagus to bleed in variceal portal hypertension. The lymphatics form extensive mucosal (lamina propria), submucosal, muscularis and adventitia plexuses which communicate freely and lymph flows long distances in the large submucosal plexus before passing though the muscular coat to reach the adventitial plexus and draining lymph nodes. These are grouped into three main tiers: the first composed of nodes alongside the oesophagus (paraoesophageal), the second or intermediate group is made up of mediastinal lymph nodes, and the third are the deep cervical, supraclavicular, tracheobronchial and coeliac nodes from above downwards. In general, lymph drainage from the upper two-thirds of the oesophagus proceeds in a proximal direction towards the cervical region, whereas the lower third drains distally to the subdiaphragmatic region and coeliac lymph nodes. In view of the anatomic distribution and communication of oesophageal lymphatics, oncological resection should include 10 cm above and below the tumour. Lymphatic drainage of the GOJ mainly follows the arteries supplying the junction.

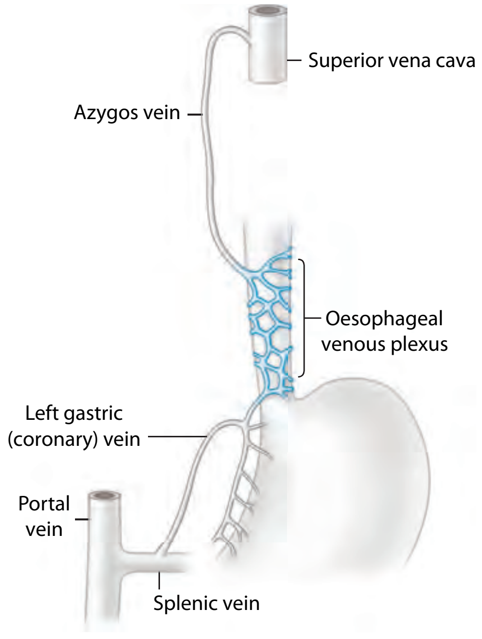


Figure 22.3 Venous drainage of the lower oesophagus.

The thoracic duct arises from the cysterna chyli, which lies in the abdomen to the right of the aorta, approximately at the level of the second lumbar vertebra. The duct enters the chest through the aortic hiatus coursing in the posterior mediastinum to the right of the midline between the aorta and the azygos vein behind the oesophagus. At the level of the fifth thoracic vertebra, it crosses behind the oesophagus to the left under the aortic arch and continues along the left side of the oesophagus ascending behind the left subclavian artery to the base of the neck. There, it curves to the right and caudally to drain into the internal jugular vein near its junction with the left subclavian vein. The majority of people have a single thoracic duct and the remainder have two or more ducts.

Nerve supply of the oesophagus

Two plexuses of nerves in the oesophageal wall (Meissner's plexus in the submucosa and Auerbach's plexus in the muscularis) form networks of multipolar ganglion cells, the processes of which are in contact with one another and receive axons from the vagus. Postganglionic fibres of these plexuses innervate the smooth muscle cells. Postganglionic sympathetic fibres from the prevertebral ganglia enter the plexuses without synapsing to reach the muscles of the blood vessels of the oesophageal wall.

Swallowing and oesophageal motility are co-ordinated by the swallowing centre in the brainstem. This is an area in the medulla oblongata and lower portion of the pons, which is closely associated with the tractus solitarius. It receives and co-ordinates sensory inputs from peripheral mechanoreceptors in the pharynx and oesophagus. Motor impulses that initiate the swallowing reflex are transmitted from the swallowing centre to the pharynx and upper oesophagus via the trigeminal, glossopharyngeal, vagus and hypoglossal nerves.

The nerve supply of the oesophagus is parasympathetic (vagal) and sympathetic. The parasympathetic fibres, which are predominantly motor, are derived from neurones of the vagal motor nuclei and travel in the glossopharyngeal, vagus and recurrent laryngeal nerves terminating in the myenteric plexus. The sensory component is formed by axons of the nodose ganglion, the cells of which are unipolar with their peripheral axons transmitted via the sensory portion of the trigeminal and glossopharyngeal nerves, which terminate in receptors situated in the pharynx and oesophagus. The central axons of the cells of the nodose ganglion communicate with the swallowing centre in the brainstem.

The sympathetic nerve supply consists of preganglionic fibres derived from neurones situated in the intermediolateral columns of spinal cord segments T5 and T6 and terminate in the cervical, thoracic and coeliac ganglia. The postganglionic sympathetic fibres then reach the oesophagus as a periarterial plexus.

The rami reaching the oesophagus communicate with a plexus containing groups of ganglion cells between the two layers of the muscular coat, the myenteric plexus. The submucous plexus of the oesophagus is rather sparse and consists mainly of nerve fibres.

Endoscopic appearance of the oesophagus

The oesophagus proper starts just distal to the cricopharyngeus muscle at around 15 cm from the incisor teeth. The mucosa is pale and lacks lustre. The lumen is collapsed until insufflated with air and then the wall is smooth. There are a number of naturally occurring anatomic narrowings in the oesophagus. The cervical constriction occurs at the level of the cricopharyngeus muscle at approximately 15 cm from the incisor teeth. The next constriction is expected where the oesophagus is crossed by the aortic arch at 22 cm, by the left main bronchus at 27 cm, and where it passes through the diaphragmatic hiatus at the cardio-oesophageal junction at 37–40 cm from the incisors depending on the sex and build of the patient. Although the left atrium is in front of the lower part of the oesophagus below the left main bronchus, it is only when the atrium is enlarged that it indents the oesophagus. At the cardio-oesophageal junction the stratified squamous epithelium is abruptly succeeded by gastric columnar epithelium, the junction is visible as a serrated line with the greyish pink smooth oesophageal mucosa contrasting with the red mamillated gastric mucosa.

Physiology of the oesophagus

The basic function of the oesophagus is to transport swallowed material from the pharynx into the stomach. It has little secretory function and no absorptive function. The pharynx is central to the swallowing complex. Besides other functions the pharynx facilitates the propulsion of food for a few seconds at a time. Conventionally, swallowing has been divided into three stages. The *voluntary stage* initiates the swallowing process. A food bolus is rolled (squeezed) posteriorly into the pharynx by pressure of the tongue upwards and backwards against the palate. Subsequently, the process of swallowing becomes automatic and involuntary. The *pharyngeal stage* constitutes the passage of food through the pharynx into the oesophagus. As food enters the pharynx it stimulates mechanoreceptors around the opening of the pharynx and on the tonsilar pillars. This stimulates a series of automatic pharyngeal muscular contractions. The soft palate is pulled upward to close the posterior layers, preventing reflux of food into the nasal cavities. The palatopharyngeal folds on either side approximate each other to form a sagittal slit allowing properly masticated food to pass with ease and yet impeding the passage of large objects. The vocal cords are strongly approximated and the larynx is pulled upward and posteriorly against the epiglottis, which swings backward over the opening of the larynx. This prevents passage of food into the trachea. The upward movement of the larynx enlarges the opening of the oesophagus and stimulates relaxation of the tonically active upper oesophageal sphincter (UOS) (cricopharyngeus). As the larynx is raised and the UOS is relaxed the entire muscular wall of the pharynx contracts beginning in the superior constrictor and spreading downwards as a rapid peristaltic wave over the middle and interior constrictors and thence into the oesophagus. This peristaltic wave propels the food into the oesophagus. This stage of swallowing is principally a reflex act. It is almost always initiated by voluntary movement of food into the back of the mouth, which in turn elicits the swallowing reflex. The *oesophageal stage* is also involuntary and promotes passage of food from the pharynx to the stomach. Food is propelled down the oesophagus by peristaltic waves. Primary peristalsis is simply a continuation of the peristaltic wave that commenced in the pharynx and spread into the oesophagus during the pharyngeal phase of swallowing. This wave passes all the way from the pharynx to the stomach in approximately 8 seconds. However, food swallowed in the upright position is usually transmitted down the oesophagus in about 5–8 seconds because of the additional effect of gravity. If the primary peristaltic wave fails to move all the food that has entered the oesophagus into the stomach secondary peristaltic waves result from the distension of the oesophagus by the retained food and these continue until all the food has emptied into the stomach. The secondary peristaltic waves are initiated partly by intrinsic neuronal circuits in the myenteric plexus and partly by reflexes that are transmitted through vagal fibres from the brainstem. It is important to note that a denervated oesophagus will continue to generate these secondary peristaltic waves in response to distension. The other types of contraction exhibited by the oesophagus are tertiary contractions which occur spontaneously and are non-propulsive. They are usually encountered in various oesophageal motility disorders but are also observed in apparently healthy individuals especially in older age. These tertiary contractions may be generalized involving the whole of the oesophageal body or localized. They are usually seen on a double contrast barium meal examination.

In between swallows the body of the oesophagus is flaccid and the lumen largely collapsed. However, both the UOS and LOS are tonically contracted. The UOS (cricopharyngeus) is clipped closed by tonic contraction induced through constant discharge from neurones originating in the cranial nuclei. The sphincter remains in tonic contraction with a resting pressure of about 100 mmHg. The physiological function of the sphincter is to prevent passage of air from the pharynx into the oesophagus and reflux of oesophageal contents into the pharynx. This reflex action is essentially protective and is aimed at preventing aspiration. In the resting state the oesophageal body has no motor activity. When stimulated by passage of food or saliva a contraction is initiated in the upper oesophagus, which progresses distally towards the stomach. Oesophageal peristaltic waves travel at 3–4 cm/s, last between 3 and 4.5 seconds, and reach a peak amplitude of 30 mmHg in the upper oesophagus which progressively gets larger as it travels down the oesophagus to around 120 mmHg in the lower oesophagus. In the resting state the pressure within the body of the oesophagus is similar to the intrathoracic pressure, being negative during inspiration and reaches 5 mmHg during expiration. At the lower 2–4 cm of the oesophagus, a high-pressure zone (HPZ) is encountered. This is due to tonic contraction of the LOS (intrinsic component) and to mechanical factors (extrinsic component).

The intrinsic part of the HPZ constitutes the 2–4 cm tonically contracted segment just proximal to the gastro-oesophageal junction. Its normal resting tone ranges from 15 to 25 mmHg relative to intragastric pressure. Three-dimensional mapping of this region shows asymmetry of the pressure profile (Figure 22.4). The segment has a spontaneous tendency to relax periodically at times unrelated to swallowing. These periodic relaxations have been termed 'transient lower oesophageal sphincter relaxations' to distinguish them from relaxations triggered by swallows. They account for the small amount of physiological reflux found in normal subjects. To allow a food bolus to enter the stomach, the LOS relaxes for 5–10 seconds and then tonic contraction returns. Relaxation is probably due to non-adrenergic non-cholinergic neurotransmitters such as vasoactive intestinal polypeptide (VIP) and nitric oxide (NO). The resting tone is largely dependent on the intrinsic muscular activity because it persists after neural input is abolished by treatment with neurotoxins. During fasting the LOS has cyclic phasic contractile activity synchronous with phases 2 and 3 of the interdigestive motor complex. This is probably regulated by motilin, which acts on the LOS, by preganglionic stimulation of cholinergic nerves.

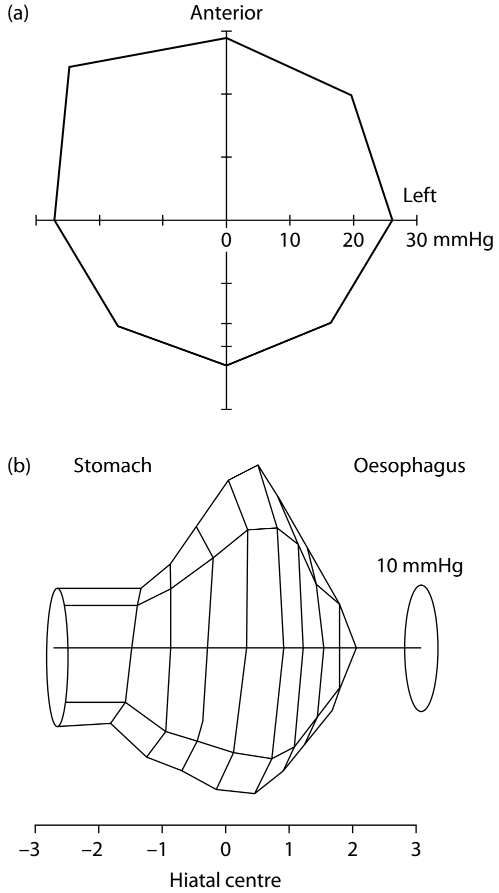

Figure 22.4 Radial (a) and axial (b) pressure profile of the gastro-oesophageal junction in an asymptomatic subject obtained using the technique of vector manometry. Position zero on the axial scale is the mid-point of the diaphragmatic hiatus.

The extrinsic component is largely determined by contractions of the diaphragmatic crura. The increase in LOS pressure is mainly during inspiration and can be as much as 100 mmHg with maximum diaphragmatic contraction. This pinchcock action of the diaphragm is a protective mechanism against reflux induced by sudden increases in intra-abdominal pressure. This mechanism is obviated when a hiatal hernia is present.

Assessment of oesophageal disease

This includes a careful history, physical examination and appropriate investigations to establish the nature of the underlying pathology.

Symptoms

The presentation of oesophageal disease is often typical with one or more of the well-known classic symptoms. Atypical presentation is not, however, infrequent, and oesophageal disease may be mistaken for cardiac and pulmonary disorders. In these patients differentiation is only possible after specialized investigations are carried out. A small cohort of patients with oesophageal symptoms have no abnormality on physical examination and intensive investigations. In some, but not all, of these patients, the symptoms reflect a psychoneurotic state. The typical symptoms of oesophageal disease are dysphagia, regurgitation, odynophagia, chest pain and water brash.

Dysphagia

Difficulty in swallowing or a sensation of food bolus arrest or delay during swallowing may be due to mechanical obstruction or functional disorder. The patient feels the food sticking and often points to a particular site on the sternum, although this does not correlate well with the exact anatomical location of the obstruction. Dysphagia for solids implies significant disease which may be mechanical or functional whereas dysphagia for liquids only is more likely to be functional (oesophageal motility disorder). In the latter, difficulty with swallowing may be intermittent or its severity variable with exacerbations and periods of relative remission. Some patients with dysphagia find that food transit through the oesophagus can be facilitated by sipping fluid after each solid bolus or by repeated swallows and various postural manoeuvres such as expiration against a closed glottis (Valsalva), etc. On the other hand, persistent and progressive dysphagia indicates mechanical narrowing of the oesophageal lumen. This is usually associated with regurgitation and is not relieved by sipping fluids or repeated swallowing. Eventually, with progression to total dysphagia, the patient is unable to swallow saliva and exhibits constant drooling. In obstructive dysphagia, the symptom begins when 20–30% of the oesophageal lumen is lost, and patients usually present when 50% of the oesophageal lumen is compromised.

The sensation of a substernal lump (globus)

When this is present a short period after eating or when fasting it is termed 'globus hystericus'. It is a neurotic symptom in patients with emotional instability but requires thorough examination to exclude organic disease. Dysphagia is never an expression of a purely psychiatric disorder. However, some patients with well-established oesophageal disease may report that their dysphagia is worse during severe emotional periods.

Regurgitation

This symptom results from regurgitation of gastric or oesophageal fluid into the throat accompanied by a sour taste in the mouth. It is often postural and occurs predominantly in the supine position especially at night, with the regurgitated material often staining the pillow. Postural regurgitation, which is a very common symptom of reflux disease, is precipitated by meals and activities associated with a rise in the intra-abdominal pressure, i.e. bending and straining. Regurgitation may also occur as an overflow phenomenon due to the accumulation of food in the oesophagus proximal to a stenosing lesion. This spillback into the pharynx and mouth at night may lead to aspiration pneumonitis. In oesophageal motility disorders both overflow and postural regurgitation may occur, although the former is more commonly encountered in these conditions.

Odynophagia

This complaint consists of localized pain, usually in the lower sternal region, which occurs immediately on swallowing certain foods or liquids. It always indicates organic disease, most commonly oesophagitis. Hot drinks, acid citrus beverages, coffee and heavily spiced foods are among the most frequent dietary items that induce this symptom. It can be severe enough to condition patients not to eat or drink the offending item, or food in general. Odynophagia can be seen after involvement of the mucosa by reflux, radiation, viral or fungal infections. Less commonly, odynophagia can be a manifestation of ulceration or cancer of the oesophagus.

Heartburn

This is the most common manifestation of oesophageal disease and may occur in up to 50% of the population. It is due to reflux of gastric juice, which is injurious to the oesophageal mucosa. The chemical injury is accentuated by a defective clearing of the refluxate by the oesophagus consequent on an impaired motility. This increases the contact time of the acid and any other injurious substance (e.g. bile salts) with the oesophageal mucosa. Some patients complain of severe heartburn, yet on endoscopy there is little or no evidence of inflammation. These individuals may still have reflux with an abnormal oesophageal mucosal sensitivity. Heartburn is often worsened by recumbency, increase in intra-abdominal pressure and may follow fatty meals or alcoholic beverages. Heartburn is usually relieved, even temporarily, by taking antacids. This symptom can increase in intensity until it is perceived as chest pain.

Chest pain

Oesophageal anterior chest pain is often described as a tightening or gripping pain, which closely simulates angina pectoris. Thus it may radiate to the back, jaw, arm and ear and may even be relieved by sublingual nitrates. This type of pain is commonly found in patients with reflux oesophagitis or oesophageal motility disorders. It may occur in association with meals when it persists for about an hour after, but is also experienced in the fasting state and is frequently precipitated by emotion and exercise.

Water brash

This symptom is uncommon and is restricted to patients with reflux disease. It is due to excessive salivation, the mouth becoming full of fluid, which has a salty taste, clear and frothy.

Atypical presentation of oesophageal disease

Patients with oesophageal disease may present with anaemia due to chronic blood loss and, less commonly, with acute upper gastrointestinal bleeding (haematemesis, melaena). Chronic blood loss is usually due to erosive oesophagitis and active bleeding results from the Mallory–Weiss syndrome or peptic ulceration in a hiatus hernia. Incarceration and strangulation of a paraoesophageal hiatus hernia and spontaneous perforation of the oesophagus (Boorhave syndrome) present acutely with a severe life-threatening illness.

Reference has already been made to the frequently encountered difficulty in distinguishing oesophageal from cardiac pain. Often, patients are treated for angina for a while until persistence/aggravation of symptoms indicates the need for coronary angiography. Approximately 20–40% of patients with chest pain and normal coronary angiography are subsequently found to have oesophageal disease.

Presentation with pulmonary symptoms is common. These include attacks of coughing, choking and repeated chest infections due to aspiration pneumonitis in patients with overflow or postural regurgitation. The chest radiograph shows areas of consolidation, abscess formation and pleural effusion. Furthermore, intrinsic asthma is often exacerbated by gastro-oesophageal reflux with aspiration particularly in infants and children. Effective treatment of the reflux disease is often followed by a considerable improvement in the asthmatic condition of these patients.

Physical signs

The oesophagus is a mediastinal structure and is inaccessible to physical examination. However, patients presenting with oesophageal diseases may have physical signs, which should be sought during the examination. These include evidence of weight loss; pallor due to anaemia; swelling in the neck due to pharyngeal pouch; enlarged lymph nodes in the left supraclavicular or cervical regions; chest signs on auscultation and percussion of the lung fields; epigastric mass due to carcinoma of the cardia enlarging downwards, hepatomegaly with or without clinical jaundice; tylosis of the hands and/or feet.

Physiological tests

These include manometry, pH-metry and tests to assess bile reflux. The Bernstein test continues to be used when a correlation between symptoms and acid reflux is required. The standard acid reflux test and the acid clearance test have largely been replaced by pH-metry in the assessment of patients with reflux symptoms.

Oesophageal manometry

This technique measures the mechanical function of the oesophageal musculature and its sphincters by recording intraluminal pressure profiles caused by the contractions. Intraluminal pressure recording is carried out using a system of water-perfused catheters or solid-state strain gauge transducers built into catheters. For sphincter pressure measurements there is a potential for the position of the sphincter to alter in relation to the pressure sensor on the catheter, especially in prolonged measurements. In these situations the Dent sleeve can be used. This is a thin, 6 cm long, open-ended, silastic sleeve which surrounds the pressure sensor ports of a water-perfused catheter. The sleeve operates by traversing the sphincter and records the averaged circumferential and axial pressure forces acting on the sleeve. An alternative is the sphinctometer. This device is usually sited distally in a multichannel microtransducer catheter and consists of a side-mounted transducer surrounded by a silicone, oil-filled silastic tube of 6 cm length and of the same diameter as the catheter. The water-perfused catheter is connected to a low-compliance hydraulic pump, which in turn is connected to a system of strain gauges and a system of readout, most commonly a computer (Figure 22.5). The solid-state strain gauge microtransducers can be connected directly to the readout system. The study commences by determination of the position of the LOS/HPZ. This is done by inserting the catheter into the stomach and withdrawing it either rapidly (rapid pull-through) or slowly (station pull-through) taking pressure recordings at each of the stations from both the sphincter and oesophageal body. The rapid pull-through technique provides information on the position and length of the sphincter. The manometry catheter can then be positioned with one pressure sensor in the middle of the sphincteric area and three pressure sensors separated by 5 cm intervals on the catheter lying within the oesophageal body. In stationary manometry, pressure recordings are taken from the sensors in response to a number of water swallows separated by 30 seconds.

This method provides sufficient information on the position, length and pressure of the LOS in addition to pressure, peristalsis and propagation of contractions within the oesophageal body (Figure 22.6). The information obtained from manometric studies is analysed according to set criteria to diagnose oesophageal motility disorders. This method is indicated for the accurate placement of pH electrodes prior to 24 hour ambulatory pH monitoring in patients suspected of having gastro-oesophageal reflux disease (GORD). This method can also be diagnostic in patients with classical motility disorders of the oesophagus.

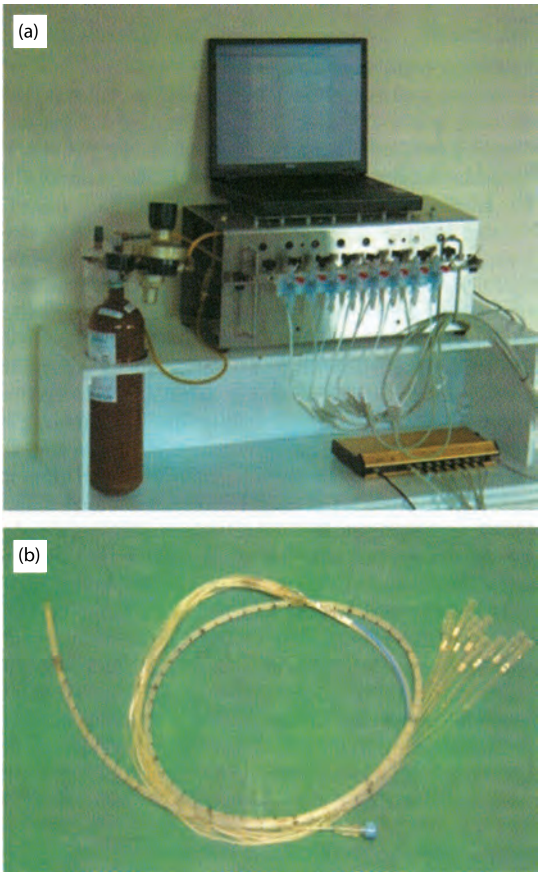

Figure 22.5 Stationary manometry. (a) This is performed using a low-compliance gas-driven hydraulic pump infusing water through a multichannel catheter connected to a system of strain gauges which feed back the pressure signals into a digital converter which is displayed on the computer screen; (b) multichannel silicone catheter used in manometry.

In patients where the stationary manometry reveals a motility disorder of the oesophagus and in those patients suspected of having an oesophageal motility disorder, prolonged ambulatory manometry is preferred. This method employs solid-state pressure transducer catheters attached to a portable recording system with event markers triggered by the patient when symptoms occur (Figure 22.7). They are particularly useful for patients with non-cardiac chest pain who may have transient motility disturbances in the oesophagus and for patients with non-specific motility disorders. Because of the diverse aetiology of these disorders, a combined recording of manometry and pH-metry is indicated.

Analysis of both manometry and pH-metry may reveal the disorder (Figure 22.8). More recently, vector manometry of the LOS has been obtained using a water-perfused catheter with eight radial channels. Although this technique has provided illustrative three-dimensional representation of the LOS, the technique suffers from poor reproducibility.

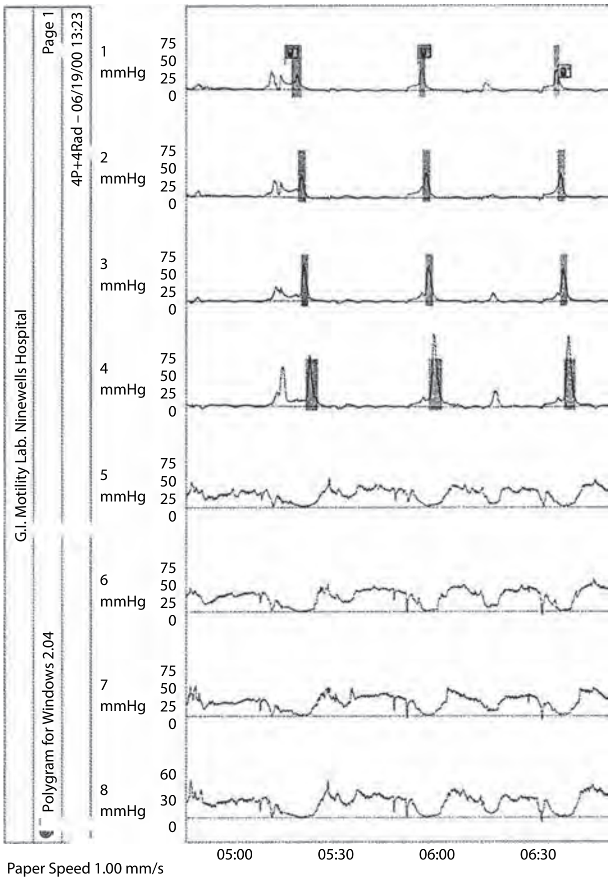

Figure 22.6 Station manometry recording using an eight-channel catheter with four radial channels at the same distance from the tip of the catheter (lower four) positioned within the lower oesophageal sphincter determined by a station pull-through technique and four channels separated by 5 cm intervals. The contractions of the oesophagus and the lower oesophageal sphincter in response to three wet swallows is demonstrated.

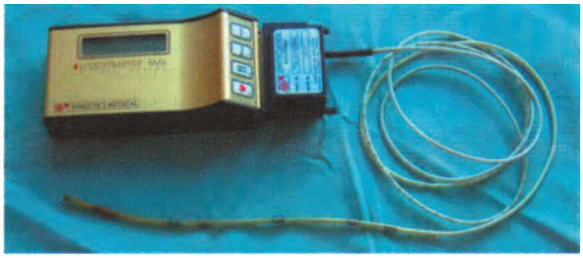

Figure 22.7 A portable recording device connected to a catheter on which three pressure transducers measure pressures and a pH electrode measures the hydrogen ion concentration.

24-hour pH monitoring

This technique involves the transnasal placement of a pH measuring electrode sited 5 cm above the manometrically identified LOS. The pH electrode monitors the changes in intraoesophageal pH over a circadian cycle (24 hours) with the information stored in a portable recording device (Figure 22.9).

A 24-hour pH profile is subsequently obtained from the recording device. This includes the frequency, duration and pattern of reflux episodes together with temporal correlation with symptoms (Figure 22.10). Conventionally, a reflux episode is defined as a pH drop to below pH 4. Specially designed software analyses the data in two ways. In reflux event analysis, all individual reflux episodes are identified and characterized: their number, mean duration, number of long reflux events more than 5 minutes and the duration of the longest reflux episodes. Cumulative oesophageal exposure analysis depicts the frequency distribution of the oesophageal pH data for the erect and supine parts of the study as well as for the whole period of study. The generated data for any one patient are then compared with that which pertains to a 'normal' population. Indications for 24-hour ambulatory pH monitoring include the definitive diagnosis of gastro-oesophageal reflux in patients who are sufficiently symptomatic to have warranted endoscopy, but in whom endoscopy is normal. In addition, it is used to investigate patients suspected of having gastro-oesophageal reflux as a cause of atypical symptoms, such as non-cardiac chest pain, respiratory and laryngeal symptoms, in whom the relevant investigations have been normal and to correlate such symptoms with reflux episodes. Further, it is used when established gastro-oesophageal reflux responds poorly to optimal medical therapy and particularly when surgical treatment is contemplated. It may also be used in the assessment of patients with complex oesophageal disorders prior to surgery.

24-hour oesophageal bile monitoring (by spectrophotometry)

In the last decade, an optical fibre sensor has been developed which can spectrophotometrically detect bilirubin in the oesophagus as a marker of enterogastro-oesophageal reflux. A fibreoptic probe inserted transnasally into the oesophagus and positioned 5 cm above the manometrically determined HPZ is connected to an ambulatory spectrophotometer. The system is marketed under the name 'Bilitec 2000' (Figure 22.11). This device registers the presence of bilirubin when it detects an absorption peak around 453 nm. This peak is said to be easily detectable both in the bile spectrum and in the spectrum of gastric juice combined with other substances (e.g. bile, food, drinks and blood). The presence of bilirubin is, for practical purposes, equivalent to the presence of bile, and the detection of an absorption peak around 453 nm implies the presence of bile. The ambulatory spectrophotometer transfers the signals to a data logger and a 24-hour profile can be recorded. The data can then be offloaded to a computer and an absorbance curve (for 453 nm) is produced for the recording period (24 hours). An episode of bile reflux is defined as an increase in absorbance over 0.14 absorbance units. This threshold has been set arbitrarily to avoid false-positive results, which can be caused by the absorbance at 453 nm of dietary substances consumed during the test. It is important to use a standard diet avoiding coloured food substances and beverages during the test. In addition, bile reflux in an acidic medium ($\text{pH} < 3.5$) may be underestimated as a result of dimer isomerization of bilirubin and a shift in absorption wavelength in this environment. Further, in a few medical conditions (Gilbert and Dubin–Johnson syndromes), there is a disproportionate secretion of bilirubin compared to bile acids. This test is indicated in patients with symptomatic gastro-oesophageal reflux with

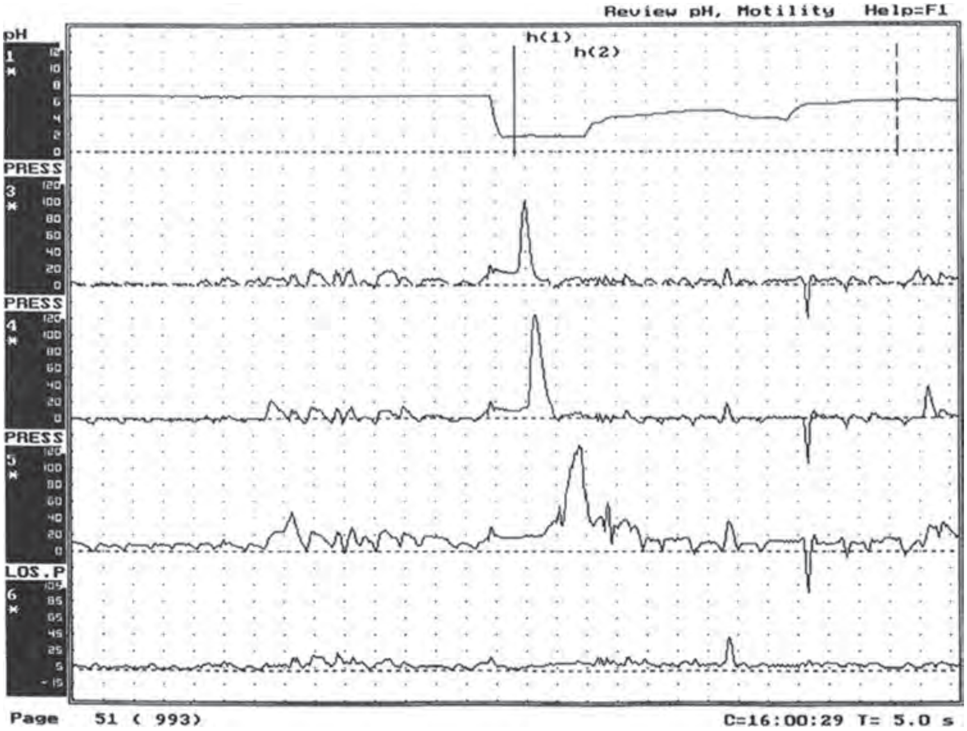

Figure 22.8 Part of a recording of 24-hour combined pressure and pH study showing the drop in pH in the lower oesophagus stimulating a peristaltic contraction to clear the oesophagus of the acid.

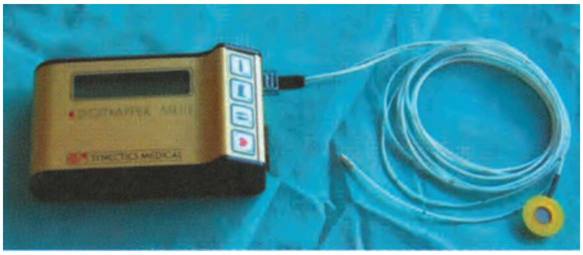

Figure 22.9 Portable recording device connected to a pH catheter with a surface electrode used for 24 hour pH monitoring.

poor response to an adequate dose of proton pump inhibitors (PPIs). It is also indicated in patients with complications of GORD such as Barrett's metaplasia, strictures and ulcers and in patients with reflux symptoms after gastrectomy. Normal values for this test have been published. Validation tests suggest that the overall accuracy of the system is sufficient for clinical use but not reliable enough to study disease mechanisms caused by duodenogastro-oesohageal reflux.

Bernstein's acid perfusion test

This detects oesophageal mucosal sensitivity to acid and is very useful in the determination of the oesophageal origin of chest pain. The patient is studied in the fasting upright position. A nasogastric tube is positioned in the middle of the oesophagus. Infusion is initially started with isotonic saline and then switched to 0.1 M HCl without informing the patient. Acid perfusion will reproduce the pain in patients with a sensitive oesophageal mucosa. After stopping the infusion the pain should subside by 20 minutes.

Motility disorders of the oesophagus

The oesophageal motility disorders are a continuum of functional conditions that affect the oesophagus and are diagnosed by the presence of specific manometric patterns assessing oesophageal peristalsis and LOS pressure and relaxation (Figure 22.12). Symptomatically, they are most frequently associated with dysphagia and chest pain and occasional regurgitative symptoms.

Although several authorities have attempted classification of the variety of abnormal manometric profiles encountered, none has found universal acceptance in the medical community, particularly as the clinical significance of many of these patterns remains unclear. More frequently, oesophageal motility disorders are classified as being of primary and idiopathic (where the oesophagus is the originating site of pathology but its exact cause is unknown) or secondary origin (oesophageal dysmotility being the result of a systemic condition) (Box 22.1).

This section will focus on those oesophageal motility disorders where characteristic radiological and manometric features have allowed for a well-formed clinical definition and the development of medical and surgical treatment modalities targeting both patient symptomatology and the pathophysiological process as it is currently understood.

Achalasia

Epidemiology

Achalasia (lit. failure to relax) is the most regularly diagnosed of the primary motility disorders with an annual incidence of 0.4–0.6/100 000 and point prevalence of 8/100 000 people.

pH Channel

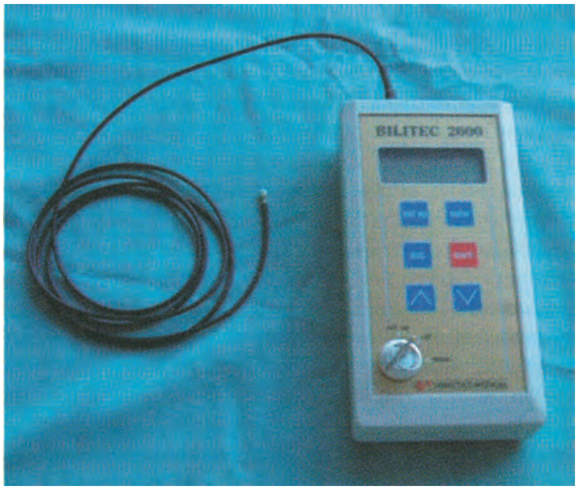

Figure 22.11 An ambulatory spectrophotometer connected to a fibreoptic probe used for prolonged ambulatory bile reflux monitoring.

Pathology

To date, no single aetiological factor has been identified as being causative of achalasia. However, histological analyses of oesophageal samples obtained at autopsy and during surgery have consistently demonstrated pathological changes in the myenteric (or Auerbach's) plexus. This network of nerves, a part of the enteric nervous system, is located between the longitudinal and circular muscles in the muscularis externa and provides motor innervation along the gut. The typical features seen in the plexus are a patchy inflammatory response with infiltration of T-lymphocytes, eosinophils and mast cells which eventually leads to neural fibrosis and permanent destruction of the postganglionic inhibitory neurones. These inhibitory neurones are responsible for the release of the neurotransmitters NO and VIP, which dampen the effects of postganglionic cholinergic neurones and result in relaxation of the LOS. As a result, there is an unopposed action of the cholinergic neurones, resulting in a permanently contracted lower oesophagus, one of two principal features of achalasia. Aperistalsis, the second cardinal sign of the condition, results from loss of the progressive neurotransmitter-mediated gradient that permits sequential contractions along the oesophagus.

Clinical features

Many symptoms are associated with achalasia, of which dysphagia and chest pain are the most prominent and frequently reported (Box 22.2). Dysphagia is the most common presenting symptom of achalasia with as many as 94% of patients reporting it in one study. It is usually gradual in onset and present in many cases for many years prior to presentation. The dysphagia will initially be intermittent and to solids only, progressively extending to fluids and is occasionally associated with regurgitation, particularly in the advanced stages when the oesophagus is dilated, and on lying flat, giving a sensation of vomiting or choking.

Chest pain and odynophagia are usually features of early achalasia when oesophageal dilatation is minimal and diminishes as the degree of widening increases. However, as mentioned, regurgitation also increases with dilatation, and some 90% of patients will produce a foamy mucoid saliva. Food stasis and carbonated drinks, which patients consume to empty the oesophagus, are speculated to ferment and produce dyspepsia (in up to 52% patients) and halitosis.

As might be expected, in very advanced achalasia the lack of peristalsis and oesophageal emptying can produce a massively dilated and tortuous oesophagus together with similarly severe

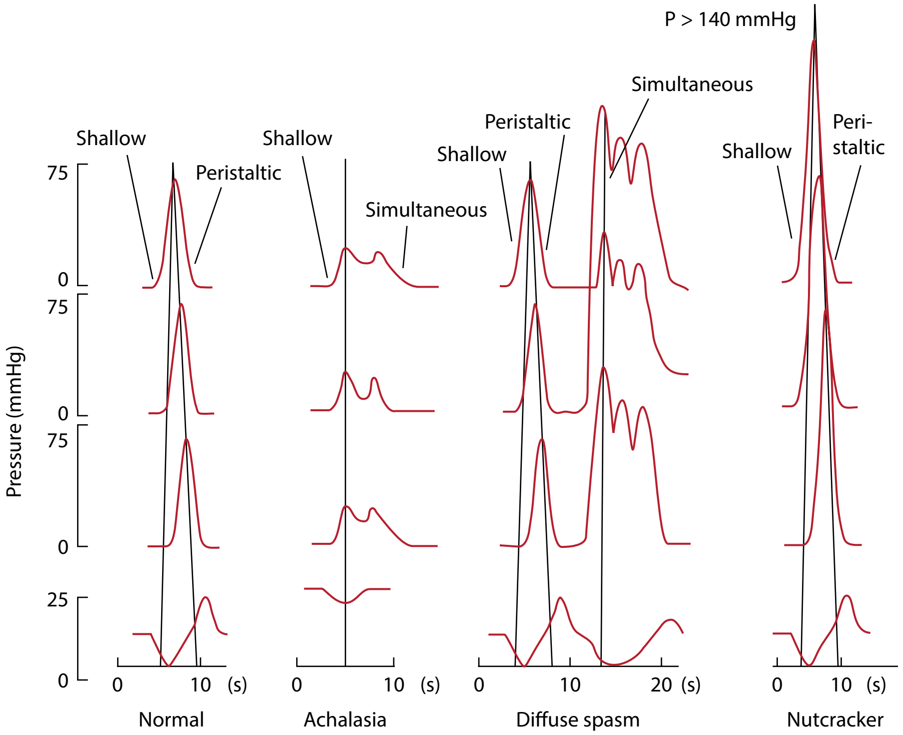

Figure 22.12 Schematic diagram summarizing the normal and disordered motility profiles.

BOX 22.1 Primary and secondary oesophageal motility disorders (note that this is not a comprehensive list of secondary disorders)

Primary causes of oesophageal motility disorders

- Achalasia
- Diffuse oesophageal spasm
- Hypercontracting oesophagus (hypertensive/nutcracker oesophagus)
- Hypocontracting oesophagus (ineffective oesophageal motility)

Secondary causes of oesophageal motility disorders

- Collagen vascular disease (e.g. systemic sclerosis)
- Diabetes mellitus
- Chagas disease
- Amyloidosis
- Alcohol excess
- Myxoedema
- Multiple sclerosis
- Idiopathic pseudo-obstruction
- Old age
- Dermatomyositis
- Systemic lupus erythematosus
- Malignancy

dysphagia, regurgitation, weight loss (as food is undigested), anaemia and respiratory complications, e.g. pneumonia.

As 3–7% of patients with achalasia develop cancer, it is important to have a high suspicious rate of cancer if patients develop new onset of symptoms. A repeat endoscopy is advisable in those patients.

BOX 22.2 Clinical features of achalasia

- Dysphagia
- Chest pain
- Regurgitation
- Odynophagia
- Dyspepsia
- Halitosis
- Weight loss
- Mega-oesophagus
- Anaemia
- Respiratory complications, e.g. pneumonia

Diagnosis

Although there are many symptoms that can be indicative of achalasia, as can be readily appreciated, they are very non-specific and consequently a more objective assessment is needed to confirm the diagnosis.

Radiology

Barium swallow with fluoroscopy has traditionally been the first-line investigation for suspected achalasia. However, with the advent of manometry, its role is diminishing, but remains important as a relatively cheaper and more easily accessible imaging modality.

In the early part of the disease, the study will usually show a normal diameter oesophagus, with some loss of normal peristalsis. Progressively, the disease will result in an increasingly dilated and tortuous oesophagus with retained food and saliva being demonstrated as an air–fluid interface. The classical features, however, will be of a dilated distal oesophagus which gradually

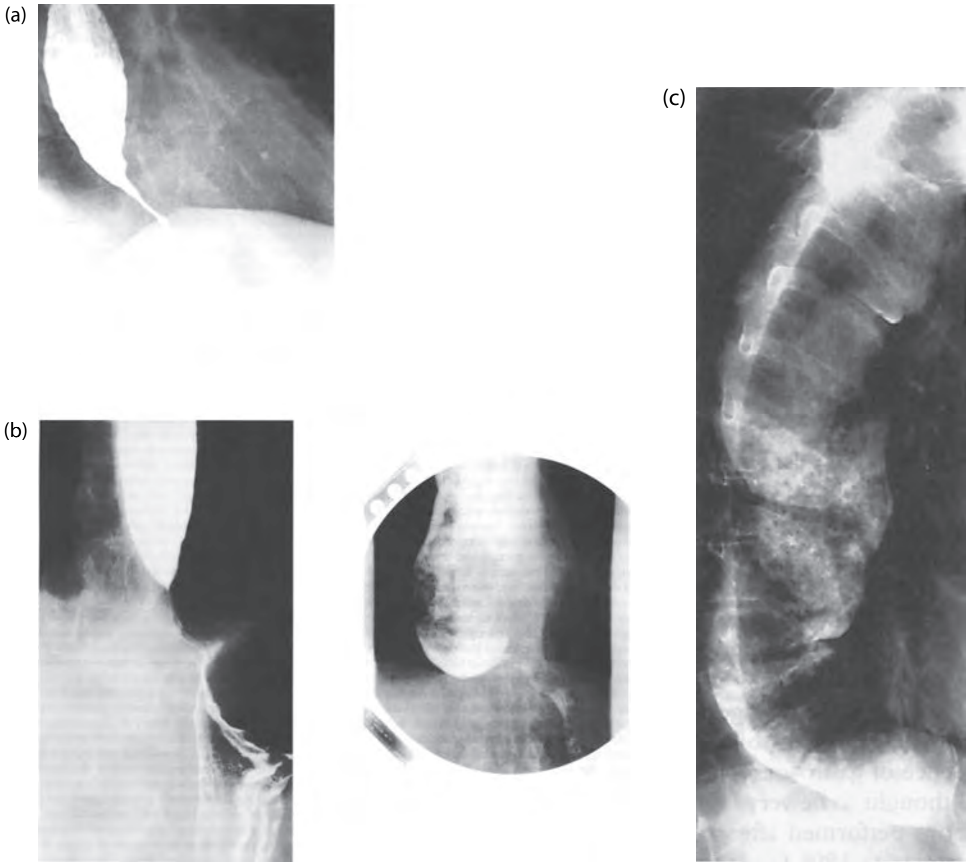

Figure 22.13 (a) Barium swallow in a patient with achalasia of the oesophagus is dilated above an apparent smooth narrowing of the cardia. The tapering of the oesophagus to the cardia has been likened to a 'bird beak'; (b) barium swallow showing grossly dilated sigmoid oesophagus in a patient with longstanding achalasia; (c) barium swallow in longstanding achalasia. The patients presented with total dysphagia and a neck lump which disappeared after insertion of a nasogastric tube. The grossly dilated and lengthened oesophagus has assumed a sigmoid shape. These patients do not benefit from cardiomyotomy and, if fit, are best treated by oesophagectomy with gastric tube replacement.

tapers at its lowermost portion giving an appearance of a 'bird's beak' (Figure 22.13).

Plain posteroanterior chest radiographs although of no significant diagnostic use can occasionally also show a soft-tissue shadow with a fluid level and an absent fundic air bubble in some 50% of cases and may be an indicator for further investigations in the undiagnosed individual.

Manometry

In the early stages of the disease, achalasia may not always show up on a swallow study due to the insufficient dilatation of the oesophagus. However, manometry is able to identify even the very earliest cases convincingly and confirm the diagnosis without significant delay. It is therefore increasingly becoming the first-line investigation when available (Figure 22.14).

Lower oesophageal, smooth muscle manometry is the most useful of all the available investigative techniques and regarded as the gold standard when diagnosing oesophageal motility disorders. Many investigators have propagated classification systems for dysmotility syndromes based on these unique manometric findings, but the findings have generally been too diffuse to produce any consistent, acceptable methodology.

However, in achalasia there is a clear known manometric pattern:

- Aperistalsis of the oesophagus is present and wet swallows are immediately followed by identical simultaneous contractions at an amplitude of 10–40 mmHg.
- There is an abnormal relaxation mechanism of the LOS associated with achalasia. Around 80% of patients will have either completely absent or incomplete relaxation on swallowing food or fluid, whereas manometry in the remaining 20%, which may exhibit complete LOS relaxation, is associated with short duration (<6 seconds) relaxations, which are functionally insufficient to completely empty the lower oesophagus.

Manometry has also led to the definition of a unique condition termed '*vigorous*' achalasia. This manometric entity has features of both classical achalasia and diffuse oesophageal spasm (DOS; see below), characterized by repetitive, high (or normal) amplitude aperistaltic oesophageal contractions occurring in concert with a non-relaxing LOS, where again the pressure might be high (>45 mmHg) in some 50% of patients. Clinically, it can be associated with a higher degree of chest pain than its classical counterpart but the remaining symptoms will be the same. Its management also differs very little from the standard therapy but surgical treatment, if indicated, will involve a longer myotomy extending from the level of the aortic arch to the GOJ.

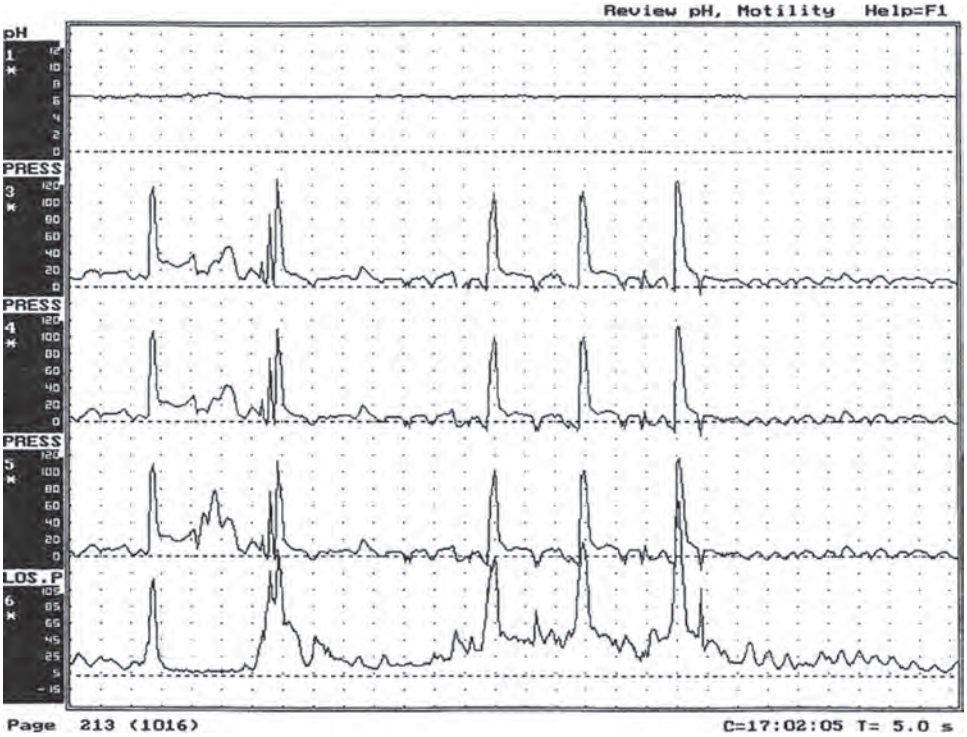

Figure 22.14 Manometric tracing obtained from a 24-hour combined pH and manometry study on a patient with achalasia. The top channel shows the pH in the lower oesophagus. Channels 3, 4 and 5 (5 cm apart in the body of the oesophagus) show aperistaltic contractions in the oesophagus, and channel 6 (in the lower oesophageal sphincter) shows failure of relaxation.

Endoscopy

Endoscopy, alongside endoscopic ultrasound (EUS) and CT, is not regarded as a direct diagnostic tool for achalasia. However, it is vitally important to exclude any organic pathology such as oesophagitis, reflux and gastro-oesophageal malignancy which may mimic its symptomology. Consequently, oesophagogastric duodenoscopy (OGD) should be carried out in patients presenting with dysphagia and chest pain. In the hands of an experienced endoscopist, evidence of reduced peristalsis and food stasis may be evident in advanced achalasia and again be an indication for further definitive investigation with barium swallow studies or manometry.

Management of achalasia

Several treatment modalities have been developed over the past century to treat achalasia, although none is consistently able to restore oesophageal peristalsis and normal relaxation of the LOS. Medical and surgical treatments are therefore used for symptomatic control by reducing the pressure gradient across the LOS, thereby reducing stasis in the lower oesophagus and its associated complications.

Medical treatment

Pharmacological treatment methods have traditionally been reserved for frail, elderly patients, those who have significant comorbidities or individuals who are unwilling to undergo surgical intervention, which appears to achieve the most sustained symptomatic control in affected patients.

Calcium channel blockers and long-acting nitrates have been used to reduce LOS spasm. Long-acting nitrates in particular are able to partially antagonize the effects of the unopposed postganglionic cholinergic fibres and have been shown to reduce LOS pressure by 66% for up to 90 minutes at a time. As a result it is often taken prophylactically or before meals to aid oesophageal emptying. An initial response is seen in as many as 70% of patients; however, its efficacy diminishes over time. A recent Cochrane Library analysis has also reported that there is insufficient evidence to give suitable implications for its off-licence use in achalasia.

Endoscopic injection of botulinum

Endoscopic injection of botulinum toxin A into the LOS has also been vigorously advocated in recent years as an effective treatment that can be readily repeated as required. The toxin, produced by a member of the *Clostridium* family, inhibits acetylcholine release at the postganglionic nerve terminals (which is responsible for the increased LOS tone), thereby, in essence, replacing the natural inhibitory function of the damaged postganglionic NO and VIP neurones. Botulinum is effective for short-term symptom control in 85–90% of patients but symptoms tend to recur within 6 months in up to 50% of cases. As with oral agents, the effectiveness of botulinum tends to reduce with repeated injections.

Both oral therapy and endoscopic injection of botulinum toxin, although useful temporizing measures for symptom relief in the short term, remain inferior to pneumatic balloon dilatation and myotomy as more definitive treatment options. Furthermore, a recent Cochrane review confirmed that pneumatic balloon dilatation offers greater symptom control over a period of 6–12 months than botulinum injection.

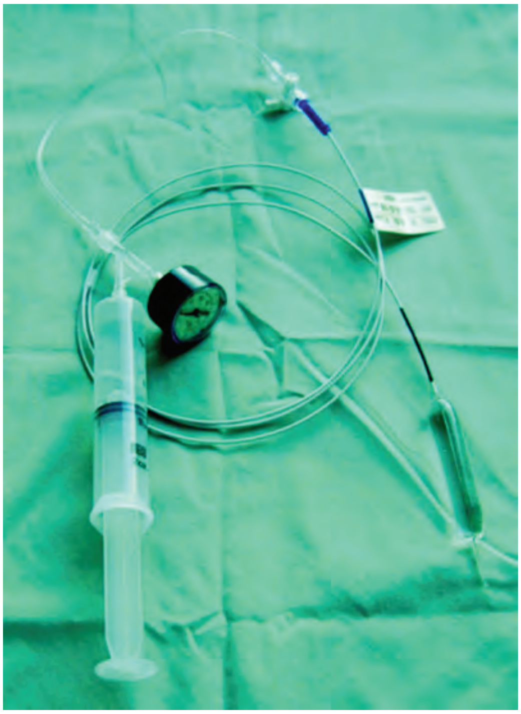

Figure 22.15 Hydrostatic polyurethane balloon dilator.

Pneumatic dilatation

Pneumatic dilatation has been used in clinical practice for many decades and involves endoscopically employing a deflated 30–40 mm diameter balloon across the LOS (Figure 22.15). This can be carried out via endoscopy or under fluoroscopy. On inflation of the balloon, which is usually performed no more than twice in the same sitting, the muscle fibres of the LOS are spread apart and torn. Patients tend to recover very quickly from the procedure, which can be performed in the outpatient setting, with studies showing symptomatic relief in 60–93% of patients, with the response being proportional to the diameter of the balloon deployed. Simultaneous fluoroscopy is frequently employed at the time of dilatation to show the passage of contrast (and food) into the stomach, indicating the success of the procedure.

Although its symptomatic control is excellent, the procedure is associated with a 2% risk of oesophageal perforation and gastro-oesophageal reflux. Additionally, some 30% of patients may require a further dilatation and around half will develop symptom recurrence over a 5 year period.

From a surgical perspective, balloon dilatation (together with botulinum infiltration) may result in scarring and destruction of the surgical planes at the GOJ and therefore may make subsequent cardiomyotomy more difficult and prone to a more uncertain outcome. However, in expert hands the effect of previous balloon dilatation or botulinum infiltration on surgery is minimal.

Surgical treatment

Laparoscopic cardiomyotomy

The standard surgical management of achalasia is laparoscopic cardiomyotomy. The myotomy that was described by Heller in 1913 involved performing two myotomies, one anteriorly and the other posteriorly, on the oesophagus. The procedure was refined by Zaaijer in the 1920s with a single myotomy being made only on the anterior surface. The current standard clinical practice is performing myotomy of the muscle coat of the distal oesophagus up to the dilated segment as well as 2–3 cm of proximal stomach. The vagus nerve should be identified and protected (Figure 22.16). Great care should be taken to avoid injury to the mucosa. Although several methods are used to divide the muscle layer to expose the mucosa, the authors' preference is distraction of the muscle using graspers without any use of energy devices such as diathermy or harmonic dissectors in order to avoid late diathermy injury. Some surgeons use a balloon to distend the GOJ and facilitate division of the muscles. Modern practice may also involve performing a partial fundoplication to prevent postoperative gastro-oesophageal reflux (Figure 22.17).

Overall surgical approaches to achalasia have managed to achieve good outcomes in 80–100% of patients with poor results being usually attributed to poor surgical technique (incomplete myotomy) or development of gastro-oesophageal reflux (due to insufficient fundoplication). The procedure has an associated morbidity of approximately 0.1%.

Although, surgery has been widely accepted as the gold standard intervention, patients are still carefully selected usually on the following criteria:

- symptom recurrence despite endoscopic therapy (botulinum infiltration and balloon dilatation)
- severe symptoms
- children in whom morbidity is increased by repeated procedures.

Several areas of debate have arisen over the years as to the best techniques:

- *Laparoscopy vs thoracoscopy.* The first laparoscopic Heller's myotomy was reported in 1991. As in the open era, the thoracoscopic approach

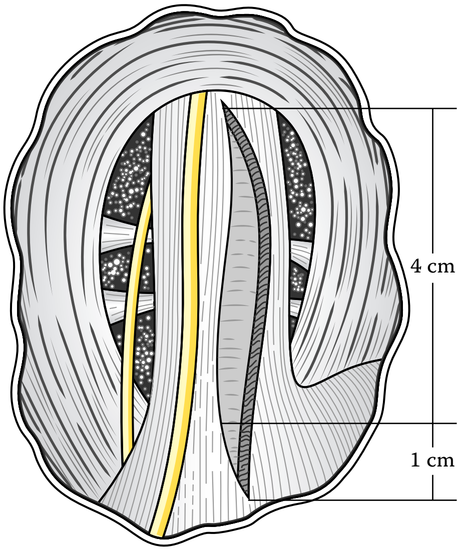

Figure 22.16 Schematic representation of modern cardiomyotomy with protection of the anterior vagus nerve.

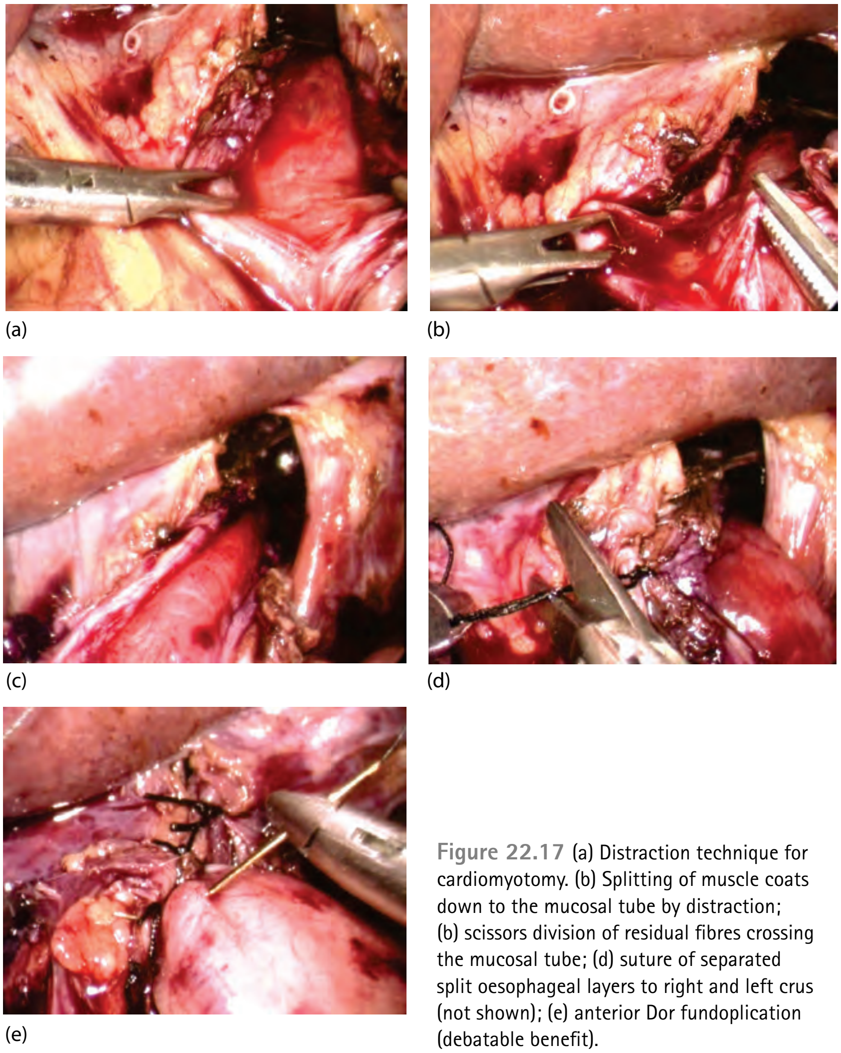

(a) (b) (c) (d) (e)

Figure 22.17 (a) Distraction technique for cardiomyotomy. (b) Splitting of muscle coats down to the mucosal tube by distraction; (b) scissors division of residual fibres crossing the mucosal tube; (d) suture of separated split oesophageal layers to right and left crus (not shown); (e) anterior Dor fundoplication (debatable benefit).

was also initially popular due to the access it afforded to the oesophagus. However, as in the open era, the same problems with complex anaesthesia and high rates of reflux ensued. Around the same time, it was being increasingly recognized that the myotomy should extend some 2–2.5 cm into the cardia to achieve the best results and that a fundoplication procedure aided in substantially reducing reflux (from 48% with myotomy alone to 9% when combined with a posterior fundoplication). Access to the stomach was easier via laparoscopy once again.

- *Complete (Nissen's) vs incomplete (Toupet/Dor) fundoplication.* In cases of gastro-oesophageal reflux, a 360° Nissen-type fundoplication is favoured, which mimics the action of the LOS to control symptoms. In achalasia, where peristalsis is absent and the LOS contracted, a total fundoplication can further impair the LOS and result in persistent dysphagia. One long-term study found that 82% of patients who had undergone myotomy with a Nissen's fundoplication developed recurrent dysphagia over a 10 year period. Additionally, a study comparing an anterior partial fundoplication (Door) to Nissen's fundoplication with myotomy showed dysphagia occurring in 2.8% and 15% of patients respectively over a 5 year period.
- *Anterior partial (Door) vs posterior partial (Toupet) fundoplication.* At present no randomized trials have reported on the superiority of the two types of partial fundoplication in aiding symptomatic relief. At the time of writing, a prospective European, multicentre randomized controlled trial comparing the two procedures is ongoing, examining postoperative pH monitoring evidence of gastro-oesophageal reflux. Proponents of the posterior approach argue that the myotomy is kept separated whereas those advocating the anterior approach contend that the mucosa can be covered to prevent reflux and there is no need for a posterior dissection, making the procedure faster. Many studies have shown a >90% improvement in dysphagia via the anterior approach.
- *Laparoscopic cardiomyotomy vs balloon dilatation.* There has been a renewed interest in re-examining the efficacy of balloon dilatation compared with the best surgical treatment. A multicentre European trial reported that, in 201 patients who had undergone pneumatic dilatation of laparoscopic Heller's myotomy with a Dor fundoplication, therapeutic success of both procedures at 1 and 2 years was equivalent at approximately 90% with no difference of pressure at the LOS after 2 years. This study would suggest that, although surgery has an important role in achalasia treatment, more marginal surgical patients may benefit equally from dilatation therapy.

Recently several groups have reported initial results with single incision, robotic and per oesophageal myotomy techniques. Although the results appear promising in relation to symptomatic relief and reduction of intraoperative oesophageal perforation, there is at the moment scant evidence to suggest whether these techniques will surpass the current open and laparoscopic approaches.

Oesophagectomy

Subtotal oesophagectomy with anastomosis in the neck is sometimes performed for selected indications such as (1) end-stage achalasia and mega-oesophagus as cardiomyotomy might not be sufficient; and (2) in patients with recurrent achalasia after redo surgery. Non-functioning oesophagus with severe symptoms, inability to maintain weight and recurrent chest infections are the indications for oesophagectomy in those cases. Minimally invasive or transhiatal oesophagectomy are the approaches that are frequently used.

Diffuse oesophageal spasm

DOS is the presence on manometry of simultaneous, uncoordinated contractions of the distal oesophagus in individuals with an otherwise normal peristalsis amplitude and duration and normally responsive LOS.

Epidemiology and pathology

This pattern is found in around 3–5% of individuals undergoing manometry for investigation of suspected oesophageal motility disorders, with patients generally being older than 50 years.

Neural dysfunction has been suggested as a possible cause in DOS, as patients have been found to be hypersensitive to the hormone pentagastrin and cholinergic stimulations. Emotional distress and olfactory stimuli have additionally been implicated in the development of abnormal oesophageal contractions, suggesting a more functional aetiology as the driver for DOS.

Clinical features

Patients are frequently found to have emotional liability with recurrent food- and exercise-induced chest pain being the most reported symptom. Confusingly for the patient and investigating physician, the pain can be very similar in nature to cardiac chest pain (i.e. substernal/left sided, constrictive with radiation to the back, jaw) and may even be responsive to nitrates. Patients will often present to the surgical clinic having had extensive cardiac investigations and a normal coronary angiogram. The more classical oesophageal dysmotility symptoms of dysphagia and reflux are usually much less severe, intermittent and non-progressive. Dysphagia can arise as a result of stress, cold fluid intake, rapid eating and extreme cold/warmth.

Female patients in particular may give a history of irritable bowel syndrome. Interestingly, patients with DOS may progress to display clinical and manometric features of achalasia, which has led some investigators to suggest some overlap, and indeed continuity, between the conditions.

Diagnosis

Owing to the considerable clinical overlap with GORD and angina combined with the advancing age of patients, it is important to investigate patients with a cardiac work-up and consider an OGD to further exclude any organic pathology at the GOJ. Additionally, a trial period of high-dose PPIs may prove useful, especially where the diagnosis remains unclear as some 80% of patients with gastro-oesophageal reflux-related chest pain will report an improvement, whereas only 20% of patients having chest pain without gastro-oesophageal reflux experience symptomatic relief with PPIs.

Manometry

Manometry will demonstrate normal peristaltic contractions, interrupted by simultaneous contractions in more than 20% but less than 100% of wet swallows (the presence of continuous simultaneous contractions is diagnostic of achalasia). The LOS is grossly unaffected

Further tests

Radiological assessment is highly variable and does not seem to be of any specific diagnostic value. However, an ambulatory 24-hour pH monitoring study is useful for picking up cases of GORD, which can concurrently occur in up to 50% of patients.

Barium swallow may demonstrate repetitive tertiary contractions which cause the typical, diagnostic corkscrew appearance. However, this is found in only in 30% of patients (Figure 22.18).

Treatment

If underlying organic pathology such as angina and malignancy has been excluded, often simple reassurance that patient symptoms are benign and not life threatening will be sufficient treatment alone. Furthermore, it is important to treat comorbidities

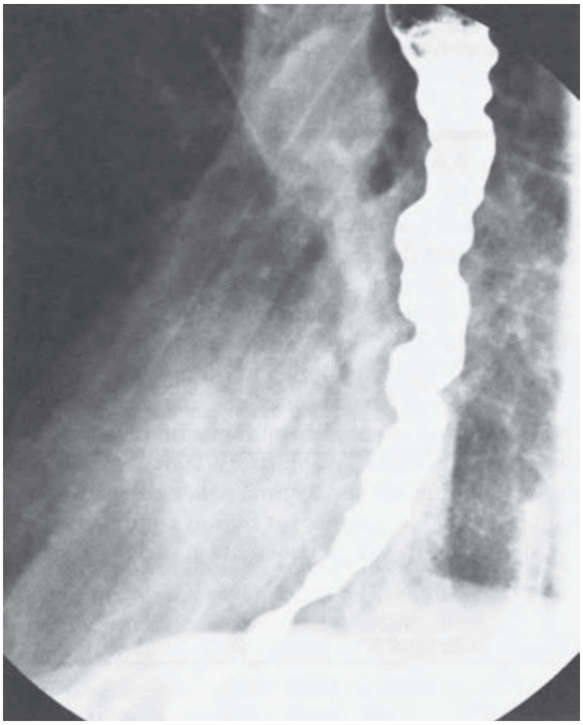

Figure 22.18 Barium swallow in a patient with diffuse oesophageal spasm showing 'corkscrew' appearance but this is only found in 30% of patients.

such as GORD which might be coincidentally identified over the course of the investigation process.

Lifestyle interventions

- Avoid spasm triggers, e.g. dietary modification to soft foods and liquids and stress reduction.
- Reduce smoking and alcohol intake as both are associated with an increase in acid reflux and subsequent oesophageal spasm.

Oral therapy

- Nitrates, e.g. glyceryl trinitrate, isosorbide dinitrate, reduce oesophageal contractile pressure and promote normal peristalsis.
- Calcium channel blockers, e.g. nifedipine, diltiazem.
- Anticholinergics, e.g. atropine, hyoscine.
- Phosphodiesterase type 5 inhibitors, e.g. sildenafil, result in increased local NO concentration in the neuronal terminals by inhibiting breakdown but can be associated with cardiovascular complications.
- Antidepressants, e.g. trazodone, imipramine, reduce patient discomfort but without significantly impacting the pathology. They reduce chest pain in the short term (1–3 months) in 50% of patients.

All the oral agents can reduce high-amplitude oesophageal contractions but are not always effective for symptomatic relief of chest pain. Additionally, none of the above medications is specifically licensed for the treatment of DOS in some countries.

Endoscopic injection of botulinum

Botulinum toxin (see above) is injected at multiple sites along the oesophagus and within the LOS itself. It has been found to completely resolve symptoms in around 50% of patients with a mean duration of 7 months.

Surgical treatment

In patients with intractable symptoms, which are unresponsive to medical therapy, a long surgical myotomy, extending from the level of the aortic arch to the GOJ, is the preferred intervention. However, the results are extremely variable and frequently not useful in improving the patient's symptoms. Thoracoscopic long myotomy may improve chest pain but not dysphagia.

Hypercontracting oesophagus

Hypercontracting oesophagus is a term used to describe individuals who have manometric oesophageal contraction pressures that are two standard deviations above the mean. These patients are further divided into two subgroups.

Hypertensive (nutcracker) oesophagus

The hypertensive oesophagus describes a situation when extremely high-amplitude contractions, greater than 180 mmHg, occur either throughout the oesophagus or in its distal portion. The term is also used when duration of distal peristalsis is >6 seconds, which will subsequently also generate persistently high pressures in the lower oesophagus. Apart from the contractions that are of increased pressure, all other contractions are seemingly unaffected, suggesting that the condition is intermittent.

Hypertensive lower oesophageal sphincter

The LOS is said to be hypertensive when its resting pressure exceeds 45 mmHg; however, peristalsis is usually unaffected.

Interestingly, manometry can often indicate the duality of the two conditions, which has led to the suggestion that they jointly represent a syndrome of hypercontractile oesophagus rather than two distinct entities. As is common with all primary oesophageal motility disorders, to date no aetiological agent has been identified and patients usually have the non-specific symptoms of chest pain (occurs in up to 48% of patients) and dysphagia.

Treatment

Treatment is along the same lines as DOS but the results can be unpredictable. Weak sedatives, antidepressants, behavioural therapy with biofeedback have also been employed to varying levels of success.

Hypocontracting oesophagus (non-specific oesophageal motility disorders)

This group of disorders describes those patients who present with a wide variety of abnormal manometry patterns that do not conform to the classical primary motility disorders but are nonetheless associated with debilitating symptoms. The non-specific motility disorders can broadly be divided into two subgroups.

Ineffective oesophageal motility

Many patients who have non-specific oesophageal motility disorders will have manometry tracings that demonstrate:

- low-amplitude (<30 mmHg) peristaltic contractions (real-time contrast studies of the oesophagus have demonstrated that an amplitude of 30 mmHg is needed to clear the oesophagus)
- simultaneous contractions of the distal oesophagus
- incomplete peristalsis (where propagated peristalsis waves do not cross the whole length of the oesophagus).

These physiological states prevent an adequate clearance of food and debris into the stomach, and consequently patients are termed to have ineffective oesophageal motility. Dyspepsia and heartburn are more common symptoms and patients are frequently noted to have gastro-oesophageal reflux and ENT complaints.

Hypotensive lower oesophageal sphincter

This patient group has a diminished LOS pressure (<10 mmHg; normal, 10–45 mmHg), which is often associated with gastro-oesophageal reflux. This would suggest that the hypocontractility of the oesophagus is the result of reflux-induced acidic damage at the distal oesophagus.

At present, no medication is available to increase peristaltic amplitude. Cisapride (a serotonin receptor agonist acting as a prokinetic agent) was previously used but withdrawn in 2000 due to a significant association with cardiac arrhythmias. Other prokinetic agents such as metoclopramide and domperidone may encourage oesophageal emptying whereas PPIs may help to inhibit the acid reflux and resultant damage at the LOS.

Motility disorders secondary to systemic disease

Secondary motility disorders are the result of a systemic illness causing oesophageal symptoms that mimic those of the primary dysmotility disorders (Box 22.3). Patients are however generally older, with a shorter duration of symptoms and will normally have signs indicating systemic illness.

It is vitally important that patients are thoroughly investigated to exclude not only a primary motility disorder but, more importantly, a malignant condition, such as GOJ tumour, which can often give symptoms similar to achalasia. Treatment will be dependent on the underlying abnormality and findings of manometry but some patients who are otherwise healthy may benefit from pneumatic balloon dilatation.

Although a variety of treatment options are available to treat various conditions, it is important to recognize that oesophageal motility disorders remain a relatively less understood and underappreciated area of surgical practice whose distressing symptoms can result in significant malnutrition, social disability and chronic morbidity. Patients should be investigated thoroughly and treated promptly. It is important to remember that interventions aim to improve the quality of life of those patients and therefore surgery should not be taken lightly if the risks are high and outweigh the benefits desired.

Gastro-oesophageal reflux disease

Introduction

GORD is a chronic, relapsing condition and is one of the commonest reasons for attending primary care. There is a clinical spectrum of disease severity, encompassing patients with mild symptoms to those who require surgical intervention to gain symptomatic control. In the developed world, an approximate prevalence of 10–20% for GORD (defined by at least weekly heartburn and/or acid regurgitation) has been identified whereas in Asia this is lower (at <5%). The incidence in the developed world is estimated to be approximately 5 per 1000 person years. GORD is a significant disease burden and the health service costs associated with GORD are considerable. An estimated four or five per 10 000 people aged 18–60 years take maintenance PPIs for oesophagitis and/or reflux, with the annual drug budget for PPIs in the NHS (UK) in excess of £300 million.

BOX 22.3 Some of the systemic diseases that can present with oesophageal dysmotility (the secondary oesophageal motility disorders)

- Collagen vascular disease (e.g. systemic sclerosis)
- Diabetes mellitus
- Chagas disease
- Amyloidosis
- Alcohol excess
- Myxoedema
- Multiple sclerosis
- Idiopathic pseudo-obstruction
- Old age
- Dermatomyositis
- Systemic lupus erythematosus
- Malignancy

Aetiology of GORD

The aetiology of GORD is complex and multifactorial in nature. Several studies have shown that there is no association between sex and GORD (despite there being a significant association between pregnancy and GORD). The effect of increasing age on the prevalence of GORD is unclear, with two European studies showing a slight but significant association. However, both the UK GP database study and Georgia Medicaid study showed an increase in the incidence of GORD symptoms up to the ages of 69 years and 55 years, respectively, after which time the trend reversed. Increasing prevalence of GORD is associated with higher body mass index, and the Georgia Medicaid study reported a clear positive relationship between GORD diagnosis and obesity [odds ratio 2.8 (95% confidence interval 2.1–3.6)]. Population-based studies comparing reflux symptoms in monozygotic and dizygotic twins have shown that genetic factors might contribute by 31% to the aetiology of symptomatic GORD. Although demographic and genetic factors may have a role in the development of GORD, reflux is likely to be mainly caused by environmental factors. Several behavioural factors are thought to trigger gastro-oesophageal reflux episodes and these include:

- tobacco smoking
- increased salt intake
- excess alcohol consumption
- coffee consumption.

An increased incidence of GORD has also been demonstrated with the use of certain prescription medications. The current use of aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), nitrates, tetracyclines and anticholinergic drug therapy has been significantly associated with an increased incidence of GORD. The past/current use of oral steroids has also been identified as a contributing factor in the development of GORD symptomatology.

There are several comorbidities that have been linked with an increased diagnosis of GORD. These include hiatus hernia, peptic ulcer disease, hypercalcaemia, Zollinger–Ellison syndrome, asthma, irritable bowel syndrome and depression. Physical exercise has been identified as the only protective lifestyle factor in reducing GORD symptomatology. Several studies have indicated that cagA-positive *Helicobacter pylori* infection may have a protective effect against GORD. However, this remains a controversial topic and it should be noted that cagA-positive *H.*

pylori is a known causative factor for both duodenal ulceration and gastric cancer.

Pathophysiology of GORD

Maintenance of the oesophageal mucosal integrity is essential in preventing symptomatic GORD. There are three mechanisms that are thought to be responsible for maintaining this oesophageal mucosal integrity:

- a pre-epithelial defence mechanism consisting of bicarbonate ion, mucus and epithelial growth factors. Submucosal glands are believed to neutralize acid reflux during sleep (note that salivary secretion is decreased at this time)
- resistance to transmucosal ion diffusion due to intercellular junctional complexes and lipid matrices
- the Na^+/H^+ antiporter maintains intracellular pH by inhibition of free-radical production and increasing cell turnover when damage has occurred.

However, once this mucosal barrier is breached, the function of these protective mechanisms is reduced. This creates the environment in which two physiological factors interact to lead to the development of symptomatic GORD. The occurrence of GORD is closely related to transient relaxation of the LOS and increased gastric acid secretion. The failure of the LOS to maintain its role in the antireflux mechanism is the main contributing factor in the pathophysiology of GORD. The resting tone of the LOS pressure is usually between 10 and 25 mmHg. The muscles of the LOS have specific physiological functions and are thought to be mediated via the vagovagal reflex pathway in response to the activation of stretch receptors in the stomach. The LOS is also subject to neuroendocrine influences. Several drugs, hormones and food substances are known to influence the contractility of the LOS. The resting tone of the LOS increases following the administration of gastrin, cholinergic and -adrenergic agents, and decreases with secretin, cholecystokinin and glucagon activity. It has been shown that foods with high fat content, coffee and nicotine from cigarette smoke reduce the LOS pressure.

There are also several factors that may contribute to LOS dysfunction. These include:

- the length of the intra-abdominal segment of the oesophagus
- the diaphragmatic crural mechanism
- the angle of His
- impaired gastric emptying.

The principal physiological components of gastric juice are acid and pepsin. Exposure of the oesophageal mucosa to gastric refluxate, principally gastric acid, is the other major factor in the pathophysiology of GORD. The importance of acid (pH <4) for reflux perception was first demonstrated in a prolonged pH monitoring study by DeMeester *et al.* In this landmark study, the frequency of acid reflux and the mean distal oesophageal acid exposure time were both significantly greater in consecutive patients with typical reflux symptoms (heartburn and/or regurgitation) or dysphagia than in asymptomatic controls. Reflux components other than acid, such as bile from duodenogastro-oesophageal reflux and pepsin, have also been known to contribute to symptom perception in patients with GORD. Pure alkaline reflux is rare and occurs in patients who have undergone gastric resection/bypass or in conditions causing achlorhydia (e.g. pernicious anaemia, somatostatinomas).

The majority of patients with GORD can be categorized into one of three groups with impaired LOS function:

- patients with a hypotensive resting LOS pressure of less than 6 mmHg have free reflux of gastric contents into the lower oesophagus
- patients with a borderline oesophageal sphincter pressure and intermittent increases in intragastric pressure – 'stress reflux'
- patients with an increased frequency and duration of transient LOS relaxations are termed as 'reflex reflux'. This group accounts for 40% of patients with GORD and 65% of patients with reflux oesophagitis.

Pathological changes associated with GORD

The normal oesophageal mucosa consists of three layers: the basal (germinal layer), the prickle cell layer (polygonal cells with numerous bridges) and the superficial or functional layer (flattened cells with pyknotic nuclei). In normal oesophageal mucosa, there are few inflammatory cells and the vascular dermal papillae project from the lamina propria to no more than half the thickness of the epithelium. The histological changes of early mucosal damage include widening of the basal layer so as to constitute more than 15% of the total epithelial thickness. In addition, the dermal papillae extend to more than two-thirds of the way through the epithelium to the luminal surface. These changes indicate an increased rate of epithelial cell turnover. With severe damage, there is accumulation of polymorph inflammatory cells. It has been demonstrated that inflammatory cytokines play an important role in inducing early inflammatory changes in patients with GORD. Specifically, interleukin (IL) 8 and IL-6 produced by leucocytes act together to induce oxidative stress mechanisms which contribute to mucosal inflammation. Studies have also shown that IL-8 gene expression is increased in both patients with GORD and those with non-erosive reflux disease (Figure 22.19).

Pathophysiological and clinical studies have shown that cagA-positive *H. pylori* infection may be protective against the development of symptomatic GORD. However, this protective effect is dependent on the extent of *Helicobacter*-induced corpus gastritis with severe corpus gastritis causing profound reduction of acid secretion.

Symptomatology of GORD

Typical symptoms of GORD include heartburn and regurgitation. When heartburn occurs on more than 2 days of each week, the patient is considered to have severe heartburn and probably GORD. According to the Montreal Consensus group's classification, GORD develops when the reflux of stomach contents causes troublesome symptoms and/or complications (e.g. oesophagitis). The characteristic GORD symptoms included in this statement are retrosternal burning

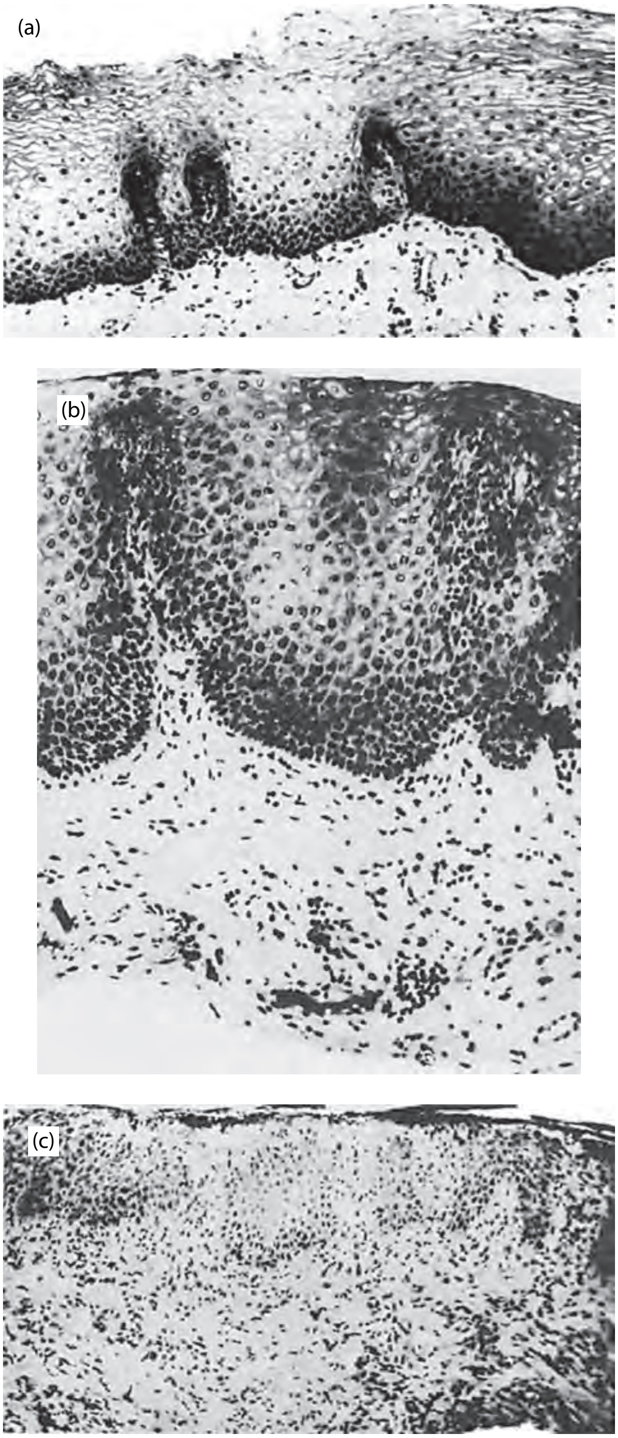

Figure 22.19 (a) Suction biopsy of the lower oesophageal mucosa. Normal histology: the basal layer is less than 15% of the total epithelial thickness. The papillae of the lamina propria extend less than two-thirds of the way to the luminal surface. No polymorphonuclear leucocytes are present in either the lamina propria or epithelium. Mononuclear cells, normal constituents of the lamina propria, are present. (b) Mild to moderate oesophagitis due to acid reflux. The basal layer occupies about 30% of the total epithelial thickness and the papillae extend nearly to the surface. No polymorphonuclear leucocytes are present. (c) Severe gastro-oesophageal reflux with gross erosion and exudate visible endoscopically. The total epithelial thickness is less than normal and is composed entirely of basal cells. The papillae are widened and extend all the way to the luminal surface where superficial necrosis is present. Many polymorphonuclear leucocytes are present in the lamina propria and within the epithelium.

and regurgitation. The term 'troublesome' is specifically included in the definition and is meant to imply that these symptoms impact on the wellbeing of affected individuals (i.e. quality of life).

Heartburn is the most common manifestation of GORD, which may occur in up to 50% of the population. Some patients report severe heartburn, yet on OGD there is little or no evidence of mucosal inflammation. These patients can still have reflux with an abnormal oesophageal mucosal sensitivity. Heartburn is often worsened by a supine position or an increase in intra-abdominal pressure. Heartburn symptoms may also be worsened by fatty meals or intake of alcohol. This symptom can increase in intensity until it is perceived as chest pain.

Regurgitation results from regurgitation of gastric fluid into the throat accompanied by a sour taste in the mouth. Regurgitation is positional and patients will report worse symptoms at night when lying down in bed. Postural regurgitation by meals and activities is associated with a rise in the intra-abdominal pressure (i.e. straining).

Water brash is an uncommon symptom that specifically occurs in patients with GORD. It is due to excessive salivation and the mouth becomes full of fluid.

Other symptoms that can be associated with GORD include dysphagia, odynophagia and chest pain (due to oesophagitis).

Complications of GORD

The complications of GORD are less common since the advent of PPIs. However, they can include reflux oesophagitis, ulcerative oesophagitis, formation of strictures and webs.

Reflux oesophagitis

The development of endoscopically identifiable changes in oesophageal mucosa represents a complication of GORD. A variety of grading systems have been suggested to reflect the severity of the oesophagitis. The most useful grading systems for this purpose include Savary–Miller and the 'Los Angeles classification'. However, a significant proportion of patients with reflux oesophagitis are asymptomatic and monitoring of their disease is important.

Ulcerative oesophagitis

This complication is usually only found in patients with longstanding disease. These patients tend to have more severe reflux and are more symptomatic. The ulcers are beyond the submucosal oesophageal layer and result in perioesophagitis and extensive mural fibrosis. This can eventually lead to stricture formation and oesophageal shortening. Anaemia through chronic blood secondary to ulceration can occur but full thickness perforation is extremely rare.

Oesophageal strictures and webs

Oesophageal webs are the result of submucosal fibrosis in a localized area of the oesophagus, most commonly due to ulcerative oesophagitis (Figure 22.20). They can cause symptoms

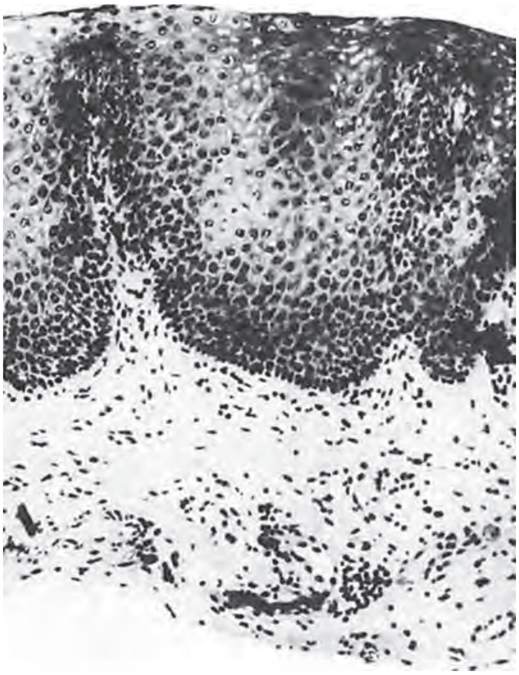

Figure 22.20 Barium swallow showing a Shatski's ring just above the gastro-oesophageal junction causing hold up to the flow of barium in a patient presenting with dysphagia.

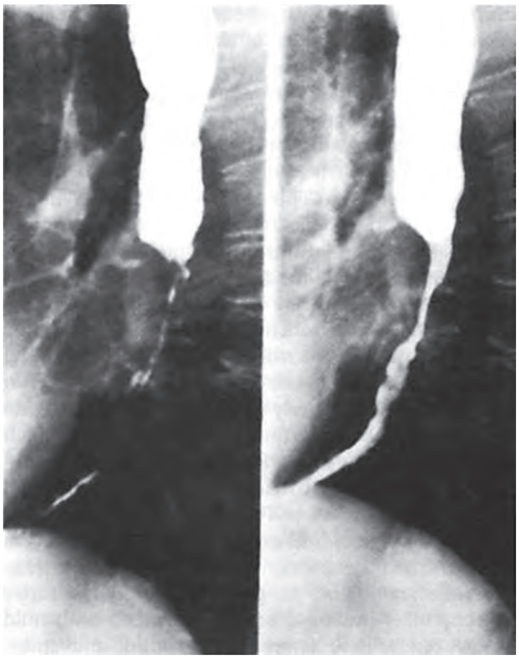

Figure 22.21 Barium swallow showing severe reflux stricture. It exceeds 3.0 cm in length.

of dysphagia and are amenable to endoscopic balloon dilatation. Stricture formation is the result of repeated oesophageal damage with fibrosis replacing the muscular coat of a segment of the oesophagus (Figure 22.21). Oesophageal stricturing occurs in approximately 10% of patients with GORD. The majority of these patients tend to be over 65 years and have a history of longstanding disease.

Treatment of GORD

Treatment of GORD includes a range of options and can be divided into three progressive steps. The first is changes to lifestyle whereby patients are advised to lose weight if overweight, reduce smoking/alcohol consumption and to alter dietary and sleeping patterns. Posture advice includes sleeping propped up to 45°, which can give significant symptomatic relief for those with mild symptoms. The second tier of treatment is the use of acid suppression therapy, using either PPIs or histamine receptor antagonists (H_2-receptor blockers). Acid suppression therapy can be intermittent, but once started on medication the majority of patients with significant GORD remain on long-term treatment. Antireflux surgery is currently considered within the third tier of management. It is usually confined to patients with severe symptoms who have failed medical therapy or whose symptoms are not sufficiently controlled. The treatment choice for GORD is very much dependent on the severity and persistence of symptoms and/or onset of complications. The main aim in the management of GORD is to improve the quality of life in these patients by either complete symptom resolution or maintenance of symptomatic control.

Medical treatment

Medical treatment is indicated when symptoms of GORD are persistent. Antacids (e.g. Gaviscon) can provide symptomatic relief in mild cases. However, neutralization and/or suppression of intragastric acidity remain the mainstay of modern medical therapy. By reducing the acidity, the gastric refluxate produced is less harmful to the oesophageal mucosa. PPIs (e.g. omeprazole, lansoprazole, pantoprazole) are the most commonly prescribed drugs for GORD. They are potent inhibitors of gastric acid secretion, which act specifically by inhibiting the enzyme H^+/K^+-ATPase, the final step in the formation of hydrochloric acid in gastric parietal cells. PPIs will heal 80–90% of patients with endoscopically demonstrable oesophagitis after an 8 week period of high-dose treatment. An alternative to PPIs are H_2-receptor blockers (e.g. cimetidine, ranitidine) and these can be effective in certain patients. H_2-receptor blockers reduce gastric acid secretion by acting as competitive antagonists of histamine at parietal H_2-receptors. However, studies have shown that PPIs are well tolerated, provide the best healing rates for acute oesophagitis and maintain remission better than H_2-receptor blockers.

If a patient has an inadequate PPI response, there are certain factors which should be considered:

- nocturnal acid breakthrough – intragastric pH <4 for more than 1 hour during an overnight period
- *H. pylori* status
- timing of PPI ingestion – decreased bioavailability and variation in drug metabolism
- delayed gastric emptying
- genetic variability in PPI metabolism – rapid metabolism is associated with the 2C19 isoform of cytochrome P450.

A proportion of patients with GORD have impaired peristaltic function and LOS dysfunction. A trial of prokinetic agents (e.g. metoclopramide, domperidone) can provide mild symptomatic relief; however, these drugs have no effect on the healing of oesophagitis.

Surgical treatment

There is evidence to suggest that symptoms of heartburn, reflux and bloating are improved after surgery compared with medical therapy. Overall rates of postoperative complications are low but surgery is not without risk. In the long term, surgery seems to be more cost effective on average than medical therapy. Indications for surgical treatment are as follows:

- GORD refractory to medical treatment
- development of GORD-related complications
- GORD contributing to a decline in respiratory function (e.g. chronic obstructive pulmonary disease, asthma, post lung transplant).

The primary goal of surgery is to improve quality of life for the patient, and therefore careful patient selection is essential. Correlation with oesophageal manometry, pH studies and treatment of a patient's dominant symptoms are the main factors in choosing the appropriate antireflux procedure. The aim of antireflux surgery is to restore an anchor of the oesophagogastric junction below the diaphragm to achieve an adequate length of intra-abdominal oesophagus (minimum 2 cm). In addition to achieving sufficient length, restoration of the competency of the lower oesophageal mechanism is essential for improving GORD symptoms.

A laparoscopic approach is considered the gold- standard technique for antireflux surgery. Studies have confirmed that laparoscopic antireflux surgery is advantageous over the open approach in terms of reduced postoperative pain, earlier mobilization, decreased postoperative morbidity and earlier discharge from hospital. The most commonly performed antireflux operation is the Nissen (360°) fundoplication and it is recommended as the surgical therapy of choice by both the Society of American Gastrointestinal & Endoscopic Surgeons (SAGES) and the European Study Group. There are also several laparoscopic partial fundoplications that can be performed such as Toupet (posterior 270°), Dor (anterior 180–200°) and Watson (anterior 120°). Other less commonly performed operations for GORD include the transthoracic Belsey Mark IV approach, the Hill posterior gastropexy and a Collis gastroplasty (an oesophageal lengthening procedure). A systematic review of five randomized controlled trials on the effect of division of short gastric vessels demonstrated that clinical outcome following laparoscopic Nissen fundoplication appears to be similar regardless of whether the short gastric vessels are divided.

A systematic review of seven randomized controlled trials comparing laparoscopic anterior and posterior fundoplication showed that oesophageal acid exposure time and the prevalence of heartburn are higher after laparoscopic anterior fundoplication than with laparoscopic posterior fundoplication. In the short term this is counterbalanced by less severe dysphagia. However, dysphagia scores become similar in the long term, with a persistent substantial increase in prevalence of heartburn and PPI use after laparoscopic anterior fundoplication. The reoperation rate is twice as high after laparoscopic anterior fundoplication as well, mainly due to reinterventions for recurrent GORD. The prevalence of gas-related symptoms is similar. This systematic review supports the use of laparoscopic posterior fundoplication as the surgical treatment of choice for GORD.

A recent meta-analysis comparing laparoscopic Nissen fundoplication and laparoscopic partial fundoplications demonstrated similar reflux control with both operations. However, Nissen fundoplication was associated with a significantly higher prevalence of postoperative dysphagia and postoperative endoscopic dilatation for dysphagia. A partial fundoplication approach was also associated with a significantly lower reintervention rate, lower dysphagia and gas-bloating symptoms. An individual patient's symptoms and the antireflux experience of the surgeon performing the operation will often dictate the choice of fundoplication.

A Cochrane systematic review of four randomized controlled trials comparing laparoscopic fundoplication with medical therapy found that laparoscopic fundoplication surgery resulted in greater improvements in health-related and GORD-specific quality of life than medical therapy in the short to medium term. There is evidence to suggest that symptoms of heartburn, reflux and bloating are improved after surgery compared with medical therapy, but a small proportion of participants have persistent postoperative dysphagia. Rates of conversion from laparoscopic to open surgery and postoperative complications are relatively low. Surgery also resulted in reductions in acid exposure in the lower oesophagus compared with preoperative values and medical therapy. At present, the evidence suggests that laparoscopic fundoplication surgery is more effective for the treatment of GORD than medical treatment but there are limited data to show whether these benefits are sustained long term. Only one study has assessed patient-reported outcome up to 3 years postoperatively. The costs of surgery are considerably higher than the cost of medical management. Cost data are based on treatment in the first year and therefore the cost and side effects associated with long-term treatment of chronic GORD need to be considered.

Results and complications of antireflux surgery

Symptomatic improvement after antireflux surgery is reported between 65% and 96%. Complete symptomatic resolution is in the range 32–82%. Healing of oesophagitis after antireflux surgery is reported between 63% and 91%. Mortality after antireflux surgery is reported in the range 0.05–0.75%.

Postoperative complications after antireflux surgery include:

- dysphagia
- abdominal bloating
- inability to belch or vomit
- early satiety
- nausea
- diarrhoea.

Recurrent reflux symptoms do occur in patients who have undergone an antireflux operation and it is estimated that about 4% of patients eventually require revision surgery. Studies have shown that laparoscopic revision antireflux surgery is safe and feasible, with good to excellent results reported in 84% of cases. However, laparoscopic revision antireflux surgery is associated with higher risk of conversion, higher morbidity, longer hospital stay and poorer outcomes than primary laparoscopic fundoplication. It is also recommended that laparoscopic revision antireflux surgery be carried out in high-volume centres by experienced surgeons.

Disorders of the diaphragm

Congenital diaphragmatic hernia

The development of the diaphragm is usually complete by the eighth to tenth week of intrauterine life. Complete absence of the diaphragm occurs rarely. Congenital hernias are the result of maldevelopment of the septum transversum. The prevalence of the condition can be up to one in 2100 births and the male to female ratio is 2:1. Approximately 80% of fetuses with congenital diaphragmatic hernias also have polyhydramnios and most cases can now be diagnosed by ultrasonography before the twenty-fifth week of gestation. Attempts at intrauterine diaphragm repair have had limited success. Attempts to temporarily occlude the main bronchus of the hypoplastic lung have also had limited success. In general terms 30% of fetuses with congenital diaphragmatic hernias are stillborn. Fifty per cent of those born alive with a congenital diaphragmatic hernia also have other congenital malformations, most frequently of the nervous system. The association with trisomy 18, 20 and 21 and with Pierre Robin syndrome is also documented. The majority of diaphragmatic hernias are left-sided (75%), some are right-sided (22%) and a few are bilateral defects (3%). The commonest type of diaphragmatic defect is a posterolateral hernia (90%), followed in frequency by eventration of the diaphragm (5%), and the least common defect being a retrosternal hernia (2%).

Posterolateral hernia (through foramen of Bochdalek)

These hernias are posteriorly situated and are due to persistence of the pleuroperitoneal canals, which are the last part of the diaphragm to close. The hernia, which is usually left-sided, presents acutely with respiratory distress in the neonatal period. In adults most of them are asymptomatic. Symptomatic patients present with digestive symptoms due to herniation of the colon, stomach or small bowel.

Parasternal hernia (through foramen of Morgagni)

The diaphragmatic hernia described by Morgagni in 1761 is a rare diaphragmatic anomaly that is nearly always congenital. This hernia is more common on the right and occurs through a triangular anterior defect lateral to the sternum between the sternal and costal attachments of the diaphragm where the superior epigastric artery, veins and lymphatics pass from the chest in to the abdomen. It is usually asymptomatic in the first years of life; it may be discovered by chance on a routine radiograph or cause problems in adult life with episodes of pain and tenderness in the right subcostal region and intermittent obstructive symptoms. Complete intestinal obstruction may supervene. The posteroanterior chest film in these patients shows a rounded gas-containing shadow to the right of the cardiac outline. This shadow is seen to lie behind the sternum on lateral chest films. In doubtful cases, a radiological contrast study is needed to confirm the diagnosis. Surgical treatment is recommended in all cases because of the risk of intestinal obstruction and strangulation. The best approach is through a midline upper abdominal incision. After reduction of the contents in to the abdomen, the sack, which is usually present, is excised and repair is performed by approximating the two diaphragmatic edges with non-absorbable interrupted sutures. Closure with a Marlex or propylene mesh is necessary for large defects. Repair of these hernias can also be performed laparoscopically. This hernia can be associated with cardiac anomalies as in the pentalogy of Cantrell.

Herniation through central tendon

The deficiency in the central tendon may be situated at the apex of the right or left cupola or involve the central part in relation to the pericardium. On the right side, a hernia through the central tendon contains a mushroom-shaped portion of liver parenchyma, which grows through the opening and enlarges on the thoracic surface of the diaphragm. The condition is usually diagnosed accidentally by a routine chest radiograph. It can be easily differentiated from a primary tumour of the diaphragm by ultrasound scanning or three-dimensional imaging. In left-sided hernias the fundus of the stomach usually protrudes as an air-containing cyst on the top of the diaphragm. A central hernia is usually associated with a defect in the pericardium, and small intestine can herniate in to the pericardial cavity. A small defect in the central tendon on the right side does not require any treatment. However, surgical repair of the other two defects is usually recommended because of the risk of mechanical gastric or intestinal complications.

Congenital hiatal hernia

This is usually the sliding type and is associated with gastro-oesophageal reflux. More rarely the hernia is of the paraoesophageal variety. Both can present in infancy and childhood.

Congenital short oesophagus

In the absence of congenital defects, gastro-oesophageal incompetence is often present in the neonate. The condition corrects itself spontaneously during the first few months of life, probably by further development of the intra-abdominal oesophagus. True congenital shortening of the oesophagus in infancy and childhood is very rare. In this condition, the cardia and a large portion of the fundus of the stomach are situated in the mediastinum without any obvious hernial sack or sliding.

Most instances of congenital shortening of the oesophagus are acquired and result from prolonged pathological reflux with fibrosis, ulceration and stricture formation. The fibrosis draws the stomach further in to the chest and, in extreme cases, the oesophageal stricture may be situated at the level of the aortic arch.

Regardless of the aetiology, the most common symptoms are those of spontaneous regurgitation when the infant or child is in the reclining position, recurrent attacks of chest infection or asthma. Aspiration may also result in the development of a lung abscess. The condition requires treatment with an antireflux procedure. Most authorities favour a Collis-type gastroplasty with a partial fundal wrap. Others recommend an intrathoracic Nissen fundoplication.

Eventration of diaphragm

Anomalous congenital development of the diaphragm or its innervation may result in unilateral elevation of the diaphragm. Alternatively, phrenic nerve injury at birth or later, or injury to the diaphragm, may result in the same problem. Differentiation between eventration of the diaphragm and a large congenital hernia, especially of the Bochdalek type, may be difficult or impossible until surgical exploration.

Eventration of the diaphragm has clinical significance only if it is associated with symptoms or when it cannot be differentiated from other serious conditions. The symptoms of eventration, which are identical to those of large congenital diaphragmatic hernias, may occur in the neonatal period and include respiratory distress and tachycardia with impaired cardiac function. In older children, digestive and respiratory symptoms are aggravated by obesity.

In adult patients, the symptoms may be minimal and management is then conservative. Surgical treatment is necessary if symptoms are severe or disabling. Approach is through a left thoracotomy. The procedures which can be used to restore the diaphragm include plication of the diaphragm (Figure 22.22). In severe cases, prosthetic replacement of a much attenuated diaphragm with a synthetic mesh is required.

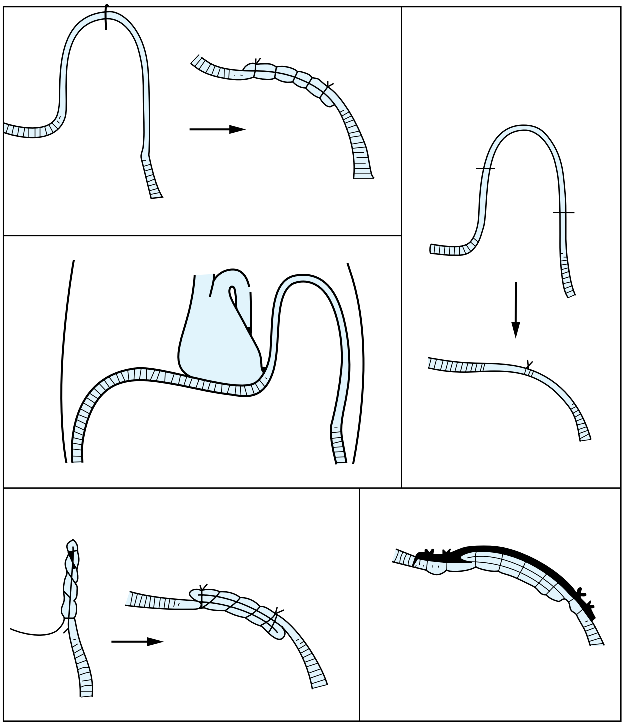

Figure 22.22 Techniques for correction of eventration of the diaphragm.

Traumatic diaphragmatic hernia

Traumatic rupture of the diaphragm may result from penetrating (25%) or blunt (75%) trauma to the abdomen and chest. The tendinous portion, especially on the left side, is the usual side of rupture (68%) as the liver protects the right side of the diaphragm from most injuries except the penetrating type. The rupture is associated with herniation of abdominal contents and may present acutely following the injury or escape detection until several months to years later. The herniation of abdominal viscera may occur acutely at the time of the injury or be delayed until some time later. The symptoms are related to the size of the herniated contents and to the onset of mechanical complications such as intestinal obstruction, strangulation, haemorrhage or progressive cardiorespiratory insufficiency.

The diagnosis is usually established on plain chest and abdominal films when a space-occupying lesion or bowel gas shadow is seen in the chest. If the omentum, spleen or liver is the main herniated structure, the shadow appears solid. The herniated spleen is usually ruptured and accompanied by severe haemorrhage. This may result in total opacification of the left chest. Otherwise, air–fluid levels may be observed indicative of herniation of hollow viscera (colon, small bowel). Passage of a nasogastric tube identifies a herniated stomach above the diaphragm. Contrast radiological studies may be needed to confirm the diagnosis. A significant proportion (40%) of traumatic diaphragmatic hernias do not produce any visible effects on plain chest radiography or three-dimensional imaging using CT, MRI or ultrasonography, making diagnosis elusive in the acute setting. The rupture may be discovered by laparoscopy (gas-free, using abdominal wall lift), thoracoscopy or at laparotomy for associated injuries or subsequently on repeat investigations or as a result of bowel obstruction or strangulation.

In acute rupture, there are often associated injuries, which take precedence over the diaphragmatic injury. However, repair of the acute tear should be performed at the same sitting whenever possible. Elective repair of a traumatic diaphragmatic hernia may be performed through either a left thoracotomy or an upper abdominal approach. In delayed cases, the operation may be difficult due to the presence of adhesions and/or atrophy of the damaged diaphragm. Primary repair is usually possible using interrupted non-absorbable sutures. Otherwise closure with a prosthetic mesh is performed.

Hiatal hernia

The oesophageal hiatus is an elliptical opening in the muscular part of the diaphragm. The crura arise from the anterior surface of the first four lumbar vertebrae on the right and from L2 and L3 vertebrae on the left to insert anteriorly into the transverse ligament of the central tendon of the diaphragm. There is some reported variability in the configuration of the oesophageal hiatus. The diaphragmatic crura are thick, musculotendinous bundles that become more tendinous and more muscular near their vertebral origins. The lowermost portions of the oesophagus and the GOJ are held in place through the hiatus by the phreno-oesophageal membrane. With age, the phreno-oesophageal membrane becomes less definite and more fatty. It is also virtually non-existent in patients with longstanding hiatal hernia. This condition is commonly encountered from the fifth decade onwards in the Western world and there is a strong aetiological association with obesity. Excessive body weight has been found a significant independent risk factor for hiatal hernia. Hiatal hernia, however, is not synonymous with gastro-oesophageal reflux. A hiatus hernia can exist without any symptoms. Further, gastro-oesophageal reflux and reflux oesophagitis can occur in the absence of a hiatus hernia. However, in the presence of hiatus hernia there is probably a higher chance of developing oesophagitis. It is possible that, in the presence of sphincter dysfunction, a hiatus hernia exacerbates reflux disease and its symptoms are worse than in the absence of such a hernia. There are rare instances of post-traumatic herniation of the stomach through the hiatus and these must be differentiated from traumatic rupture of the diaphragm. In the vast majority of cases, however, the development of hiatus hernia is spontaneous. Gallstones and colonic diverticular disease are commonly present in patients with a hiatus hernia (Saint's triad) and difficulty may be encountered in establishing which of the three disorders accounts for the patient's symptoms.

Pathology

Conventionally, three types of hiatal hernias are recognized: type 1, axial, sliding; type 2, paraoesophageal; and type 3, mixed.

Axial hernia

This accounts for the majority (70–80%) of cases. The GOJ and a variable portion of the adjacent stomach slide upward into the mediastinum carrying with them a peritoneal sac. This results in loss of the cardiac angle of His and, commonly, incompetence of the cardio-oesophageal junction. There is no uniform definition of what constitutes a sliding hiatus hernia. Surgeons, anatomists, radiologists and endoscopists all differ slightly in their views and this must be taken into account when evaluating a symptomatic patient. The symptoms and complications of this type of hernia are those which are consequent on gastro-oesophageal reflux and reflux oesophagitis (chronic blood loss, stricture formation, Barrett's epithelium, etc.) (Figure 22.23).

Paraoesophageal hernia

In this type, the fundus of the stomach rotates in front of the oesophagus and herniates through the hiatus into the mediastinum. As the cardio-oesophageal junction remains *in situ* within the abdomen (except in large hernias) cardiac incompetence and reflux are not usually encountered. This type of hernia accounts for 8–10% of cases and is found predominantly in the elderly population. In large hernias the entire stomach and pylorus may be found within the chest inside a large hernial sac, which may also contain the spleen and hepatic flexure of the colon. These large hernias are prone to incarceration and strangulation with infarction and perforation

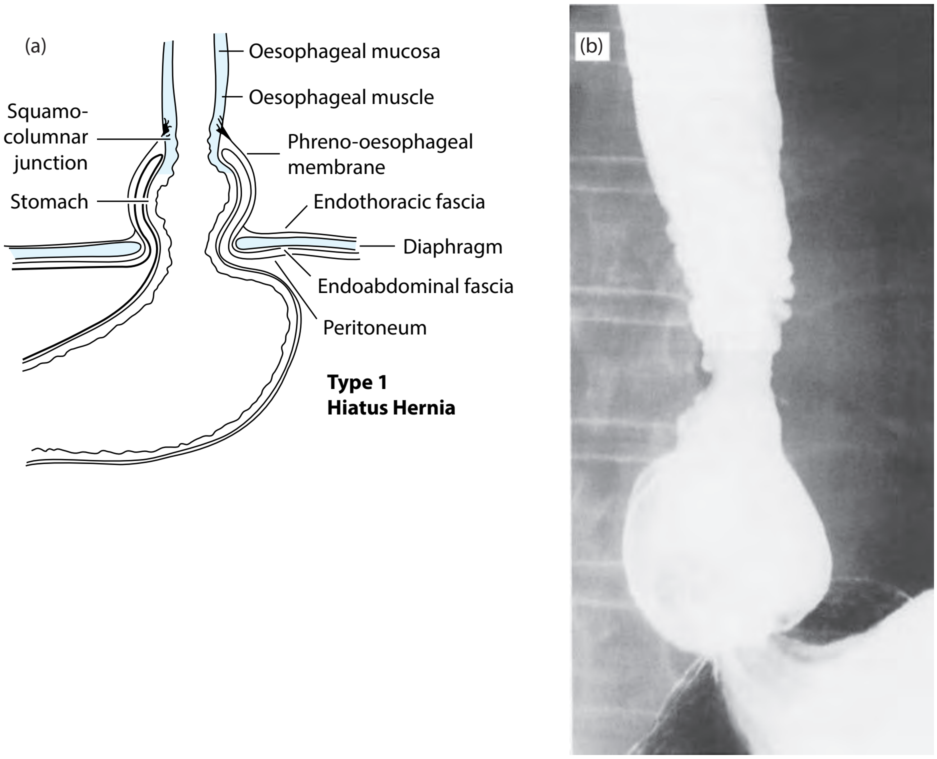

Figure 22.23 Axial (type I) hiatus hernia (a) diagrammatic representation; (b) barium swallow. Note displacement of the cardio-oesophageal junction in the chest.

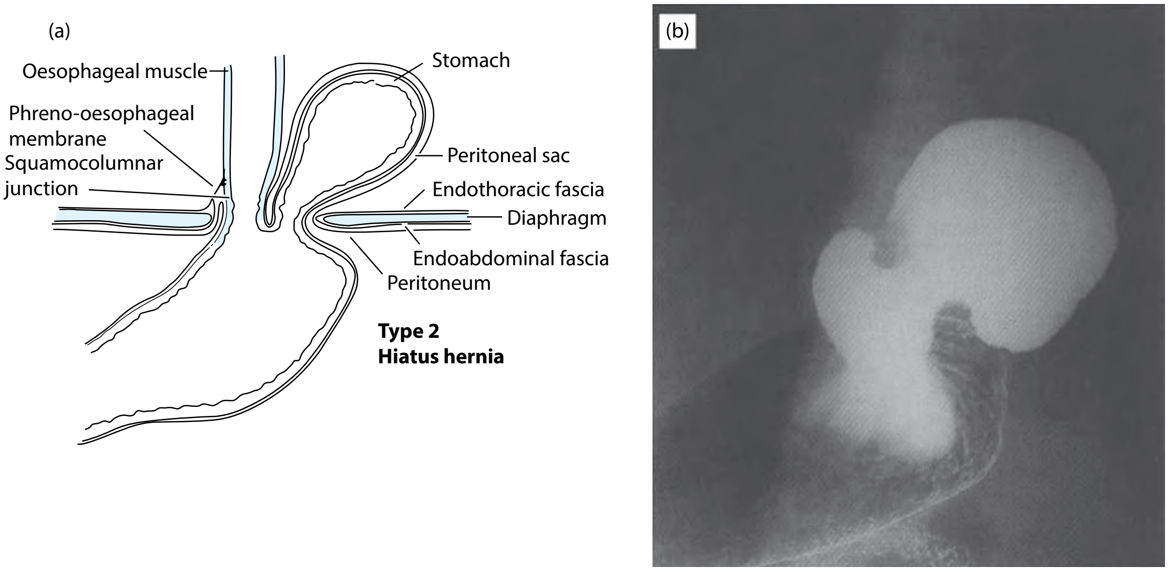

Figure 22.24 Paraoesophageal hernia (type 2). (a) Diagrammatic representation; (b) barium swallow. Note rotation of the fundus as it rolls up in front of the gastro-oesophageal junction.

of the stomach. Large hernias can also progress to complete volvulus, which results in pyloric or duodenal obstruction. When a paraoesophageal hernia bleeds, this is due either to chronic gastric ulceration in the intrathoracic stomach or to an erosive gastritis in a congested and strangulated organ. The majority of uncomplicated paraoesophageal hernias can be easily reduced through the abdomen (Figure 22.24).

Mixed hernia

This resembles a large paraoesophageal hernia but the gastro-oesophageal junction is also herniated above the diaphragm. It has features and complications of both type 1 and 2 hernias. It is found in 10–15% of patients. This type of hernia is generally considered to be a late stage of the paraoesophageal variety (Figure 22.25).

Clinical picture

This depends on the type of hernia and the onset of acute life-threatening complications, which can occur with the paraoesophageal and mixed varieties.

Axial hernia

The condition may be asymptomatic, particularly in elderly patients with limited activity and a sedentary lifestyle. When symptoms occur, they are largely due to gastro-oesophageal reflux and reflux oesophagitis. Chronic blood loss resulting in iron deficiency anaemia is common but active haemorrhage is rare. Some patients may present with dysphagia due to stricture formation without a preceding symptomatic history. Others present with dysphagia secondary to obstruction by diaphragmatic impingement on the herniated stomach.

Paraoesophageal and mixed hernia

The symptoms of paraoesophageal hernias are due to the pressure effects of the herniated stomach, especially when it becomes distended with food or gas. Reflux is rare occurring in only 3% of individuals unless the hernia is or becomes mixed. Common symptoms include pain, dyspnoea, feeling of distension and tiredness, which are precipitated by meals, bending and stooping. The pain is sharp, situated beneath the lower sternum and radiates to the back. It is often accompanied by a bloated sensation, anxiety, palpitation and dyspnoea. The attacks may simulate angina pectoris very closely, and even cardiac arrhythmias may be present during an episode. The pain, however, is often relieved by belching or vomiting. Dysphagia is found in 20% of patients with paraoesophageal hernia.

Acute presentation

Approximately 20% of patients with large paraoesophageal/mixed hernias may present acutely with severe upper gastrointestinal haemorrhage or strangulation/infarction/perforation of the intrathoracic stomach. In the latter instance the patient develops severe retrosternal pain and shock, which are often mistaken for myocardial infarction. A chest radiograph shows a large gastric gas–fluid shadow overlying the heart. With gastric infarction and perforation, mediastinal widening and emphysema, left basal collapse and pleural effusion may be outlined by this investigation. Gastric infarction and perforation carry a high mortality rate from septic mediastinitis and bacteraemia.

Management

Clinical assessment and appropriate investigations must establish that the symptoms are due to the hiatal hernia. In elderly patients and in individuals with comorbid disease, case selection for surgery requires clinical judgement based on the severity of the symptoms and cardiorespiratory reserve. Middle-aged patients with significant coronary artery disease may require myocardial revascularization before surgical treatment of the hiatal hernia.

Type 1, axial hernias are treated by reduction with an antireflux procedure. This is best achieved by a laparoscopic procedure in the majority of patients. The majority of uncomplicated paraoesophageal hernias can also be approached similarly and are easily reducible via this approach. Following reduction of

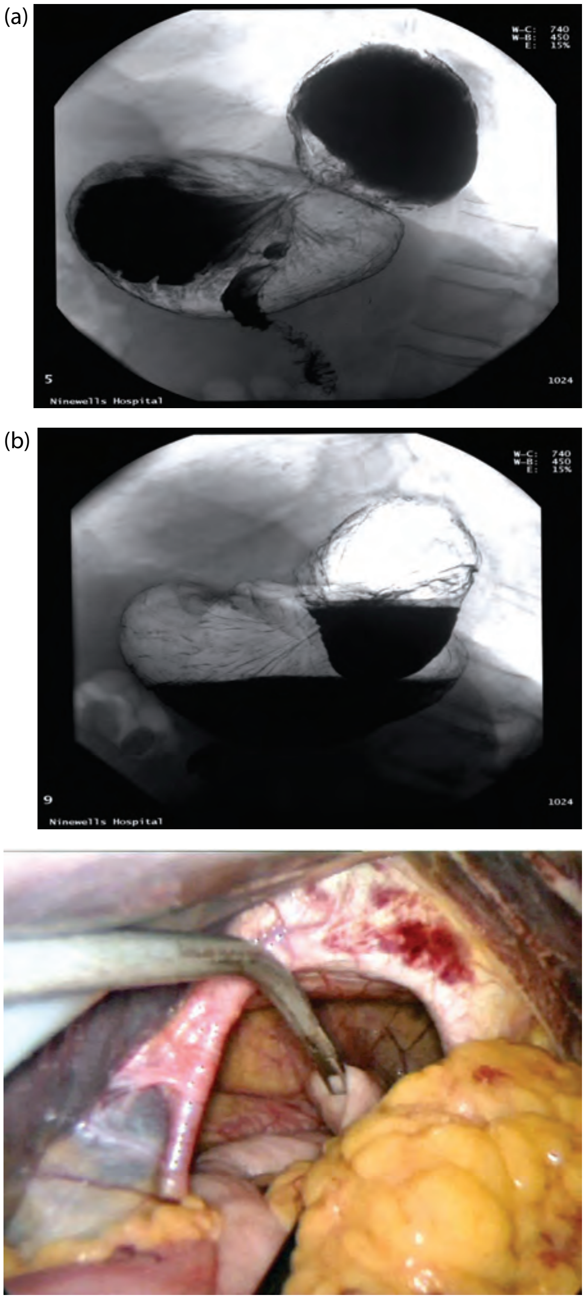

Figure 22.25 Mixed (type 3) hiatal hernia. (a,b) Barium swallow showing large totally intrathoracic herniated stomach with organoaxial volvulus; (c) laparoscopic view of the same patient. The herniation involved the whole stomach, small intestine and spleen. These hernias are particularly prone to strangulation.

the hernia, a small or moderate-sized hiatus is repaired with interrupted non-absorbable sutures and the GOJ fixed beneath the diaphragm after restoring the oesophagogastric angle. Some surgeons advocate a Nissen fundoplication in addition to reduction and crural repair of these hernias. If the hiatal defect is large, a synthetic mesh can be fashioned around the oesophagus and sutured to the edge of the large defect (Figure 22.26). In addition to the above, some surgeons advocate a gastropexy in the form of a tube gastrostomy or otherwise to prevent recurrence. These patients can be managed by the laparoscopic approach by experienced surgeons. They are, however, challenging cases in time and effort.

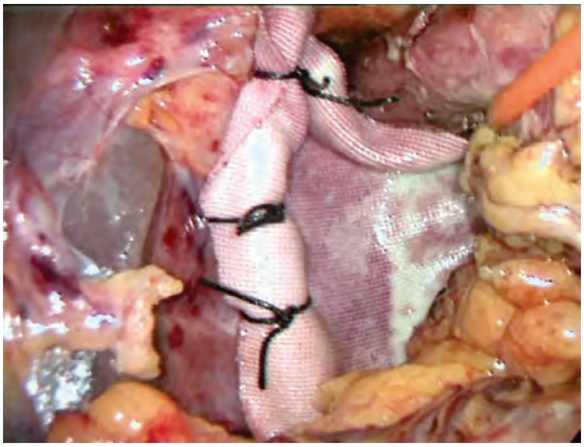

Figure 22.26 Mesh repair of a crural defect in a giant hiatus hernia. The operation is completed by total fundoplication and an anterior gastropexy. Even so recurrence occurs in up to 30% but most are asymptomatic.

Strangulated/infarcted paraoesophageal and mixed hernias require an emergency thoracotomy. If the stomach is viable it is unrotated and reduced into the abdomen and crural repair is performed. Resection of the infarcted stomach with mediastinal and pleural lavage is necessary for those patients presenting with this serious complication.

Oesophageal diverticula

Oesophageal diverticula are an uncommon pathology that can occur at any level of the oesophagus. They are predominantly an acquired pathology caused by pulsion or traction.

Oesophageal diverticula are defined anatomically or by the mechanism which produces them:

- Anatomically
  - upper oesophagus (pharyngo-oesophageal junction)
  - mid-oesophagus (parabronchial)
  - lower oesophagus (epiphrenic).
- Mechanism of formation
  - Traction – chronic inflammation of the mediastinum, particularly mediastinal lymph nodes, involves the mid-oesophagus wall. Fibrosis eventually occurs between the two structures, resulting in the oesophageal wall (mucosa and muscle) being pulled outwards to form a pouch. They are usually small, wide necked and clinically non-significant, producing few (if any) symptoms.
  - Pulsion – an increased intraluminal pressure forces the oesophageal mucosa to herniate, resulting in diverticula formation. Herniation occurs in regions of the oesophagus which are weakened or have a low resistance. Killian's triangle, based in the posterior pharynx and bounded by the cricopharyngeal and thyropharyngeal muscles, is an area of natural weakness and frequently the site of pharyngo-oesophageal (Zenker's) diverticula. Alternatively, oesophageal dysmotility syndromes such as achalasia can alter oesophageal peristalsis, creating uneven pressures and mucosal tears, where again diverticula can develop.

The clinically important diverticula can be divided as follows:

- pharyngo-oesophageal – Zenker's diverticulum (65%)
- mid-thoracic (15%)
- lower oesophagus – epiphrenic diverticulum (20%).

In this section we will primarily discuss the pharyngo-oesophageal and epiphrenic diverticula together with their investigation and treatment.

Pharyngo-oesophageal (Zenker's) diverticula

Zenker's diverticulum is a pulsion-type diverticulum that forms in the midline of the neck, usually in the naturally weak Killian's triangle (see above). The UOS, predominantly formed by the cricopharyngeus muscle, relaxes on swallowing to allow food into the oesophagus and also contracts to prevent backflow into the pharynx. Although there is considerable controversy as to the exact pathology, dysfunction of the sphincter is widely believed to generate excessive pressures which coupled with the weakness in Killian's triangle results in forming Zenker's diverticulum.

The outpouching that forms is mainly composed of the mucosa and submucosa layers and an incomplete muscular coat. Over time, the diverticulum progressively enlarges. However, as the spine prevents indefinite posterior diverticular extension, it instead displaces the oesophagus and comes to lie on the side of the neck (usually on the left) in line with the pharynx (Figure 22.27).

As a result of this anatomical repositioning, food can occupy the diverticulum, where it is retained and be subsequently associated with multiple symptoms and complications.

Clinical features

Box 22.4 shows some of the clinical signs and complications that can be associated with pharyngo-oesophageal diverticula. As can be appreciated, the diffuse, non-specific and highly variable nature of the symptoms makes a clinical diagnosis near impossible, except for in the most advanced cases when the pronounced swelling of the pouch may be palpable and associated with gurgling sounds. As a result, definitive diagnosis relies heavily on imaging of the oropharynx and oesophagus.

Diagnosis

Barium swallow

Barium meal study with fluoroscopy is regarded as the first-line investigation for suspected cases. This should show the definitive swelling of the condition in the pharyngeal area and exclude any advance oesophageal motility disorder or hiatus hernia whose symptoms can overlap with those of oesophageal diverticula (Figure 22.28).

Further tests

Endoscopy, manometry and pH monitoring are occasionally used as adjunct tests in suspected cases. Endoscopy in particular must be undertaken with great care as there is a documented risk of iatrogenic perforation of the diverticulum. It does, however, allow the entire length of the upper gastrointestinal tract to be visualized and exclude gross organic pathology, reassuring both the patient and the surgeon. Manometry helps to exclude an oesophageal motility disorder, which may or may not be present, whereas pH monitoring helps to exclude GORD.

Treatment

Definitive treatment of Zenker's diverticulum is always interventional but dependent on the severity of symptoms, the patient's willingness to undergo surgery and indeed the degree of comorbidity. However, in the modern era, all but extremely frail patients should be suitable for endoscopic treatment under sedation. Patients can be treated equally well with open or minimal access approaches. However, on balance, it seems that high-risk patients with medium-sized diverticula are likely to benefit more from endoscopic/fibreoptic diverticulostomy whereas those with small or giant diverticula are probably best served by open surgery.

Open approach

The open approach is through an incision at the anterior margin of the sternomastoid muscle to the anterior end of the clavicle on the side at which the diverticulum is most prominent (usually the left).

As the UOS is considered defective, a myotomy is performed of the cricopharyngeus muscle, which by itself may be sufficient to relieve symptoms in cases of small diverticula. If the diverticulum is large, then the myotomy is combined with a diverticulectomy or diverticulopexy.

Endoscopic stapling diverticulostomy

Under general anaesthesia, a diverticuloscope with two blades is placed through the pharynx into both the oesophageal lumen

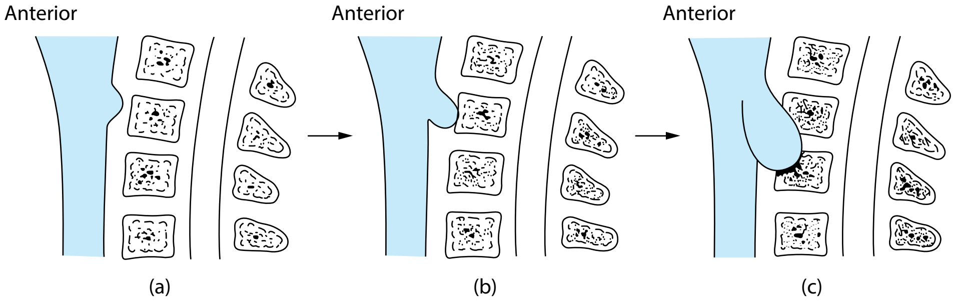

Figure 22.27 Diagrammatic representation of the development and progression of a pharyngo-oesophageal diverticulum. The cricopharyngeal dysfunction and resultant high intraluminal pressure cause a mucosal herniation between the oblique fibres of the inferior constrictor and the transverse fibres of the cricopharyngeus (a). Enlargement of the pouch is limited posteriorly by the spine (b). It therefore becomes dependent and bulges lateral to the oesophagus usually on the left side (c). As it becomes dependent, food tends to enter the sac rather than the oesophageal lumen, which may be compressed by the pouch.

and the diverticulum. A smaller, 5 mm endoscope is passed through to visualize the septum dividing the oesophagus and diverticulum. Prior to stapling, the length of the diverticulum is measured with a graduated rod. Stapling is used to bring together the adjoining walls of the oesophagus and pouch that form the septum, which is then transected forming a diverticulostomy. Cautery is also occasionally used in place of stapling to achieve the same result. The procedure is fast, taking around 20 minutes to perform in skilled hands but nonetheless involves a general anaesthetic.

BOX 22.4 Clinical features and complications of Zenker's diverticulum

- M>F (3:1), middle aged/elderly more affected
- Dysphagia – due to food being stuck within the pharynx and oesophageal compression
- Cough
- Throat irritation
- Food regurgitation of non-acidic material (food is from the pouch)
- Food aspiration – this can lead to pulmonary complications such as pneumonia
- Neck swelling (if the pouch is sufficiently large) with gurgling
- Halitosis (food stasis and fermentation)
- Anorexia
- Higher risk of perforation on endoscopy
- Bleeding
- Carcinoma (0.3%)

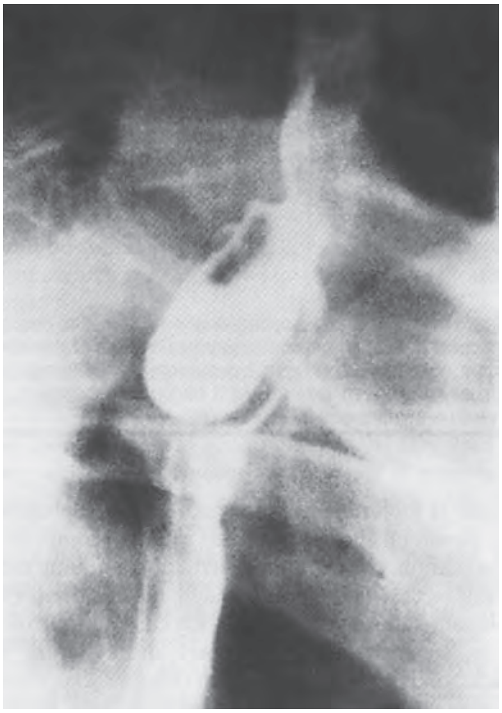

Figure 22.28 Barium swallow demonstrating a large pharyngeal pouch accompanied by an aspiration lung abscess.

Fibreoptic endoscopy

This procedure is performed under sedation and is an alternative to endoscopic stapling under general anaesthesia, making it particularly useful for treating the frail and elderly populations. A fibreoptic endoscope is used to visualize the dividing septum, which is then obliterated using cautery, argon plasma coagulator or CO_2 laser and ends in formation of a diverticulostomy. Diverticula <2 cm in size can be managed in a single sitting with this technique but larger pouches may require repeated procedures.

Complications

Endoscopic treatment is faster and less invasive than open surgical therapy with fewer reported complications. However, whereas the results of surgical myotomy are highly favourable with a good outcome in almost all patients, with endoscopic therapy good outcomes are more variable between 75% and 100%. Additionally, all invasive modalities have associated complications (Box 22.5).

Mid-thoracic diverticula

Mid-thoracic diverticula are the least common of the oesophageal pouches and can arise as a result of pulsion (secondary to an oesophageal motility disorder causing increased intraluminal pressure and wall weakness) or traction (from fibrotic adhesions between the oesophageal wall and mediastinal structures such as inflamed lymph nodes). The diverticula tend to possess a narrow neck and a limited muscular coat. Asymptomatic or minimally symptomatic patients are usually managed conservatively, whereas those with extensive pouches are surgically treated by excision and layered oesophageal closure through a right-sided thoracotomy.

Epiphrenic diverticula

Although the second most common of the oesophageal diverticula, epiphrenic diverticula are nearly five times less common that Zenker's pouches, which are themselves infrequent pathologies. The great proportion of epiphrenic diverticula are acquired as a result of raised intraluminal oesophageal pressure secondary to a motility disorder such as DOS or achalasia. Occasionally, they may arise in conjunction with a hiatus hernia or gastro-oesophageal reflux. The symptoms are largely due to the underlying disorder, although ulceration and bleeding within the diverticulum has been documented as a rare cause of haematemesis (Box 22.6).

BOX 22.5 Complications of surgical therapy for Zenker's diverticulum

- Haematoma
- Recurrent nerve palsy
- Suture line leakage
- Cardiovascular complications (especially in elderly/frail patients)

BOX 22.6 Clinical features of epiphrenic diverticula. As with other oesophageal diverticula and oesophageal conditions in general, many of the symptoms are shared making a purely clinical diagnosis very difficult

- Dysphagia
- Cough
- Food regurgitation (occurs in 50% of patients who seek medical attention)
- Retrosternal chest pain
- Heartburn
- Halitosis (food stasis and fermentation)
- Anorexia
- Ulceration and bleeding
- Carcinoma
- Spontaneous perforation (similar to Boerhaave syndrome)

Diagnosis

Barium swallow, as in Zenker's diverticula, will show the clear outline of the pouch in the lower part of the oesophagus. Given its association with motility disorders, manometry is an important part of the diagnostic work-up, which can show tertiary contractions and further evidence of dysmotility such as aperistalsis or failure of relaxation of the LOS. Standard manometry fails to show dysmotility in around 25% of cases, but prolonged manometry may pick up more subtle dysmotility.

Treatment

Treatment is dependent on patient severity and the underlying condition that has produced the diverticulum. Generally, asymptomatic or minimally symptomatic individuals are managed conservatively and may be imaged infrequently to ensure that the diverticulum is not growing to a disproportionate size or beginning to cause symptoms.

Additionally, if an underlying motility disorder or reflux disease has been identified, it is important to treat it as far as possible, thereby removing the causative agent of the epiphrenic diverticulum's formation and preventing further enlargement. In cases where the diverticulum is large or symptomatic, i.e. compressing the oesophagus, or is unable to drain or inflamed, then surgical intervention is the preferred approach with the primary aim being to excise the diverticulum and, if applicable, correcting any underlying disorder that has contributed to pouch formation.

Traditionally, surgical treatment involves:

- diverticulectomy
- oesophageal myotomy – if an underlying motility disorder such as achalasia has been identified
- antireflux procedure – e.g. Door partial fundoplication to prevent gastro-oesophageal reflux post myotomy.

Thoracotomy/thoracoscopy

Prior to the laparoscopic era, a right-sided thoracotomy was the preferred surgical approach, as this allowed sufficient access to the offending pouch to be excised and to the oesophagus to perform a myotomy.

This preference was carried into the laparoscopic era, where a four-port right-sided thoracoscopy was performed. The epiphrenic diverticulum would be identified intraoperatively by endoscopy and then isolated by blunt dissection. The diverticulectomy would be performed by staple application at its base followed by a layered closure of the oesophagus. The endoscope could then be used to test the efficacy of the closure and identify any missed perforations.

Although this approach had a symptom success rate of 85%, there was a risk, as with all thoracotomy/thoracoscopy, of staple line leak and mortality. Furthermore, the complex nature of the anaesthetic, positioning of the patient and inaccessibility to the stomach to perform a fundoplication has resulted in the technique being largely abandoned for the laparoscopic approach.

Laparoscopy

Abdominal laparoscopy is also performed using a four-port technique to access the hiatal structures and the diverticulum within the mediastinum, staying close to the oesophageal wall. Once the diverticulum is isolated, its neck is sutured and a linear endoscopic stapler applied to transect the pouch. Prior to the transection, the oesophagus can be inflated endoscopically or a bougie placed in order to prevent luminal narrowing during transection.

If oesophageal dysmotility is identified preoperatively, a myotomy is then performed on the lower oesophagus extending for 2–2.5 cm on to the gastric cardia. As gastro-oesophageal reflux is the main complication of a myotomy, a Dor anterior fundoplication is additionally fashioned. Overall results of this procedure are excellent with much greater gastric access, less morbidity and a faster recovery than the thoracoscopic approach.

Oesophageal injury

Oesophageal perforation

Oesophageal perforation is traditionally regarded as a surgical emergency with very high associated morbidity and mortality rates of 10–40% reported. Treatment of oesophageal perforation remains an area of interest and debate for oesophageal surgeons. There is now consensus that patients with oesophageal perforations are best treated with early diagnosis and referral to specialist tertiary centres.

Aetiology

- Instrumental
- Intraoperative iatrogenic injury
- Trauma
- Boerhaave syndrome
- Foreign body

The commonest cause of oesophageal injury is instrumental following upper gastrointestinal endoscopy. The incidence of oesophageal perforation following insertion of a rigid endoscope is 0.5%. Rigid endoscopy is rarely used in current gastrointestinal clinical practice but it is still used by otolaryngology surgeons. Oesophageal perforation may occur following therapeutic endoscopy for dilatation or intubation of strictures. The incidence of perforation is 1–5% after pneumatic dilatation for achalasia using 4 cm balloons. Endoscopic injuries also occur during EUS and endoscopic retrograde cholangiopancreatography (ERCP). Oesophageal intubation with a transoesophageal echo probe during cardiac ablation is another cause of oesophageal injury. The commonest site of injury during therapeutic endoscopy is the location of intervention, i.e. stricture, whereas cervical oesophagus is the commonest site for injury during EUS, ERCP and echo cardiography. Oesophageal diverticulum is an important predisposing factor of cervical iatrogenic endoscopic injury.

Intraoperative perforation occurs due to oesophageal damage sustained during paraoesophageal surgery, e.g. fundoplication, repair of hiatus hernia, thoracic aortic surgery and bariatric surgery. It is a technical error during surgery. Redo surgery, poor surgical exposure and inadequate surgical expertise are important factors that underline such technical errors.

Trauma of the oesophagus may occur due to penetrating gun shot or stab wounds. The cervical oesophagus is the segment most commonly involved. It is usually associated with injuries to adjacent structures.

Boerhaave syndrome is a serious condition of forceful vomiting followed by severe chest pain due to a complete tear of the lower thoracic oesophagus, just above the cardia. It was first described by Herman Boerhaave in a Dutch admiral. This aristocratic gentleman succumbed in this way following a bout of overindulgence of food and drink. However, only a minority of complete spontaneous perforations of the lower thoracic oesophagus fit the classical description of Boerhaave. The condition is very uncommon and occurs usually between the ages of 40 and 60 years with a male to female ratio of 2:1. There is frequently a long history of indigestion and chronic gastrointestinal disease such as duodenal ulcer, reflux oesophagitis and hiatal hernia. Apart from overeating, other predisposing factors include neurological disorders, tumours and gastrointestinal obstruction.

Ingestion of a foreign body such as a fish bone is a rare cause of oesophageal perforation. It is usually difficult to recognize and, on many occasions, it can only be diagnosed retrospectively on taking a detailed history or after surgery.

Clinical picture

The clinical presentation depends on the cause and onset of perforation, site of perforation and the extent of perforation and subsequently the degree of contamination and its systemic effect.

The acute manifestations of an oesophageal perforation are severe pain, dyspnoea, tachycardia and fever. The site of the pain and its radiation vary with the oesophageal segment involved. Haematemesis may also be found in cervical perforations. Subcutaneous emphysema is observed in 60% of cervical and 30% of mid-oesophageal injuries. In thoracic injuries, respiratory distress is common due to effusion and the systemic effect of sepsis due to mediastinitis. Upper abdominal tenderness indicates perforation of the abdominal segment of the oesophagus or gastro-oesophageal junction with oesophageal contents tracking into the abdomen. On the other hand, pain may be the only symptom in minor injuries and may not be associated with systemic signs of sepsis. The onset of symptoms in relation to the underlying cause is usually noticeable specially following endoscopic interventions or paraoesophageal surgery. In non-iatrogenic perforation, the clinical picture may be misleading as pain, sepsis and respiratory compromise may simulate acute chest conditions.

In late presentation, the clinical picture is that of established sepsis with its systemic cardiovascular and respiratory effects. A detailed history will elicit the early manifestations that are misdiagnosed with other conditions. In this group of patients, oesophageal perforation is usually diagnosed during investigations for sepsis. It is essential that clinical history should include evaluation of the onset of perforation, comorbidity, quality of life and the degree of patient dependency in old patients. In case of oesophageal strictures, determination of the underlying pathology is important. Those factors are crucial in deciding management strategy.

The diagnosis is usually confirmed by imaging. Plain radiographs are frequently diagnostic but cannot accurately localize the site of perforation. The radiological features include the presence of surgical emphysema in the mediastinum or neck, widening of the mediastinum or mediastinal air at the cardiac border (Figure 22.29). Free air under the diaphragm may be detected in patients with injuries to the abdominal oesophagus. CT scan of neck, chest and upper abdomen with intravenous and oral contrast is always required. It determines the level of perforation and the presence of collection in the mediastinum or communication with the pleural cavity. In cases of minor perforations, only mediastinal air is seen with no evidence of extravasation of contrast. A water-soluble contrast swallow is helpful to localize the perforation and the side of perforation, which is important in determining the surgical approach if needed (Figure 22.30). Endoscopy is required if the surgical option has been decided because endoscopy is the most accurate investigation to determine the extent of mucosal injury, which is often larger than the size of muscle tear.

Investigations should include blood count and biochemistry and cardiac and respiratory assessment as part of the management plan. Frequent blood gases and lactate levels are important. In cases requiring surgical interventions and those with cardiorespiratory compromise, early involvement of an anaesthetist and intensive care team is important.

Management

The management of oesophageal perforations consists of (1) optimum resuscitation of patients, (2) establishing adequate nutrition, preferably via the enteral route, and (3) control of sepsis.

Adequate resuscitation is a key component in the management of oesophageal perforations whether surgical or conservative approaches are adopted. Patients with cardiorespiratory

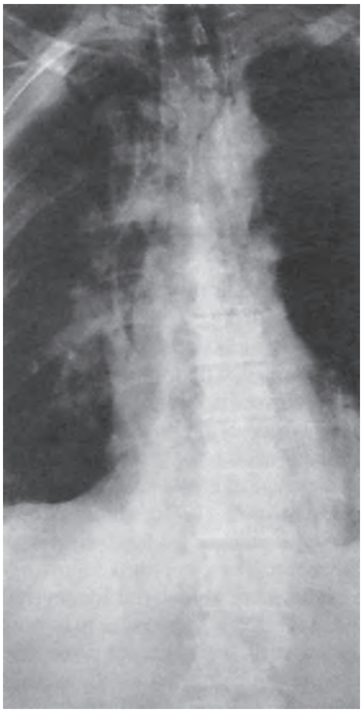

Figure 22.29 Plain radiograph of the chest showing surgical emphysema in the mediastinum following oesophageal perforation.

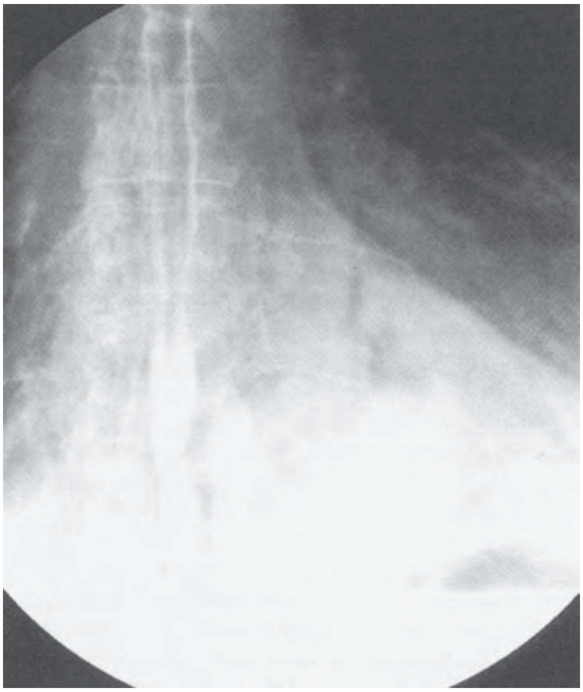

Figure 22.30 Water-soluble contrast swallow confirming and outlining the site of perforation in the lower oesophagus.

compromise or severe sepsis should be treated in high-dependency units or in the intensive care unit. Monitoring the response to management and the early detection of any deterioration are essential.

Nutrition should be established at an early stage. In patients requiring surgery, insertion of feeding jejunostomy provides an enteral route that is easy to manage and allows the patients to go home on supplementary feeding if required. In patients with minor perforations who are expected to recover within a few weeks, fine-bore nasojejunal or nasogastric tubes (in cases with no reflux) provide a short-term enteral route. Total parenteral nutrition may also be an option in some cases until the enteral route is established.

Control of sepsis needs antimicrobial therapy with broad-spectrum antibiotics (which includes anaerobic cover) and antifungal medications. This should start as soon as a diagnosis is made. Drainage of collections is essential. Drains into the pleural cavity or radiologically guided drains into the chest/abdominal abscess cavity are important for sepsis control. The aim of surgical interventions is to repair the perforation in order to control sepsis. Patients need to remain nil by mouth with drainage of the stomach via nasogastric tube or gastrostomy until healing of the perforation is demonstrated.

Conservative approach

The indications for a conservative approach are:

1. minor perforations with either no leakage of contrast (only mediastinal air demonstrated on CT) or a small contained leak
2. controlled sepsis with no signs of systemic cardiorespiratory compromise
3. no underlying pathology or distal obstruction
4. in late presentations where surgical repair would be associated with increased morbidity
5. in high cervical injuries below the cricopharyngeus where surgical access would be limited for adequate repair.

The conservative approach is sometimes forced to be adopted because of patient frailty and comorbidity that make surgical options likely to be unsuccessful.

The principles of conservative management are detailed above and consist of optimum resuscitation, adequate nutrition and control of sepsis. Adequate drainage of sepsis needs monitoring of patient condition and imaging the progress of the size of residual collections related to the leak. New collections or inadequate drainage need insertion of new drains. Insertion of a double-lumen drain provides a means for continuous irrigation as a closed irrigation system for contained cavities.

Endoscopic therapy of oesophageal perforations

The endoscopic treatment of oesophageal perforations can be used as part of the conservative approach. Application of metal clips or sealing glue may be used. These methods work when the edges are not fibrotic or very friable and hence they are more suited for early small perforations.

Oesophageal intubation with covered self-expanding metallic stents is gaining popularity for sealing oesophageal perforations in some centres. It only works in perforations of the thoracic oesophagus. Perforations within 2 cm of the cricopharyngeus or in dilated oesophagus are not suitable for stent placement. Oesophageal stents are usually used for benign perforations. In perforation of malignant strictures, stent placement is considered either as a salvage procedure to bridge the time before definitive surgery or as a palliative procedure because tumour perforation is considered as a local spread. Oesophageal stents can be used for early- and late-diagnosed perforations and for small or large tears. Temporary drainage of gastric contents can be achieved by a percutaneous endoscopic gastrostomy, which can be performed at the same sitting and through this aperture a jejunal feeding tube can be introduced and directed through the pylorus for nutritional support.

For selection of stents, the non-flared portion of the stent should be more than 21 mm if no stenosis is associated with the perforation. The length of the stent should be 12–15 cm to adequately cover the perforation and prevent reflux into the perforation.

Surgical treatment

The overall aim is to seal the perforation, clear gut contents extravasated outside the lumen, drain the site of perforation, drain the stomach to minimize the reflux into the repair site and maintain an enteral route for nutrition usually via a feeding jejunostomy.

Factors that influence surgical treatment

- Onset of presentation
- Level and site of perforation
- Underlying pathology – cause of perforation
- The degree of established local sepsis
- Size of perforation – quality of adjacent oesophageal tissue.

The best results are obtained with early perforations as the mortality increases significantly when perforation is treated after 48 hours of onset. Early presentation usually allows direct repair because of the adequate quality of adjacent oesophageal tissue and the ability to control local sepsis.

Surgical approach

The surgical approach depends on the level (cervical, thoracic, lower oesophageal) and the site (right or left) of oesophageal perforation. *Cervical injuries* are approached through an incision along the anterior border of the left sternomastoid muscle whereas *thoracic perforations* are approached through a right or left thoracotomy (depending on the exact level and site of perforation). *Lower thoracic* and *abdominal oesophageal perforations* are approached via the diaphragmatic hiatus through a midline laparotomy or via a left thoracoabdominal incision in cases of long oesophageal tears.

Oesophageal repair

There are several options on how to deal with the perforated oesophagus. An upper gastrointestinal endoscopy is essential to accurately determine the size of mucosal tear, which usually exceeds the size of muscle tear.

1. *Direct repair* entails refreshing the edges of the tear to realize good quality tissue that enables direct suturing usually with 3/0 PDS. Some surgeons recommend buttressing the thoracic oesophagus with pleural or intercostal flaps for high perforations and a diaphragm flap, pericardial patch or omental patch for low repair. Repair of the abdominal oesophagus may be reinforced by an anterior fundal patch or a Nissen fundoplication in posterior injuries. The risk of narrowing the lumen can be minimized when repairing the oesophagus while the endoscope is left *in situ*.
2. *Suturing the perforation over a T-tube (silicon, size 22–24 French)* can be used in cases of late presentation with poor quality of adjacent oesophageal tissue and established local sepsis that cannot be controlled with local drainage. This option is preferred over resection in patients with poor comorbidity who cannot withstand the impact of oesophagectomy.
3. *Oesophagectomy* can be carried out in cases of perforations with underlying pathology that impair healing, malignant perforations, and in late presentations with established local sepsis. Patient comorbidity and clinical status is vital in deciding oesophageal resection. Joining the oesophagus with the stomach conduit to restore gut continuity should be carried out in the neck to avoid having the anastomosis in the presence of local sepsis. Primary reconstruction is preferred.
4. *Oesophageal diversion with neck oesophagostomy* will be performed in cases of uncontrolled sepsis with local measures of drainage. This may be accompanied with oesophagectomy depending on the clinical status of the patient. Reconstruction of gut continuity with colonic interposition can be performed at a later stage after the patient recovers from sepsis and improves his/her nutritional status (Figure 22.31).

Oesophageal repair is the first step towards control of sepsis. Good lavage of the surgical field is essential. Pleural and mediastinal drains should be inserted.

Mallory–Weiss syndrome

This syndrome consists of painless haematemesis after vomiting and straining induced by, usually, excess alcohol intake. There is a high incidence of associated gastro-oesophageal disease. The Mallory–Weiss syndrome is common and accounts for 5–10% of patients undergoing endoscopy for haematemesis.

The lesion consists of a longitudinal mucosal tear involving the mucosa alone or the mucosa and submucosa on the gastric side of the oesophagogastric junction. The tear, which may be single or multiple, is located on the lesser curve side in the majority of cases (85%). Associated lesions are found in 75% of patients and include hiatal hernia, oesophagitis, oesophageal varices and duodenitis/peptic ulceration. Although the bleeding stops spontaneously in the majority of patients, it may be severe and recurrent.

The condition is more often found in males with a history of alcoholism but not invariably. The diagnosis is confirmed by upper gastrointestinal endoscopy. The treatment is conservative with gastric acid suppression. Endoscopic therapy is reserved for patients with actively bleeding tears at the time of endoscopy. Conservative management is usually successful. Surgical

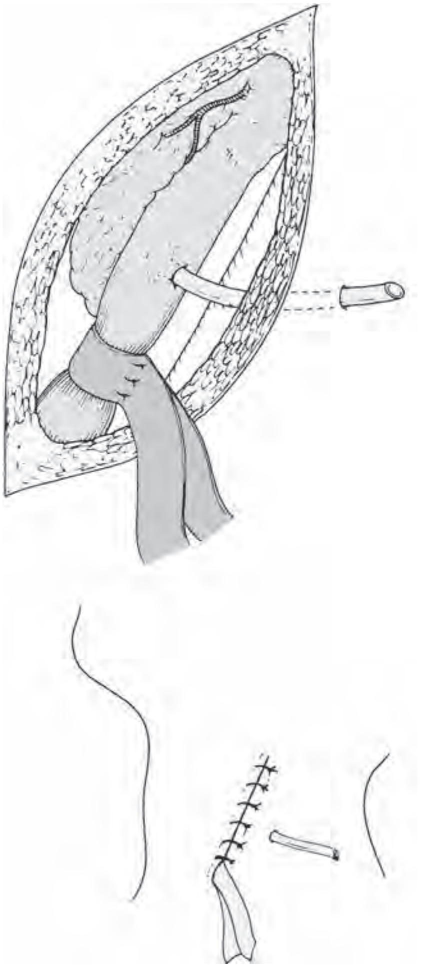

Figure 22.31 Technique of T-tube temporary total diverting cervical oesophagostomy with banding of the oesophagus for high thoracic injuries. The long limbs of the band used to occlude the oesophageal lumen are brought out through the lower end of the incision. (From Hennessey, Cuschieri, *Surgery of the Oesophagus.* Oxford, UK: Butterworth Heineman, 1992, with permission.)

treatment is only indicated for those patients who continue to bleed or in whom the haemorrhage recurs after the above measures. It consists of suture ligation of the bleeding mucosal tears through a generous gastrostomy. Percutaneous embolization of the left gastric artery may be used in poor risk patients such as cirrhotic individuals.

Intramural haematoma

This is very rare entity. It may occur either spontaneously or following transoesophageal echo and cardiac ablation in patients having anticoagulation therapy. In spontaneous cases, it arises from an oesophageal mucosal tear associated with submucosal bleeding with dissection of this plane by the expanding intramural haematoma. Patients give a history of gagging or choking while eating, followed by sharp mid-epigastric/lower retrosternal pain radiating to the back and associated with haematemesis. The patient subsequently develops dysphagia. The diagnosis is usually made on CT imaging and history. The condition is self-limiting.

Atrio-oesophageal fistula

This is a rare condition that typically happens 2 weeks following cardiac interventions. In those cases the majority of patients present with severe sepsis, cerebral abscesses and diminished level of consciousness that requires admission to the intensive care unit. A high level of suspicion is required to reach the diagnosis of those patients. Brain CT is diagnostic, whereas imaging of the chest rarely demonstrates the fistula between the heart and oesophagus. This condition is fatal. In addition to supportive measures, reported cases who survived the condition underwent surgical intervention to repair the heart and oesophagus.

Benign oesophageal strictures

Aetiology

- Gastro-oesophageal reflux
- Postinflammatory conditions
- Post radiation
- Postendoscopic mucosal resection and HALO
- Caustic agents
- Connective tissue disorders, e.g. scleroderma.

Gastro-oesophageal reflux is the most common cause of benign oesophageal strictures. The stricture is caused by chronic fibrosis and scarring in response to chronic reflux injury in the lower oesophagus. Reflux and Barrett's strictures usually occur at the GOJ.

HIV-related benign oesophageal strictures have been reported secondary to idiopathic oesophageal ulceration, cytomegalovirus (CMV) oesophagitis, herpetic oesophagitis and increased sensitivity to radiation therapy. Despite the extensive and deep nature of CMV ulceration, stricture formation is uncommon. There have been anecdotal reports of oesophageal strictures secondary to CMV infection in HIV patients. Oesophageal stricture has been reported during active CMV ulceration and subsequent to successful treatment.

Benign oesophageal strictures occur following radiation therapy to the chest and mediastinum. Oesophageal strictures may also result from chemoradiotherapy treatment of squamous cell carcinoma of the oesophagus. It is crucial in those cases to differentiate between fibrotic benign strictures from recurrent cases and those with residual disease. Also, benign stricture may follow endoscopic therapy of early oesophageal cancer lesions in Barrett's segment such as endoscopic mucosal resection, photodynamic therapy and thermal ablation techniques. Resection of at least 50% of the oesophageal mucosal circumference is strongly associated with stricture formation. Patients with strong histories of tobacco use may also be more likely to develop oesophageal strictures following endoscopic mucosal resections. Again, exclusion of cancerous lesions is mandatory. Benign strictures of the oesophagus occur following oesophageal variceal sclerotherapy in up to 30% of patients and less commonly following oesophageal variceal ligation.

Another cause of benign strictures is ingestion of caustic agents. Caustic stricture formation occurs in up to 30% of patients within 8 weeks and persists. These strictures are often long and may involve the whole length of the oesophagus.

Medication such as alendronate, tetracycline, doxycycline, mycophenolate mofetil, homeopathic pills and NSAIDs can cause oesophageal injury, ulceration and strictures. Rarely, connective tissue disorders such as scleroderma are associated with benign oesophageal strictures.

Clinical picture

Dysphagia is the dominant symptom for oesophageal strictures. The characteristics of dysphagia should be evaluated in terms of onset, duration and the amount of food and nutrition that the patient is able to tolerate. History should be directed to elicit the effects of dysphagia on nutritional status and body weight, and whether the patient has symptoms to suggest respiratory aspiration. History should also seek causes of stricture such as reflux symptoms, endoscopic therapy, radiotherapy, medication and other cause of oesophagitis. An accurate diagnosis is essential, as it affects the treatment options for the oesophageal stricture itself and any underlying disease.

A barium swallow is the initial diagnostic test to establish the length and width of the stricture and the presence of hiatus hernia. It also provides useful information for planning the endoscopy and dilatation. Endoscopic visualization with biopsy and brush cytology should establish the nature of the stricture. The flexible endoscope can also be used for dilatation of the stricture in order to obtain more representative biopsies. A normal barium swallow and endoscopy should rule out a stricture as a cause of dysphagia and in these circumstances a motility disorder of the oesophagus should be considered.

Management

The principles for the management of patients with benign oesophageal strictures are (1) accurate diagnosis of its benign nature and exclusion of malignancy, (2) dilatation to obviate dysphagia and (3) in cases of recurrent symptoms a long-term strategy should be planned.

Dilatation

The principal aim of dilatation is to stretch the fibrous component of the stricture gradually to achieve an oesophageal lumen of 10–15 mm in diameter. The endpoint of dilatation depends on the initial size of the stricture, the general condition of the patient and the predisposing factors. Most strictures can be dilated, but severe long and tortuous strictures are difficult, carry an increased risk of perforation and recur following dilatation. The complications of dilatation include haemorrhage, and perforation. Various types of dilating systems are currently available:

Wire-guided dilators such as the Savery/Gillard dilators, Puestow, Celestin and Gruntzig are useful in all types of strictures. They are more rigid and are less likely to bend or coil. They have a central core so that they can be passed over a preinserted guide wire. Some consist of metal olives (Eder/Puestow) and some are more substantial graduated polyvinyl dilators (Savery/Gillard, Celestin). The guide wire should have a flexible tip and can be inserted either endoscopically or using fluoroscopy. Hydrophilic guide wires tend to be less rigid and more expensive but easier to pass through long and tortuous strictures. When the guide wire is inserted endoscopically it is safer to check the position of the wire by fluoroscopy. When the guide wire is in position the endoscope can be withdrawn and the dilators passed over the guide wire across the strictured part of the oesophagus. Advancement of the dilator should be coupled with rotation of the dilator around the guide wire. When undue resistance is encountered, dilatation should be halted. For severe strictures the dilatation requires to be gradual and the procedure may necessitate two or more sessions with rest intervals of 1–2 weeks between sessions. During each session, dilatation should not exceed a 6–8 mm increase in diameter. If available, routine fluoroscopy should be used for all wire-guided dilatations.

Hydrostatic polyurethane balloon dilators are of two types: those used via the endoscope and dilators over a guide wire under fluoroscopy. The balloons are hydrostatically pressurized to inflate to a maximum diameter. Some versions produce a variable balloon maximum diameter dependent on the hydrostatic pressure. The balloon catheter tip is flexible and atraumatic and can negotiate tortuous or narrow strictures. Hydrostatic balloons are most popular, largely safe and can be used progressively to dilate long strictures.

Once adequate dilatation is achieved, patients should be advised on lifestyle adjustment and should be prescribed PPIs. Patients with reflux symptoms may require antireflux procedures. The majority of patients achieve a satisfactory freedom from dysphagia using this approach. The rest will require frequent dilatations. A single dilatation usually obviates all oesophageal rings and webs; however, medication-and caustic-induced strictures and radiation strictures may require repeat dilatations.

Stent insertion

For patients who require repeated dilatations, removable fully covered self-expandable metal or plastic stents can be inserted to provide long-term alleviation of dysphagia. The success rate in complete remission of dysphagia is 30–50%. Those stents are usually endoscopically removed after 4 weeks. Biodegradable stents have been increasingly used recently to treat benign oesophageal strictures. They have a lower reintervention rate and may potentially reduce complications during stent removal. Complications of stent insertion are haemorrhage and perforation. If the strictures are resistant to stent treatment and the patients are fit, oesophagectomy and replacement surgery should be considered.

Surgical treatment

Indications for surgery are fit young patients in whom repeated dilatation and stent intubations have failed to alleviate dysphagia. Also, surgery is indicated in impassable strictures associated with Barrett's oesophagus as malignancy may not be excluded with certainty.

All young patients with peptic strictures that respond to dilatation and PPIs should be considered for standard *antireflux surgery*. If there is significant oesophageal shortening a *Collis gastroplasty* is indicated to create a neo-oesophagus around which a wrap is formed.

Resection of refractory benign oesophageal strictures is the next therapeutic option. Lower oesophageal segment/gastro-oesophageal stricture can be replaced by *interposed isoperistaltic jejunum*. For long strictures, *subtotal oesophagectomy* with replacement by stomach or colon is reserved. The best long-term results are probably achieved by a vagus-sparing oesophagectomy with an interposed isoperistaltic jejunum or left colon placed in the posterior mediastinum. The use of a gastric pull-through would necessarily incur division of the vagus but would make the operation technically easier and less demanding for the patient.

Oesophageal cancer

Epidemiology

Oesophageal adenocarcinoma has been rapidly increasing in Western countries during the past half century, especially in white males. In the UK, USA and Australia, the incidence of oesophageal adenocarcinoma among white men was 0.5–0.9 per 100 000 population in the 1970s but has increased to 3.2–4 per 100 000 over the following two decades. In these countries the ratio of squamous cancer to adenocarcinoma has decreased significantly, with the dominant cancer in Western countries being oesophageal adenocarcinoma since the 1980s. Among Asian countries, the incidence of oesophageal adenocarcinoma is quite low and the incidence of oesophageal squamous carcinoma is higher, especially in East Asia. Oesophageal squamous cell carcinoma is the dominant type of oesophageal cancer in China, Hong Kong, Taiwan, Korea and Japan.

The increase in oesophageal adenocarcinoma seems to be correlated with the increased prevalence of GORD and being overweight. The risk associated with GORD is related to Barrett's metaplasia. It was found that the pattern of ethnic differences in Barrett's oesophagus is quite similar to that found in the relative incidence of oesophageal adenocarcinoma in epidemiological studies. It was also shown that a raised body mass index (BMI) is a risk factor for oesophageal adenocarcinoma, independently of the occurrence of gastro-oesophageal reflux. Barrett's oesophagus and oesophageal adenocarcinoma seem to be in parallel with the development of socioeconomic status and, geographical differences in the epidemiology of oesophageal carcinoma seem to be correlated with the socioeconomic status.

Aetiology

Gastro-oesophageal reflux

In a meta-analysis of the association of adenocarcinoma with symptoms of GORD, frequent symptoms are strongly associated with oesophageal adenocarcinoma. At least weekly symptoms of GORD increases the odds of oesophageal adenocarcinoma fivefold and daily symptoms increase the odds sevenfold, each compared with individuals without symptoms or less frequent symptoms.

Obesity

A meta-analysis of 14 studies has found that oesophageal adenocarcinoma risk increased two-to threefold in overweight and obese patients. It also observed a dose-dependent relationship, with the risk being higher in obese than in overweight people. Several additional population-based cohort studies of obesity and oesophageal adenocarcinoma risk also showed two- to threefold increased risk and a dose-dependent relationship.

Also obesity predisposes to hiatus hernia and reflux, which contributes to the increased risk of oesophageal adenocarcinoma. There is increased risk only found in obese women (BMI >30), whereas in men it was observed in both overweight (BMI 25–29.9) and obese (BMI >30). In the Million Women Study in the UK, 50% of cases of oesophageal adenocarcinoma in postmenopausal women were attributed to obesity. It was also shown that the male pattern of abdominal obesity (central and retroperitoneal) is more likely to be associated with malignant transformation.

Smoking

In another meta-analysis of 33 studies, compared with never smokers the pooled relative risk was 1.76 for ever smokers, 2.32 for current smokers and 1.62 for ex-smokers. There was a direct association with those with more than 20 cigarettes a day and duration for more than 70 years of cigarette consumption.

Alcohol consumption

The increased risk of oesophageal cancer associated with alcohol use is perhaps limited to oesophageal squamous cell carcinoma. Excessive amounts of alcohol (three or more drinks per day) has almost universally been associated with an elevated risk of oesophageal squamous cell carcinoma, typically increasing risk by three- to fivefold. In contrast, there is little evidence for an association between alcohol drinking and oesophageal adenocarcinoma. The exact mechanism of carcinogenicity of alcohol is not known because alcohol itself does not bind DNA, is not mutagenic and does not cause cancer in animals. However, mechanisms have been suggested, including its conversion to acetaldehyde acting as a solvent for other carcinogens and causing nutritional deficiency.

Helicobacter pylori

Meta-analysis showed that *H. pylori* colonization of the stomach is associated with an early 50% reduction in the risk of oesophageal adenocarcinoma. *H. pylori* may decrease the risk of oesophageal carcinoma by reducing gastric acid production and hence reducing acid reflux from the stomach to the oesophagus. It may also reduce oesophageal adenocarcinoma risk by decreasing the production of ghrelin, a hormone that is mostly produced in the stomach and stimulates appetite. A reduction in the level of ghrelin may lead to lower rates of obesity, an important risk factor for oesophageal adenocarcinoma. In contrast to its association with oesophageal adenocarcinoma, *H. pylori* has not shown a consistent association with oesophageal squamous cell carcinoma. Three meta-analyses on the association of *H. pylori* with squamous cell carcinoma found no overall association, with the summary odds ratio close to unity. In a case-controlled study, the role of *H. pylori* infection and atrophic gastritis was examined in cardia cancer. The study suggested there were two categories of cardia cancer, one associated with *H. pylori* atrophic gastritis resembling non-cardia gastric cancer and the other associated with non-atrophic gastric mucosa resembling oesophageal adenocarcinoma.

Non-steroidal anti-inflammatory drugs

A meta-analysis of nine studies concluded that aspirin and other NSAIDs reduce the risk of oesophageal cancer in a dose–response manner. More frequent use was associated with lower risk, with an overall risk reduction of approximately 40%. This meta-analysis showed similar inverse association with oesophageal squamous cell carcinoma and oesophageal adenocarcinoma. This association may be due to reverse causation: people with a history of upper gastrointestinal symptoms who are also at high risk of cancer may limit the use of aspirin and other NSAIDs. However, some studies stratified their results by having or not having upper gastrointestinal disorder and did not find a difference in the results in these two groups of patients. If the associations are causal, aspirin and NSAIDs may reduce risk by reducing inflammation and affecting the inflammation–metaplasia–cancer sequence at the earliest stage.

Achalasia

Most case studies have reported oesophageal carcinoma in 3–7% of achalasia patients, which is higher than the rates seen in normal populations. Follow-up studies of achalasia patients have consistently shown a substantial increase in the risk of oesophageal carcinoma. One of the largest studies in Sweden showed a 10-fold increased risk in both oesophageal squamous cell carcinoma and oesophageal adenocarcinoma in achalasia patients compared with the rest of the population.

Eating pattern

There is a decreased risk of oesophageal squamous cell carcinoma but not oesophageal adenocarcinoma with higher intake of both fruit and vegetables. On the other hand, eating pickled vegetables was once very common in high-risk areas of China and was thought to be a major risk factor for oesophageal carcinoma in those areas. The results of epidemiological studies have been inconsistent, where some case-controlled studies have shown an association between pickled vegetable intake and oesophageal carcinoma, typically with increased risk of two- to threefold. Other case–control or cohort studies have shown no association.

Poor oral hygiene and tooth loss

Case–control studies showed that tooth loss was associated with a two- to threefold increase in oesophageal carcinoma. Nearly all studies of the association between poor oral health and oesophageal carcinoma risk has been done in areas of oesophageal squamous cell carcinoma. To date there have been no studies specifically evaluating the association between poor oral health and oesophageal adenocarcinoma.

Low socioeconomic status

It has been long known that oesophageal carcinoma is a disease of the poor and socially disadvantaged. Large numbers of epidemiological studies have confirmed that oesophageal carcinoma risk is higher in the population with lower socioeconomic status using different designs (case–control, cohort, comparison of incident cases with the general population), and different socioeconomic class indices and from all parts of the world. The finding that oesophageal carcinoma is more common in lower socioeconomic status is universal. Most studies reported an increased risk of two- to fourfold among those with lower than those with higher socioeconomic status. The majority of studies of socioeconomic status and oesophageal carcinoma have been conducted in populations with a high risk of oesophageal squamous cell carcinoma. There are few data concerning risk association with oesophageal adenocarcinoma, although rich socioeconomic status may link to oesophageal adenocarcinoma.

Summary

Three important risk factors have been identified for oesophageal adenocarcinoma: gastro-oesophageal acid reflux, obesity and smoking. Absence of *H. pylori* in the stomach is also becoming an increasingly recognized risk factor.

Excessive use of alcohol, tobacco use, low intake of fruit and vegetables and low socioeconomic status are risk factors for oesophageal squamous cell carcinoma. Achalasia may predispose people to high risk of oesophageal squamous cell carcinoma.

Clinical presentation

Dysphagia is one of the classical symptoms of oesophageal cancer. It is reported to be present in about 40–50% of patients with a mean duration of about 2 months. It starts with solid food and progresses towards soft food and fluids. Dysphagia usually presents late in the natural history of the disease and becomes severe only when more than 60% of the oesophageal circumference is infiltrated with cancer. The majority of patients who present with dysphagia also have weight loss due to inadequate oral intake and as a consequence of advanced stage of the disease. Any patient with dysphagia should be investigated with upper gastrointestinal endoscopy regardless of age.

There are increasing numbers of patients with early disease who are diagnosed during surveillance for Barrett's oesophagus or investigations for long history of GORD, accounting for about 20–25% of patients at the time of presentation. About 25–30% of patients present with anaemia, chest/abdominal discomfort and bleeding.

Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation and malignant pleural effusion.

Investigations to stage oesophageal cancer

The aim of investigations for patients presenting with the above symptoms is to confirm the nature of the disease and determine the stage of cancer. A multimodality approach including upper gastrointestinal endoscopy, CT, positron emission tomography (PET), EUS and laparoscopy is recommended.

Upper gastrointestinal endoscopy

Upper gastrointestinal endoscopy is the gold standard first investigation to diagnose oesophageal cancer. It allows biopsy tissue to be obtained for diagnosis and the description of the level and morphology of the tumour. Accurate documentation of the length and the level of the tumour are crucial as they will influence management options. Skip cancer lesions can be also seen and biopsied. The appearance of small early lesions will signal the need for further evaluation with a view to endoscopic curative management rather than the surgical option. The ability to pass the endoscope to the stomach should also be reported, as it indicates the ability of the patient to maintain oral intake.

Failure to diagnose malignancy in the first endoscopy is in the range of 10% and about 10–20% of patients require a second endoscopy. If the histology does not confirm oesophageal cancer but the endoscopist has a high suspicion of cancer from the appearance of the lesion, endoscopy should be repeated and further tissue should be sent for histological evaluation. Multiple four-quadrant biopsies of Barrett's lesions at 2 cm intervals along its entire length have been shown to increase diagnostic accuracy and allow differentiation of high-grade dysplasia from adenocarcinoma. For patients with Barrett's oesophagus, continuing treatment with antacid medications can decrease inflammation, making targeted biopsies and histological examination easier.

Chromoendoscopy and high-resolution endoscopy have been introduced to increase the diagnostic accuracy of high-grade dysplasia and early cancer lesions. Lugol's iodine is used for dysplastic and malignant squamous mucosa whereas acetic acid chromatography enhances the detection of occult neoplasia in Barrett's oesophagus. Imaging modalities such as narrow-band and zoom (magnifying) endoscopy are used in selected centres to increase diagnostic accuracy of early lesions. Nevertheless those techniques are not currently in routine clinical practice.

Computed tomography

CT of the chest, abdomen and pelvis is the investigation of choice after confirming the nature of oesophageal lesions on endoscopic biopsies. It is widely available and indicates the local stage and the presence of metastasis. A CT scan should be performed with intravenous contrast (unless contraindicated) and distension of the oesophagus and stomach with about 1 L of water (as long as patients can tolerate this amount) and sometimes gas-forming granules. The use of thin slices (2 mm) and multiplanar reformatted images provides accurate information about the extent and possible invasion of the tumour to adjacent structures such as the diaphragm and aorta.

CT is generally not helpful for T1 disease but provides important information for more advanced stages. The accuracy of CT on staging oesophageal cancer shows a sensitivity and specificity of about 84% for T staging, a sensitivity of 50% and specificity of 85% for N status and a sensitivity of 52% and specificity of 91% for metastatic disease.

^{18}F-Fludeoxyglucose positron emission tomography

Recently, PET and in particular PET-CT are emerging as valuable tools in the staging and in providing prognostic information such as the response to neoadjuvant chemotherapy. Meta-analysis on the yield of CT scan on staging oesophageal cancer showed a sensitivity and specificity of about 87% for T staging, a sensitivity of 50% and specificity of 83% for N status and a sensitivity of 71% and specificity of 93% for metastatic disease. In one study, patients with no metastasis on CT scan, ^{18}F-fludeoxyglucose (FDG)-PET identified distant disease in 4.8% of patients. The distant metastasis in PET should be carefully evaluated and may be confirmed by tissue biopsy before excluding patients from curative surgery, as at least 3.7% are false positives.

Endoscopic ultrasound

This modality has the highest accuracy in evaluating the local stage of the disease. EUS has gained popularity over the last 10 years as the modality of choice for pretherapeutic assessment of depth of tumour infiltration into the oesophageal wall and lymph node status. EUS was confirmed to be reasonably accurate in the identification of T3 tumours (83%). T2 tumours were correctly identified by EUS in only 42% of patients. Even less accurate was the identification of T1 or *in situ* tumours. T1 lesions were correctly classified in 29% of patients, but *in situ* tumours cannot be correctly identified preoperatively.

EUS has a specificity of 70% and a sensitivity of 80% in the diagnosis of regional lymph node metastasis. Although EUS has less overall accuracy for T1 disease, it is important for detecting nodal metastasis when planning endoscopic curative therapies. Endosonographic features predictive of malignancy in increasing order of importance are echo-poor (hypoechoic) structure, sharply demarcated borders, rounded contour and size greater than 10 mm. Collectively, the EUS features produce an additive effect with respect to accuracy in the prediction of malignant lymph node involvement; malignancy could be predicted with 100% accuracy when all four features are present. A careful and systematic approach to the endosonographic assessment of lymph node metastasis can improve staging accuracy.

One of the advantages of EUS is the ability to obtain fine-needle aspiration cytology to confirm local lymph node involvement. EUS can also determine the exact longitudinal extent of the disease, because of its ability to diagnose submucosal extension. The EUS report includes the start and end of the tumour and any involvement of the stomach as well as the level of landmark structures such as carina, crura of the diaphragm and GOJ. This is important in deciding the surgical approach and the extent of resection.

The accuracy of EUS decreases dramatically after neoadjuvant chemotherapy. It also has a limited value when malignant strictures do not allow the passage of the endoscopy for complete assessment.

Staging laparoscopy

Staging laparoscopy should be performed with all lower oesophageal and GOJ tumours to detect peritoneal and small liver deposits that are too small for the resolution of CT and PET imaging. It is also important to inspect the cardia and lesser curvature for tumour extension into the stomach. Serosal gastric extension can sometimes be seen during laparoscopy. Peritoneal lavage is routinely done during laparoscopy for lower oesophageal and gastro-oesophageal junctional tumours. Additional information from staging laparoscopy that influences the treatment decision is obtained in about 15% of patients. Many surgeons prefer to repeat the upper gastrointestinal endoscopy themselves at the time of staging laparoscopy to inspect the tumour and plan the surgical approach.

Bronchoscopy

This is important for tumours at or above the level of the carina that are adherent to the bronchial tree. The examination may be supplemented with endobronchial ultrasound, which also allows fine-needle aspiration of lymph nodes along the trachea that cannot be approached via EUS.

Stages of oesophageal cancer (TNM version 7)

This classification applies to carcinoma and includes adenocarcinoma of the oesophagogastric junction. There should be histological confirmation of the disease and division of cases by topographic localization and histological type. A tumour the epicentre of which is within 5 cm of the oesophagogastric junction and which also extends into the oesophagus is classified and staged using the oesophageal scheme. Tumours with an epicentre in the stomach greater than 5 cm from the oesophagogastric junction or those within 5 cm of the oesophagogastric junction without extension in the oesophagus are classified and staged using the gastric carcinoma scheme. The procedures for assessing T, N and M categories are physical examination, imaging, endoscopy (including bronchoscopy) and/or surgical exploration.

Anatomical subsites

1. Cervical oesophagus: this commences at the lower border of the cricoid cartilage and ends at the thoracic inlet (suprasternal notch), approximately 18 cm from the upper incisor teeth.
2. Intrathoracic oesophagus
   a. The upper thoracic portion extends from the thoracic inlet to the level of the tracheal bifurcation, approximately 24 cm from the upper incisor teeth.
   b. The mid-thoracic portion is the proximal half of the oesophagus between the tracheal bifurcation and the oesophagogastric junction. The lower level is approximately 32 cm from the upper incisor teeth.
   c. The lower thoracic portion, approximately 8 cm in length (includes abdominal oesophagus), is the distal half of the oesophagus between the tracheal bifurcation and the oesophagogastric junction. The lower level is approximately 40 cm from the upper incisor teeth.
3. Oesophagogastric junction.

Regional lymph nodes

The regional lymph nodes, irrespective of the site of the primary tumour, are those in the oesophageal drainage area including the coeliac axis nodes and the paraoesophageal nodes in the neck, but not the supraclavicular nodes.

TNM clinical classification

T – Primary tumour

- TX: Primary tumour cannot be assessed
- T0: No evidence of primary tumour
- Tis: Carcinoma *in situ*/high-grade dysplasia
- T1: Tumour invades lamina propria, muscularis mucosae or submucosa
  - T1a: Tumour invades lamina propria or muscularis mucosae
  - T1b: Tumour invades submucosa
- T2: Tumour invades muscularis propria
- T3: Tumour invades adventitia
- T4: Tumour invades adjacent structures
  - T4a: Tumour invades pleura, pericardium, or diaphragm
  - T4b: Tumour invades other adjacent structures such as aorta, vertebral body or trachea

N – Regional lymph nodes

- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Metastasis in one to two regional lymph nodes
- N2: Metastasis in three to six regional lymph nodes
- N3: Metastasis in seven or more regional lymph nodes

M – Distant metastasis

- M0: No distant metastasis
- M1: Distant metastasis

pTNM pathological classification

The pT and pN categories correspond to the T and N categories.

- pN0: Histological examination of a regional lymphadenectomy specimen will originally include six or more lymph nodes. If the lymph nodes are negative, but the number ordinarily examined is not met, classify as pN0.
- pM1: Distant metastasis microscopically confirmed

G – Histopathological grading

- GX: Grade of differentiation cannot be assessed
- G1: Well differentiated
- G2: Moderately differentiated
- G3: Poorly differentiated
- G4: Undifferentiated

Stage grouping of carcinomas of the oesophagus and oesophagogastric junction:

- Stage 0: TisN0M0
- Stage 1A: T1N0M0
- Stage 1B: T2N0M0
- Stage IIA: T3N0M0

- Stage IIB: T1,T2N1M0
- Stage IIIA: T4aN0M0
  - T3N1M0
  - T1,T2N2M0
- Stage IIIB: T3N2M0
- Stage IIIC: T4aN1,N2M0
  - T4b: Any NM0
  - Any TN3M0
- Stage IV: Any T, Any NM1

Summary: oesophagus (includes oesophagogastric junction)

- T1: Lamina propria (T1a), submucosa (T1b)
- T2: Muscularis propria
- T3: Adventitia
- T4a: Pleura, pericardium, diaphragm
- T4b: Aorta, vertebral body, trachea
- N1: one or two nodes
- N2: three to six nodes
- N3: seven or more regional
- M1: Distant metastasis

Adenocarcinoma at the oesophagogastric junction

Siewert and Stein proposed the classification of adenocarcinoma of the GOJ in 1996, which was based on topographic anatomical criteria. Adenocarcinoma of the GOJ is divided into three types, each of which had different characteristics, thereby influencing the selection of the surgical strategy:

- Type I: tumours in which the centre is located 1–5 cm above the GOJ, regardless of invasion to the GOJ.
- Type II: tumours invading the GOJ, in which the centre is located between 1 cm above and 2 cm below the GOJ.
- Type III: tumours invading the GOJ, in which the centre is located 2–5 cm below the GOJ.

This classification was approved at the consensus conference of the International Gastric Cancer Association (IGCA) and the International Society for Diseases of the Oesophagus (ISDE), and has been accepted and is now used worldwide. The Siewert subtype should be determined prospectively, based on the findings of endoscopy, contrast radiography and CT. A definition of anatomical cardia is determined by the findings of endoscopy.

Theoretically, type I tumours arise from the oesophageal glandular epithelium or Barrett's oesophagus. The prevalence of Barrett's oesophagus in patients with type I tumours is higher than that in patients with type II/III tumours, in both Western and Eastern countries. Type II tumours are true adenocarcinoma of the oesophagogastric junction arising from the junctional epithelium; however, some type II tumours can arise from the same origin as type I tumours, and some can arise from the same origin as type III tumours. Many previous studies have demonstrated that the characteristics of type II tumours are more like those of type III tumours than those of type I tumours, thus indicating that the origin of type II tumours is similar to that of type III tumours. Type III tumours arise from the gastric mucosa, and this origin might be associated with *H. pylori* and atrophic gastritis. Tumours whose centre is located 2–5 cm below the GOJ are classified as non-junctional or true gastric cancers when the tumours do not invade the GOJ. The tumour classification changes to AEG type III when they invade the GOJ by horizontal progression. Therefore, subcardial gastric cancers are classified as type III tumours when they are enlarged. Type III tumours should be treated as gastric cancers invading the GOJ, considering the origin of the tumours. In summary, adenocarcinoma of the oesophagogastric junction may contain two distinct aetiologies. It is often difficult to determine the tumour origin, especially in advanced cases.

Management of disease confined to the mucosa

Vascular invasion and lymph node metastasis are very uncommon in intramucosal cancer (T1a), whereas 25% of patients with submucosal cancer (T1b) have lymph node metastasis. Therefore high-grade dysplasia and intramucosal cancer are suitable candidates for endoscopic curative interventions. There are several options to treat those early lesions. The multidisciplinary team should determine the management strategy depending on local expertise of the surgical and medical teams and on the availability of different endoscopic technologies.

Surgical resection has been the curative option in the majority of centres for patients with high-grade dysplasia and carcinoma *in situ*. The rationale behind the surgical approach is (1) the curative nature of the interventions as no oesophageal cancer-related death has been reported after surgery; (2) the demonstrated safety of surgery in high-volume centres with a postoperative mortality approaching zero in large series; (3) the adequacy of the non-radical approach, such as transhiatal, vagal sparing and minimal invasive oesophagectomy, with its reduced impact on postoperative adverse events and quality of life; and (4) the discovery of incidental intramucosal or invasive cancer in resected specimens that were not diagnosed preoperatively in the range of 15–40% in large series. However, surgery is associated with significant morbidity, mortality in high-risk patients and change in the quality of life.

Recently, with the development of different endoscopic therapies, endoscopic interventions are gaining popularity as an alternative favourable option to surgery. The combination of mucosal resection and radiofrequency ablation are the current popular strategy. The rationale behind this approach is (1) adequate pathological examination with mucosal resection to exclude submucosal invasive cancer; (2) the low rate of 5% or less of missing invasive cancer with the advances in diagnostic endoscopic techniques; (3) safety of the techniques even in patients with significant comorbidity; and (4) avoiding side effects of surgery in terms of postoperative complications and the effect on quality of life. However, patients undergoing definitive endoscopic therapy require a careful follow-up programme with frequent endoscopic examinations.

Endoscopic interventions are divided into mucosal ablative therapy and endoscopic mucosal resection. Ablative therapies destroy the metaplastic epithelium allowing replacement with neosquamous epithelium. The main ablation modalities are radiofrequency ablation and photodynamic therapy. In radiofrequency ablation, a high-power short burst of energy is applied to the columnar epithelium via direct contact. A dose of 10–12 Js/cm^2 removes all epithelium without damage to the underlying submucosa, resulting in a lower incidence of treatment-related stricture and improved rates of ablation of dysplasia and Barrett's oesophagus. In a multicentre sham-controlled randomized trial, 127 patients with dysplastic Barrett's oesophagus were randomized to receive either radiofrequency ablation (ablation group) or a sham procedure (control group). In the intention-to-treat analyses, among patients with low-grade dysplasia, complete eradication of dysplasia occurred in 90% of those in the ablation group, compared with 23% in the control group. Among patients with high-grade dysplasia, complete eradication occurred in 81% in the ablation group, compared with 19% in the control group. Overall, 77% of patients in the ablation group had complete eradication of intestinal metaplasia, compared with 2.3% in the control group. Patients in the ablation group had less disease progression (3.6% vs 16.3%) and fewer cancers (1.2% vs 9.3%). Patients reported having more chest pain after the ablation procedure than after the sham procedure. In the ablation group, one patient had upper gastrointestinal haemorrhage, and five patients (6.0%) had oesophageal stricture. This study has clearly documented the value and safety of radiofrequency ablation in the management of dysplastic oesophagus. This modality has replaced photodynamic therapy, which suffers from a high prevalence of incomplete ablation, 30% prevalence of strictures and lack of availability in most centres.

A limitation of all ablative therapies is the lack of specimens for histological examination. With endoscopic mucosal resection, this limitation is overcome. Owing to the inability to see high-grade dysplastic lesions for mucosal resection and the frequency of multifocal carcinoma within dysplastic Barrett's oesophagus, a concomitant ablative procedure of Barrett's oesophagus is required to ensure complete eradication of disease. Endoscopic mucosal resection should generally be limited to less than 5 cm in diameter and used primarily for resection of nodules associated with Barrett's oesophagus rather than for complete Barrett's eradication. In a study of 100 consecutive patients with low-risk adenocarcinoma of the oesophagus who underwent endoscopic resection, no major complications and only 11 minor cases of bleeding were reported. Complete local remission was achieved in 99 of the 100 patients after 1.9 months with a maximum of three resections. During a mean follow-up period of 36.7 months, recurrent or metachronous carcinomas were found in 11% of the patients, but successful repeat treatment with endoscopic resection was possible in all of these cases. The calculated 5 year survival rate was 98%. Two patients died of other causes.

There are no prospective trials comparing outcomes of endoscopic and surgical interventions for Barrett's oesophagus and high-grade dysplasia, although a number of retrospective studies have been reported. Those studies do not show a survival difference for either surgery or ablation with or without mucosal resection, although early mortality was higher in the surgical group. There was significant treatment failure observed in the endoscopic intervention groups as 10–20% of patients develop new or metachronous cancer. There was no cancer recurrence in the surgical group.

Surgical management of oesophageal cancer

Preparation of patients for oesophageal surgery is crucial. This should entail a discussion by the multidisciplinary oesophageal cancer team for accurate cancer staging and evaluation of fitness for surgery. Optimization of cardiorespiratory and nutritional status is essential to minimize postoperative complications. Stopping smoking, regular exercise and adequate nutrition should be routine advice for patients undergoing oesophageal surgery.

Different surgical approaches

The following definitions describe access to oesophagectomy:

- *Transthoracic oesophagectomy:* open resection of the oesophagus employing thoracotomy, including all single-, two- and three-site approaches utilizing either a right or left thoracotomy or thoracoabdominal incisions.
- *Transhiatal oesophagectomy*: open resection of the oesophagus performed through the oesophageal hiatus and thoracic inlet without open thoracotomy.
- *Minimally invasive oesophagectomy*: minimal access approach via laparoscopy and/or thoracoscopy. A hybrid procedure is often performed combining a minimal access approach with laparotomy or thoracotomy.

Extent of lymphadenectomy

This describes the field of lymphadenectomy performed in the abdomen, chest or the neck as follows:

- Radical lymphadenectomy procedures
  - *Three-field lymphadenectomy* with lymph node resection encompassing upper abdominal (D2), inferior middle and superior mediastinal lymph nodes, and inferior cervical nodes.
  - *Two-field lymphadenectomy*, which is the same as the above with the exception of removal of the cervical nodes.
  - *Infracarinal two-field lymphadenectomy* which omits both cervical lymph nodes and a formal superior mediastinal nodal dissection.
- Non-radical lymphadenectomy is a conservative lymphadenectomy in which only the nodes in direct proximity to the tumour, the oesophagus and upper stomach are removed.

It is important for surgeons not to mix the approach with the field of lymphadenectomy. Ivor Lewis oesophagectomy entails laparotomy and right thoracotomy. This may or may not entail radical lymphadenectomy in the form of abdominal and infracarinal two-field lymphadenectomy.

Rationale for lymphadenectomy

Prevelance of lymph node metastasis with oesophageal cancer

Lymph node involvement is very common with oesophageal cancer even with early disease. As tumour depth increases the extent of lymph node involvement increases in terms of both the number of nodes involved and the involvement of distant nodes. Lymph node metastases have been found in up to 35% of T1b tumours and in 78–85% of T3 tumours. Lymph node involvement may occur in the abdominal, thoracic or cervical nodes regardless of whether the primary tumour is located at the GOJ, distal, mid- or upper oesophagus. Metastatic nodes in the cervical lymph nodes have been found in 17% of GOJ tumours and 23% of distal third tumours.

Accurate staging

The Surveillance, Epidemiology and End-Results (SEER) database study of 2597 patients showed that N0 had fewer lymph nodes identified than those classified as N. Other investigators have reported a strong correlation between the number of lymph nodes examined and the number involved. For example, patients who were N0 had a mean lymph node count of 14.2 ± 7.1, whereas the lymph node count was 18.0 ± 9.3 in patients found to have lymph node metastases. In another study of 366 patients, those who had 15 lymph nodes examined were more likely to have positive lymph node metastases than patients who had less than 15 nodes examined.

Influence of the extent of lymphadenectomy on survival

Several authors in Western centres have reported case series of radical lymphadenectomy with improved long-term survival (Altorki and Skinner; Lerut *et al.*; Hagen and DeMeester). Also, radical three-field lymphadenectomy is the standard surgical approach in Japan with 5 year survival of 68–54%. A randomized trial of cervical and upper mediastinal lymph node dissection for squamous cell carcinoma of the thoracic oesophagus reported overall survival of 66% at 5 years for the extended dissection with harvest of a mean of 82 nodes vs 48% for standard dissection with a harvest of 43 nodes. In a study examining the effect of one-, two- or three-field lymphadenectomy increased survival was reported with increasing extent of lymph nodes resection. Overall survival at 5 years was 21.2% vs 36.3% vs 53.7% for patients resected with a one-, two- or three-field lymphadenectomy. However, the benefit of more extensive lymphadenectomy was predominantly in the N0 group, suggesting that the benefit is predominantly related to stage migration.

Influence of the number of lymph nodes resected on survival

The SEER 1973–2003 database study examined the relationships between the number of lymph nodes examined and overall survival in a cohort of 5620 patients. On multivariate analysis, total lymph node count (or negative lymph node count, respectively) was an independent prognostic variable. Higher total lymph node count (>30) and negative lymph node count (>15) categories were associated with best overall survival and lowest 90 day mortality. The numeric lymph node effect on overall survival was independent from nodal status or histology. Greater total and negative lymph node counts are associated with longer survival. Although the mechanism remains uncertain in this study, it does not appear to be limited to stage migration. There was an optimum cut-off point for the number of lymph nodes resected above which there was no further improvement in survival.

Another international study of 2303 patients from nine centres who underwent R0 oesophagectomy showed that the number of lymph nodes removed is an independent predictor of survival after oesophagectomy for cancer. To maximize this survival benefit a minimum of 23 regional lymph nodes must be removed.

Influence of lymphadenectomy on local recurrence

Local recurrence has been shown to be very uncommon (<5–10%) following radical three-field lymphadenectomy, which contrasts with a 35% prevalence of local failure following transhiatal oesophagectomy and a 15–20% prevalence after Ivor Lewis resection. These findings may be explained by the removal of unrecognized, often microscopic, disease with more extensive lymph node dissection. Involved nodes that are left behind during simple oesophagectomy are probably the cause of recurrent local disease. Local recurrence is very difficult to treat and affects the quality of life and may also influence long-term survival.

Safety of radical procedures

With centralization of surgical services, the postoperative mortality of radical oesophagectomy has fallen significantly to <5% in Western centres. In some centres, the mortality reaches <1%. High hospital volume drives the process of care and therefore the improvement in the postoperative pathway and in managing postoperative complications results in a significant reduction in mortality in spite of a relatively high postoperative complication rate.

Quality of evidence for comparative studies of transthoracic vs transhiatal oesophagectomy

In a systematic review of the quality of evidence and meta-analysis of outcomes, survival was shown to be equivalent in randomized trials and comparative studies but more advanced cancer and inadequate surgical quality (including inadequate lymph node clearance) of transthoracic oesophagectomy were found to be significant confounding factors. Although transhiatal resection was chosen significantly more frequently for early stage tumours, the transthoracic approach was more often adopted for advanced stage IV tumours. This may be influenced by stage migration since significantly more lymph nodes were harvested from patients in the transthoracic group.

Also, rating the reported quality of surgical resections shows that no study met all minimum surgical quality standards. Only four of the 52 studies presented lymph node data in a format that was suitable for meta-analysis. This is of significant concern as the number of resected lymph nodes has been shown to be a determinant factor for survival in oesophageal cancer. Therefore, evidence from those randomized trials and comparative studies should be viewed with caution.

The extent of radicality of lymphadenectomy

If radical lymphadenectomy provides better survival and lower local recurrence rate, it is expected that three-field lymphadenectomy would have superior results to infracarinal lymphadenectomy. This is particularly with squamous cell carcinoma as 30% of patients will have lymph node metastasis in the neck and around recurrent laryngeal nerves in the superior mediastinum. It is also likely to be the case, although less evidence is available, for adenocarcinoma where 15% of patients have positive cervical lymph nodes. The vast majority of patients have T2 and T3 tumours, with the majority having positive lymph nodes. Some surgeons in Western centres have moved from infracarinal lymphadenectomy to three-field lymphadenectomy.

Transthoracic vs transhiatal oesophagectomy

Meta-analysis of 52 studies, comprising 5905 patients (3389 transthoracic and 2516 transhiatal) showed that transthoracic operations took longer and were associated with a longer length of stay. There was no difference in blood loss. The transthoracic group had significantly more respiratory complications, wound infections and early postoperative mortality, whereas anastomotic leak, anastomotic stricture and recurrent laryngeal nerve palsy rate were more common in the transhiatal group. The lymph node harvest was only reported in four studies and was significantly greater in the transthoracic group by on average only eight lymph nodes. Complete 5 year follow-up was only present in a single paper and using actuarial 5 year survival there was no significant difference found. No study met all minimum surgical quality standards and therefore the evidence of those studies should be viewed with caution.

Technical aspects of oesophagectomy

Stapled vs hand-sewn anastomosis

Meta-analysis of 10 studies comprising 936 patients and comparing hand-sewn with stapled anastomosis showed 10.04% anastomotic leaks in the hand-sewn group and 51 (10.9%) in the stapled anastomosis group with no significant difference between the groups.

Methods of reconstruction

This depends on the location of the tumour and previous surgical procedures. Stomach conduit is the most commonly used. The stomach has a reliable blood supply and its mobilization can be performed with standard lymph node dissection. The reconstruction has a single anastomosis. Disadvantages include the loss of the gastric reservoir and increased risk of acid reflux.

Colonic reconstruction has the potential advantages of providing a peristaltic conduit, preserving the gastric reservoir and, overall, has a lower incidence of postresection oesophageal reflux. Disadvantages include a much longer, more complex operation with three anastomoses, a less predictable blood supply and an increased risk of internal hernias, and a tendency for even well-constructed colonic interpositions to become tortuous and dilated over time.

Roux-en-Y jejunal reconstructions are used when stomach or colon is unavailable and are limited with extent to proximal extension, although optimum mobilization can allow anastomosis above the inferior pulmonary vein. Free jejunal interpositions with microvascular anastomosis can be used for cervical reconstruction.

Pyloric drainage after gastric tube reconstruction

Meta-analysis of six comparative studies showed that pyloric drainage procedures showed a non-significant trend towards fewer anastomotic leaks, pulmonary complications and reduced gastric stasis when employed following oesophagectomy. However, the ideal technique remains unproven.

The practice of the authors is to test the emptying of the gastric conduit in the course of a postoperative contrast study that is carried out to test the integrity of the anastomosis. If delayed emptying through the pylorus is encountered, balloon dilatation under radiological guidance is carried out.

Multimodality oncological management

A meta-analysis of 24 studies including 4188 patients was reported in 2011 examining survival benefits of neoadjuvant chemotherapy and neoadjuvant chemoradiotherapy compared with surgery alone in oesophageal cancer. This meta-analysis provides strong evidence for a survival benefit of neoadjuvant chemoradiotherapy or chemotherapy over surgery alone in patients with oesophageal carcinoma. A clear advantage of neoadjuvant chemoradiotherapy over neoadjuvant chemotherapy has not been established.

Neoadjuvant chemotherapy

The UK Medical Research Council (MRC – EO2) randomized controlled trial of 802 patients into surgery alone compared with two 3 week cycles of cisplatin + 5-fluorouracil chemotherapy followed by surgery showed that the neoadjuvant chemotherapy group had better 2 year survival (43% vs 34%) and 5 year survival (23% vs 17%) than surgery alone.

This survival benefit was not observed in the US Intergroup-0113 study, which randomized 467 patients into surgery alone or three cycles of cisplatin + 5-fluorouracil chemotherapy followed by surgery and postoperative cisplatin + 5-fluorouracil chemotherapy for responders. However, there was a significant improvement in 5 year survival for patients who underwent R0 resection vs patients who had resection margins that were either microscopically or grossly positive (32% vs 5%). Also, patients who underwent incomplete resections (R1 or greater) had survival rates that were equivalent to those who did not undergo surgery at all. These findings highlight the importance of negative resection margins in combined modality treatment. Furthermore, patients who had an objective response to neoadjuvant chemotherapy had significantly better survival rates.

Several factors may account for the difference in results between those two trials using similar chemotherapeutic regimens. The MRC trial larger sample size might have allowed the detection of statistically small yet clinically significant survival advantage that could not be detected with a small sample size trial. Also, the histology for the two trials was different: about two-thirds of patients in the MRC trial had adenocarcinoma compared with about 54% in the Intergroup trial.

The perioperative chemotherapy MAGIC trial using three cycles of preoperative and postoperative epirubicin (E) 50 mg/m^2, cisplatin (C) 60 mg/m^2 and continuous intravenous infusion of 5-fluorouracil (F) 200 mg/m^2 per day (ECF) significantly improved 5-year survival from 23% with surgery alone to 36.3%. In this trial, 26% of patients had distal oesophageal or gastro-oesophageal adenocarcinoma. This regimen is currently the standard practice in the UK for those tumours.

Neoadjuvant chemoradiotherapy

A systematic review of 38 papers, comprising 3640 patients, published between 2000 and 2008 showed that neoadjuvant chemoradiation regimens for oesophageal cancer vary widely with a predominance of 5-fluorouracil/cisplatin chemotherapy. Chemoradiation-related toxicity was reported in only 10 studies and consisted mainly of neutropenia. The chemoradiation-related in-hospital mortality rate was 2.3% compared with 5.2% for oesophagectomy following chemoradiation. The mean R0 resection rate and pathological complete response rate were 88.4% and 25.8% respectively. Five-year survival rates varied from 16% to 59% in all patients and from 34% to 62% in those with a complete pathological response. Chemoradiation had a temporary negative effect on quality of life.

The question is whether neoadjuvant chemoradiotherapy increases the morbidity and mortality of oesophagectomy. Studies have demonstrated that oesophagectomy can be performed safely with low mortality and acceptable morbidity following neoadjuvant chemoradiotherapy with no increase in hospital stay for patients with complications.

A recent randomized trial (CROSS study) for resectable (T2-3N0-1M0) oesophageal tumours randomized 363 patients into preoperative chemoradiotherapy consisting of weekly administrations of paclitaxel and carboplatin for 5 weeks and concurrent radiotherapy (41.4 Gy in 23 fractions, 5 days per week) followed by surgery vs surgery alone. The complete pathological response was 32.6%. In-hospital mortality was 3.7% in the surgery alone arm vs 3.8% in the chemoradiotherapy arm. The toxicity of this regimen was also acceptable. The overall survival was significantly better in the group of patients treated with neoadjuvant chemoradiotherapy. Median survival was 49 months in the chemoradiotherapy arm vs 26 months in the surgery alone arm. One, 2 and 3 year survival rates are 82%, 67% and 59%, respectively, in the chemoradiotherapy arm and 70%, 52% and 48%, respectively, in the surgery alone arm.

Squamous cell cancer has a better response to chemoradiotherapy than adenocarcinoma. This has been shown in subgroup analysis of prospective clinical trials. Tumour response to neoadjuvant chemotherapy is an independent prognostic factor in patients with squamous cell carcinoma.

Definitive chemoradiotherapy

The Intergroup RTOG 85-01 study was the landmark study of definitive radiotherapy with or without chemotherapy in patients with resectable squamous or adenocarcinoma of the oesophagus (T1–3N0–1M0) not subjected to routine oesophagectomy. Patients were randomized to four cycles of 5-fluorouracil and cisplatin with concurrent 50 Gy total dose radiotherapy compared with 64 Gy total dose radiotherapy alone. Five-year survival was 26% in the chemoradiotherapy arm vs 0% in the radiotherapy alone group and the survival benefit was maintained at 8 year follow-up (22% vs 0%). Persistence of disease despite therapy was the most common mode of treatment failure, but it was less common in patients receiving combined therapy (26%) than in the group treated with radiotherapy alone (37%). Severe acute toxic effects were greater in the combined therapy groups but there were no significant differences in severe late toxic effects between the groups.

Two European randomized clinical trials have investigated the value of surgery in a combined modality approach to oesophageal cancer. All of the patients in the Stahl study and 90% of the patients in the Bedenne trial had squamous cell carcinoma. In the Stahl study, patients with locally advanced squamous cell carcinoma of the oesophagus were randomly allocated to either induction chemotherapy followed by chemoradiotherapy (40 Gy) followed by surgery, or the same induction chemotherapy followed by chemoradiotherapy (at least 65 Gy) without surgery. The study concluded that 'adding surgery to chemoradiotherapy improves local tumour control but does not increase survival of patients with locally advanced oesophageal SCC. Tumour response to induction chemotherapy identifies a favourable prognostic group within these high-risk patients, regardless of the treatment group'.

All patients in the Bedenne trial received two cycles of fluorouracil and cisplatin and either conventional (46 Gy in 4.5 weeks) or split-course (15 Gy, days 1–5 and 22–26) concomitant radiotherapy. Patients with response and no contraindication to either treatment were randomly assigned to surgery or continuation of chemoradiation [three cycles of fluorouracil/cisplatin and either conventional (20 Gy) or split-course (15 Gy) radiotherapy]. The 2-year local control rate was better in the surgical arm than in the definitive chemoradiotherapy group (66.4% vs 57.0%) and stents were also required less in the surgery arm (5% vs 32%).

From both trials, response to induction therapy should be the deciding factor as to who proceeds to surgery, as patients with a good response to therapy had equal (or better) survival to the group that eventually underwent surgery. Surgery provided better local control vs chemoradiotherapy alone, and, for those patients who did not respond to induction therapy, complete surgical resection improved survival. Nevertheless, oesophagectomy should be performed with low mortality rates, otherwise the survival benefits will be mitigated.

Palliative management of oesophageal cancer

First-line palliative chemotherapy

In patients with incurable disease, it is essential to consider patient comorbidity, functional status and quality of life. Patients with oesophageal cancer have the same benefits from palliative chemotherapy as those with gastric cancer and oesophagogastric junctional tumours. For patients who can withstand chemotherapy, the benefits of palliative chemotherapy over the best supportive measures have been shown in randomized controlled clinical trials.

In randomized controlled trials, combination therapy of ECF had superior response rates (45% vs 21%), median overall survival (8.9 vs 5.7 months) and 2 year survival (13.5% vs 5.4%) over FAMTX (5-fluorouracil, Adriamycin and methotrexate). Also, ECF had similar response and survival rates to MCF (mitomycin C, cisplatin and 5-fluorouracil) but better quality of life measures.

In the REAL-2 study, a two-by-two design, we randomly assigned 1002 patients to receive triplet therapy with epirubicin and cisplatin plus either fluorouracil (ECF) or capecitabine (ECX) or triplet therapy with epirubicin and oxaliplatin plus either fluorouracil (EOF) or capecitabine (EOX). The primary endpoint was non-inferiority in overall survival for the triplet therapies containing capecitabine compared with fluorouracil and for those containing oxaliplatin compared with cisplatin. Median survival times in the ECF, ECX, EOF and EOX groups were 9.9 months, 9.9 months, 9.3 months and 11.2 months, respectively; survival rates at 1 year were 37.7%, 40.8%, 40.4% and 46.8%, respectively. In the secondary analysis, overall survival was longer with EOX than with ECF, with a hazard ratio for death of 0.80 in the EOX group. Progression-free survival and response rates did not differ significantly among the regimens. The study concluded that capecitabine and oxaliplatin are as effective as fluorouracil and cisplatin, respectively, in patients with previously untreated oesophagogastric cancer.

In summary, patients with good performance status but inoperable oesophagogastric cancer should be offered combination therapy of EOX or ECX.

Target agent in combination with chemotherapy

In patients who have HER-2-positive oesophagogastric junctional or gastric tumours, the addition of trastuzumab to cisplatin and 5-fluorouracil resulted in significant improvement in response rate (47.3% vs 34.5%), progression-free survival (6.7 vs 5.5 months) and median overall survival (13.8 vs 11.1 months). Tumours are considered to be HER-2 positive if the immunohistochemistry score is 3+ or if the tumour is positive for fluorescent *in situ* hybridization.

Interventions for dysphagia

A Cochrane systematic review of 40 randomized controlled trials including 2542 patients with inoperable or unresectable primary oesophageal cancer who underwent palliative treatment was carried out. The review included different interventions such as rigid plastic intubation, self-expanding metallic stent insertion, brachytherapy, external beam radiotherapy, chemotherapy, oesophageal bypass surgery, and chemical and thermal ablation therapy. The primary outcome was improvement of dysphagia. Secondary outcomes included recurrent dysphagia, technical success, procedure-related mortality, 30-day mortality, adverse effects and quality of life (Figure 22.32).

The results of the analysis showed that self-expanding metallic stent insertion is safer and more effective than plastic tube insertion. Thermal and chemical ablative therapy provide comparable dysphagia palliation but have an increased requirement for reinterventions and adverse effects. Antireflux stents provide comparable dysphagia palliation to conventional metal stents. Some antireflux stents might reduce gastro-oesophageal reflux compared with conventional metal stents. Brachytherapy might be a suitable alternative to self-expanding metallic stents in providing a survival advantage and possibly a better quality of life.

The review concluded that ‘self-expanding metal stent insertion is safe, effective and quicker in palliating dysphagia than other modalities. However, high-dose intraluminal brachytherapy is a suitable alternative and might provide additional survival benefit with a better quality of life. Self-expanding metal stent insertion and brachytherapy provide comparable palliation to endoscopic ablative therapy but are preferable due to the reduced requirement for reinterventions. Rigid plastic tube insertion, dilatation alone or in combination with other modalities, chemotherapy alone, combination chemoradiotherapy and bypass surgery are not recommended for palliation of dysphagia due to a high incidence of delayed complications and recurrent dysphagia’.

Benign oesophageal tumours

Benign tumours of the oesophagus are part of a diverse and relatively rare group of pathologies which present infrequently as part of the general surgeon’s operative case mix. It is however important to recognize these tumours and distinguish them from life-threatening or malignant lesions, with which they may

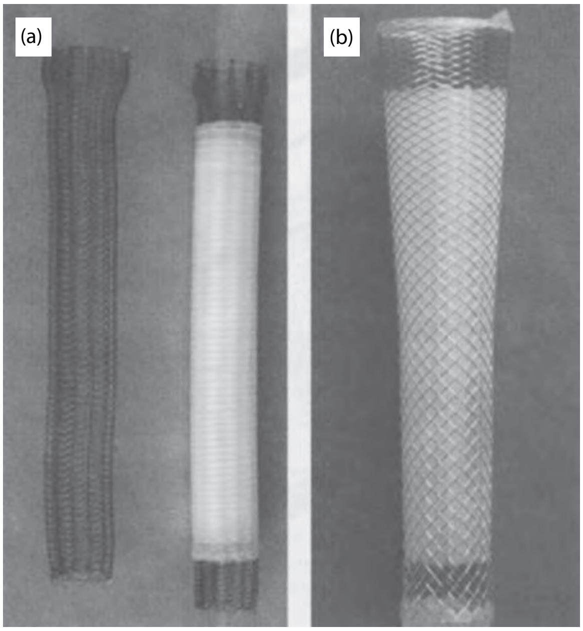

Figure 22.32 Palliation of dysphagia by stenting. (a) Ultraflex stents (covered and uncovered); (b) covered Flamingo stent.

coexist and intermittently be mistaken, and treat them with the aim of restoring oesophageal integrity and function, preferably through a minimally invasive approach.

Although several hundred cases of benign tumours have been reported over the past centuries under a plethora of names, their true prevalence is unknown. A number of autopsy reviews in the past century have reported a prevalence of 0.17–0.59% with the mid- to lower oesophagus being the most common sites of occurrence. More certainly, retrospective reviews have shown these tumours to constitute less than 10% of all resected oesophageal specimens.

Perhaps due to their paucity and range, classification of the benign tumours is also extremely varied. Historically, these disorders have been grouped according to the tissue histology (Box 22.7) or their relative location in the oesophageal wall (Box 22.8).

Clinical features of benign oesophageal tumours

Benign oesophageal tumours, although usually asymptomatic, are recognized to have a large range of presenting features (Box 22.9):

- *Asymptomatic.* The great majority of benign tumours are slow growing, arising in the submucosa or intramural portion of the oesophagus. As a result they tend to be insidious in nature, being discovered only incidentally during endoscopic or radiological investigation of the upper gastrointestinal tract. Owing to their nature, many patients with benign lesions may never be aware of their condition, which may account for the significant portion of cases in the premodern era that were found at autopsy without any obvious ill effect.
- *Obstruction from intraluminal growth.* Obstructive symptoms are usually the outcome of intraluminal lesion growth or extension from the oesophageal wall. Clinical symptoms tend to occur late in the

- Ulceration and bleeding

disease process, usually when the tumours are large (>5 cm), resulting in varying levels of dysphagia, vomiting, cough and substernal discomfort. Although the most common feature in the symptomatic patient, dysphagia in association with benign oesophageal tumours occurs only sporadically. Moersch and Harrington, in a large retrospective review of 11 000 patients presenting with dysphagia from any cause, found benign tumours to be the underlying pathology in only 15 patients (0.14%).

- *Compression of adjacent structures by extramural tumour.* Benign tumours may occasionally grow to such a size that they result in compression of mediastinal structures and subsequent atelectasis, airway obstruction and superior vena cava syndrome. Furthermore, as benign tumours can coexist with other oesophageal disorders such as malignancy, achalasia, diverticulum and hiatal hernia, it is of critical importance to exclude any additional or alternative pathology to ensure the optimum operative outcome.
- *Regurgitation of pedunculated tumour.* Tumours arising from the smooth muscle of the muscularis mucosae can pedunculate and protrude into the oesophageal lumen. Pedunculated tumours are occasionally found following regurgitation into the upper airway where they can cause obstruction and death in severe cases.
- *Ulceration and bleeding.* Vascular lesions such as haemangiomas or pedunculated tumours with a large vascular pedicle may spontaneously ulcerate, resulting in acute bleeding. Additionally, endoscopic examination and histological sampling of a similar lesion will also produce acute haemorrhage.

Treatment of benign oesophageal tumours

Most authors advocate excision of the tumour through enucleation, regardless of the tumour type, due to the potential for coexisting malignant disease and risk of complication.

Regardless of the approach taken, a preoperative work-up aiming to characterize the lesion using a combination of endoscopy, barium swallow and CT scan is essential, thereby allowing exclusion of any coexisting comorbidity, malignant change and extraoesophageal involvement.

Treatment typically falls into one of four categories:

- observation
- endoscopic excision/ablation
- open surgery (laparotomy/thoracotomy)
- minimally invasive surgery (laparoscopy/thoracoscopy).

Observation

As most tumours are asymptomatic, slow growing and generally incidental findings, it has been advocated that, following exclusion of significant comorbidity and malignancy, it is occasionally possible to actively observe patients and intervene only if symptoms develop or if a further pathology requires operative treatment.

Endoscopic excision/ablation

As with the excision of colonic polyps, it has been advocated that the endoscopic approach would be feasible for removing oesophageal lesions. In particular, where tumours arise from the muscularis propria, the presence of a normal mucosal layer overlying the tumour permits its enucleation whilst preserving the submucosa. As with other polyps, a saline injection is used to lift the tumour away from the submucosa and delineate it more precisely, thereby allowing polypectomy via a snare approach. The procedure is associated with bleeding, which can usually be controlled through the use of an argon plasma beam or endoscopic clips. Conversion rates specifically for endoscopically removed benign oesophageal tumours are not known but the indications and incidence should typically be the same as for other endoscopic procedures.

Open surgery (laparotomy/thoracotomy)

Surgical approaches in the pre-endoscopic era typically involved either laparotomy or (right sided) thoracotomy. The precise approach depended on the location of the pathology. A thoracotomy was the preferred modality as it allowed the oesophagus to be accessed throughout its length from the cricopharyngeus to the diaphragmatic hiatus. Additionally, large tumours are more easily enucleated through the open approach and where necessary, in rare instances, oesophagectomy can also be performed.

Minimally invasive surgery (laparoscopy/thoracoscopy)

The minimally invasive approach has largely superseded the open approach over the past 20 years, particularly when operating on small or medium-sized lesions (typically up to 7–8 cm in length).

Patients are usually placed in the left lateral decubitus (for right-sided access) or prone position and intubated with a double-lumen endotracheal tube to permit single lung ventilation. An intraoperative, on-table endoscopy is advocated by some authors to identify the site of the lesion more accurately, determine the presence of any fibrosis surrounding the tumour which may complicate surgery by obliterating the anatomical planes, and ensure the mucosa remains intact postoperatively.

Once access is gained, the tumour is identified and myotomy performed, developing the plane between the tumour, muscularis propria and submucosa leading to eventual enucleation and excision. Some authors will endoscopically confirm that the mucosa is intact and, following this, the muscle layer is sequentially closed to complete the procedure.

In cases where a lesion lies in close proximity to the hiatus or GOJ, a laparoscopic approach is occasionally taken to excise the tumour and, where necessary, a fundoplication procedure is further conducted to prevent postoperative reflux.

The remainder of this section will focus on the common benign oesophageal tumours and their specific presentation and management.

Leiomyoma

Oesophageal leiomyomas are the commonest benign oesophageal tumours accounting for more than 50% of all such lesions at both autopsy and surgery. The oesophagus is the site of 10–12% of all gastrointestinal leiomyomas with a peak incidence between the third and sixth decades and a reported propensity for men more than women (1.8:1).

Pathology

Leiomyomas are usually singular (but multiple in 2.4% of cases), arising largely from smooth muscle cells and, due to the presence of striated (skeletal) muscle in the upper oesophagus, are found mainly in the mid- and lower oesophagus (Box 22.10). Tumours can very occasionally extend into the mediastinum, causing compressive symptoms. In a series of 838 cases, 97% of leiomyomas were found to be intramural, 1% polypoid intraluminal and 2% extraoesophageal.

Histologically they are composed of smooth muscle arranged in elongated, interconnected spindle cells with blunted nuclei and eosinophilic cytoplasm surrounded by hypovascular connective tissue. Although malignant change has been reported within leiomyomas, it appears to be a rare complication.

BOX 22.10 Anatomical location of oesophageal leiomyomas

- Upper oesophagus (10%)
- Mid-oesophagus (40%)
- Lower oesophagus (50%)

Clinical features

As is the case with benign oesophageal tumours in general, the great majority of leiomyomas are also asymptomatic, with symptoms typically occurring only when the tumour is >5 cm in size and causing a degree of luminal occlusion or mediastinal mass effect. The symptom range is extremely wide and non-specific (Box 22.11), with dysphagia and retrosternal discomfort the most common. Odynophagia results from oesophageal stretching or is due to the passage of a food bolus in the face of a compressed oesophageal lumen.

Diagnosis

As a result of the predominant intramural growth and limited intraluminal effect, diagnosis of leiomyoma is usually incidental during contrast studies, radiology or endoscopic examination of the upper gastrointestinal tract.

- *X-ray* can occasionally show a mediastinal mass particularly when calcified but is not in itself diagnostic.
- *Contrast studies* will show (1) a crescent-shaped filling defect within the oesophagus, (2) flattening of the mucosal folds overlying the tumour, (3) a mobile tumour mass on swallowing, (4) sharp demarcation of the tumour poles with the oesophageal wall and (5) splitting of the barium column as on passing the lesion (Figure 22.33).
- *Computed tomography* will further delineate the margins of the tumour and where malignancy or extraoesophageal involvement is suspected, would confirm the exact mass effects and nodal involvement (if any).
- *Upper gastrointestinal endoscopy* will most commonly show a round, moveable submucosal mass covered by a normal, easily displaced mucosa. Biopsy would confirm the lesion to be benign in nature.

BOX 22.11 Presenting features in symptomatic leiomyomas

- Dysphagia/odynophagia
- Retro/substernal pain
- Hypersalivation
- Postpranidal epigastric pain
- Dyspepsia
- Weight loss
- Bloating
- Cough
- Wheeze
- Dyspnoea
- Anaemia
- Regurgitation
- Nausea
- Vomiting

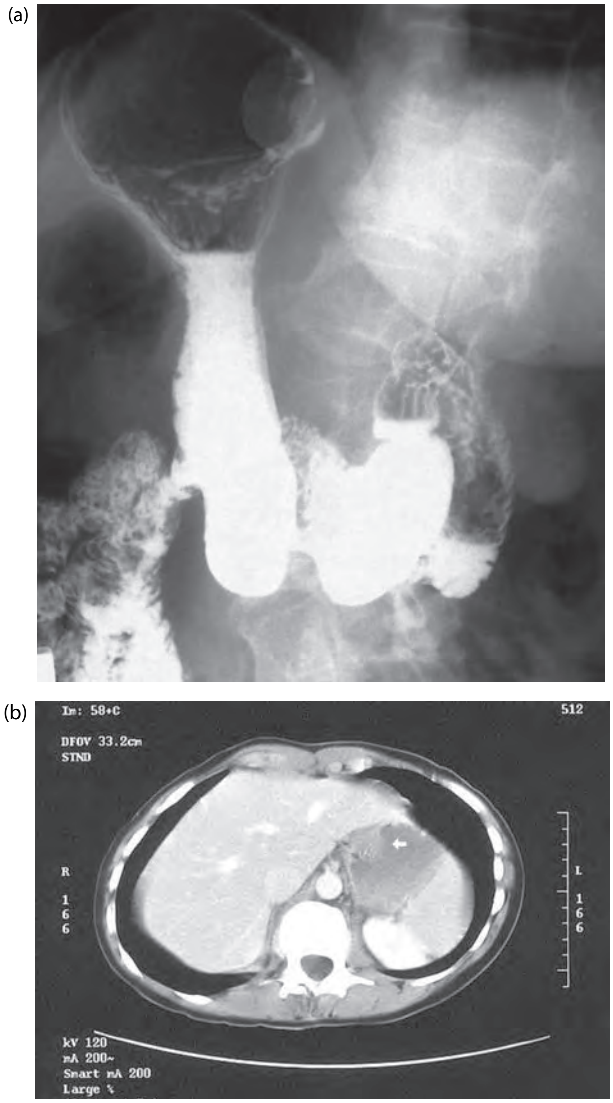

Figure 22.33 (a) Barium swallow showing a smooth ovoid tumour at the gastro-oesophageal junction. The lesion was a benign leiomyoma. (b) CT scan of the same patient.

Treatment

Surgical treatment consists of enucleation and excision according to the principles described previously. It is important to bear in mind that leiomyomas can coexist with diseases such as malignancy, diverticulum and hiatal hernia in which surgical treatment will usually be necessary.

Oesophageal inclusion and duplication cysts

Oesophageal cysts are the second most common benign oesophageal tumours, having an autopsy prevalence of one in 8200.

Inclusion cysts tend to be intramural and are often found in the upper oesophagus, in close proximity to the tracheal bifurcation. They consist of a mucosal lining of ciliated columnar or stratified squamous epithelium and contain a clear mucoid or brownish fluid. Oesophageal duplication cysts, where a portion of the oesophagus is doubled, are by comparison much rarer than inclusion cysts. Twenty per cent of gastrointestinal tract duplications occur in the thorax and some 60% of thoracic duplication cysts occur in the lower third of the oesophagus.

Clinical features

The effects of the cysts are usually the result of pressure exerted in the mediastinum. Particularly when in proximity to the tracheobronchial system, inclusion cysts can cause airway obstruction and recurrent respiratory tract infection.

Duplication cysts are extramural lesions, sharing a common muscular wall with the native oesophagus, extending for a variable distance parallel to the oesophagus with a predominantly gastric mucosa lining. The mucosa is associated with acid production which can subsequently result in ulceration, haemorrhage and oesophageal perforation.

Owing to the variety of potential complications that result from inclusion and duplication cysts, surgical excision and reformation of the oesophagus is the most widely practised treatment.

Fibrovascular polyp

These have been variously labelled in the medical literature as fibroma, fibrolipoma, myxofibroma, benign oesophageal polyp, fibroepithelial polyp and pedunculated lipoma. Fibrovascular polyps are the commonest intraluminal benign oesophageal tumours, mainly seen in men in their fifties and sixties.

Pathology

Although able to develop at any level, the normally solitary fibrovascular polyp is most often (>85%) found in the upper oesophagus lumen or wall, distal to the cricopharyngeus. The lesions usually start as small polypoid mucosal tumours which, with time, become elongated and pedunculated due to peristalsis and repeated swallowing. Seventy-five per cent of polyps are 7 cm or longer when patients present, with lengths of up to 20 cm being reported.

Microscopically, the polyps are thin, composed of loose fibrovascular tissue with mucosal folds or large elongated pedicles containing varying levels of blood vessels, adipose cells and stroma covered by normal squamous mucosa.

Clinical features

In the symptomatic patient, dysphagia is the usual presenting symptom. A review of 16 patients with symptomatic fibrovascular polyps found 87% and 25%, respectively, to have dysphagia and respiratory symptoms such as cough, wheeze and stridor. If sufficiently large, the distal tip of the polyp may ulcerate, resulting in bleeding and pain. Patients have infrequently been reported to present with tumour regurgitation into the mouth prior to the condition being recognized which can be associated with life-threatening airway obstruction.

Diagnosis

As with all benign tumours, diagnosis is largely coincidental. Most dramatically in the case of the fibrovascular polyp, it presents with oral regurgitation. More conventionally, the lesion, when combined with digestive or respiratory symptoms can be recognized on radiographs, which can show a relatively radiolucent oesophageal neoplasm. This may be more clearly delineated on contrast examination or CT. Endoscopy may also reveal the diagnosis, but if present intramurally the polyp may not always be evident.

Treatment

Fibrovascular polyps, once diagnosed, are treated with surgical resection to prevent possible oral regurgitation and fatal asphyxia due to laryngeal impaction. Small lesions can generally be excised endoscopically; however, the presence of a highly vascular pedicle can necessitate a cervical incision or even thoracic intervention. A minimal access approach is potentially possible for a polyp that is bound in the intramural space and can be freed up using a small myotomy, or with dissection within the oesophageal wall through a cervical incision.

Squamous cell papilloma

Squamous cell papillomas are small (typically measuring <1.5 cm), rare lesions (autopsy incidence of 0.01–0.04%) which occur usually in the elderly population.

Occasionally, multiple papillomas can occur, especially in the lower oesophagus, having the appearance of a mass of sessile warty lesions covered by a squamous mucosa with a fibrous core. This mass appearance of papillomas can be confused with a verrucous squamous cell carcinoma, with only biopsy providing the definitive diagnosis.

Histologically, the tumours show multiple finger-like projections of hyperplastic squamous epithelium with a central connective tissue core. The tumour has been associated with human papilloma virus and a single case of malignant degeneration has been reported, but overall this seems to be a rare complication. Treatment will be based on excision along established lines as discussed previously.

Granular cell tumour

These are rare lesions, approximately 0.5–2 cm in size, firm in consistency, arising from the submucosa and appearing as submucosal yellow, sessile polypoid structures with an intact mucosa, most frequently in the distal oesophagus.

The most common anatomical locations are:

- tongue (40%)
- skin (30%)
- breast (15%)
- alimentary tract (5%).

Oesophageal granular cell tumours account for 1–2% of all tumour cases.

Histologically, the tumours consist of polygonal cells with a distinct cellular border and pale cytoplasm filled with eosinophilic granules. Occasionally the tumours may be mistaken for squamous cell carcinoma because of pseudoepitheliomatous hyperplasia of the overlying mucosa.

Granular cell tumours are reported to stay stable over an extended period of time without much growth. However, malignant change has been reported in 3.4% of cases, suggesting that active resection is a preferable approach to that of watchful waiting.

Inflammatory pseudotumours

These are localized pedunculated tumours arising from the mucosa and found mainly in the distal oesophagus. They are associated with marked inflammatory changes within and may resemble a malignant carcinoma. Histological differentiation from a malignant process can be difficult but is vitally important to distinguish the two as pseudotumours do not usually require any specific treatment.

Inflammatory polyps

Inflammatory polyps result from reflux oesophagitis appearing macroscopically as oedematous inflamed gastric folds at the GOJ. Histologically, the polyp will demonstrate non-specific inflammatory infiltrates in the gastric mucosa, which contain plasma cells, eosinophils, multinucleated giant cells and fibroblasts. Managing the underlying gastro-oesophageal reflux will usually also be definitive for treating the polyp itself.

Adenomatous polyps

These lesions arise as a result of hyperplasia involving the epithelial cell itself, basement membrane and underlying vascular and connective tissues. They may additionally arise as a segment of columnar epithelium (Barrett's) with dysplastic change, which may occasionally be of a high grade requiring surgical excision.

Haemangioma

Haemangiomas result from hypertrophy of submucosal vascular tissue, appearing as solitary blue nodules, and account for some 2–3% of all benign tumours.

Patients are usually asymptomatic but can present with spontaneous bleeding if the overlying mucosa becomes ulcerated or following endoscopic biopsy or trauma.

Owing to the potential for unimpaired growth and haemorrhage, localized lesions are usually considered for surgical resection. However, one series examining the incidence of oesophageal haemangiomas reported 16 such lesions of which 12 were found at autopsy. This would suggest that surveillance is appropriate and treatment indicated if the lesions enlarge or bleed.

Summary

Benign solid tumours of the oesophagus are a rare but interesting selection of pathologies, which are usually diagnosed as incidental findings on endoscopic examination of the oesophagus. Although surgical treatment usually produces excellent results, it is vital that a thorough, accurate diagnostic work-up is conducted to exclude any coexisting pathologies and malignancy and ensure an optimum patient outcome without significant morbidity.

CHAPTER 23

Disorders of the stomach and duodenum

SIR ALFRED CUSCHIERI AND GEORGE B. HANNA

Surgical anatomy

Macroscopic anatomy of the stomach

The stomach has an irregular pyriform shape tapering towards the duodenum and curved anteriorly so that its proximal (cardiac) orifice at the junction with the oesophagus and the distal end (pyloric sphincter) are at a more posterior plane near the retroperitoneum than the middle section (body) of the organ. It is anatomically divisible into three parts: the fundus, body and pyloric regions (antrum and pyloric canal). The fundus is the globular proximal portion to the left of the oesophagus separated from it by the cardiac notch and attached by fascia to the left crus and adjacent diaphragm and the gastrophrenic peritoneal fold. The pyloric region extends from the angular notch on the lesser curvature to the pyloric sphincter and consists of the antrum (proximal tapering portion) and the pyloric canal (tubular distal part just proximal to the pyloric sphincter), which is made up of a thickening of the circular muscle coat discontinuous with the equivalent muscle layer of the duodenum. The site of the pylorus is marked by a shallow superficial serosal notch and by the two veins of Mayo (superior and inferior) that cross its anterior surface. The anterior wall of the stomach is more voluminous that the posterior wall and this is important in antireflux surgery.

The normal stomach is lined by two types of mucosa:

- Parietal (oxyntic) lining the fundus and stomach contains parietal acid-secreting and chief cells that secrete pepsins. Surface mucosa has rugae and is acid.
- Antropyloric mucosa contains mucus-secreting and G-cells that secrete gastrin. Surface mucosa is smooth and neutral or slightly alkaline.

There are no surface markings for the antroparietal junction and the extent of the antral mucosa varies, but on average is approximately 5.0 cm from the pyloric orifice.

The stomach rests on the stomach bed consisting of retroperitoneal structures and organs: spleen, diaphragm, left kidney and adrenal, pancreas, splenic artery, transverse colon and mesocolon – hence the complexity of its vascular supply and lymph node drainage. It is almost completely lined by peritoneum anteriorly from the greater sac and posteriorly from the omental bursa (lesser sac). Above the lesser curvature of the stomach, these meet to form the lesser omentum, which is attached superiorly to the liver. The lesser omentum is usually thin; encloses the bile duct, hepatic artery and portal vein at its right extremity; and has a clear portion (devoid of fat) on the extreme left referred to as the pars flaccid that overlies the caudate lobe of the liver near the right crus of the diaphragm. The branches of the left and right gastric arteries run along the lesser curvature between the two layers of the lesser omentum. The two peritoneal layers meet along the greater curvature of the stomach to form a much larger and fattier fold, which has different names in its various sections, but which from the surgical standpoint should be considered as one structure sweeping from the entire margin of the greater curvature and fundus.

- Greater omentum – attached to the transverse colon and mesocolon, from which it can be separated through the embryonic vascular plane.

- Gastrosplenic ligament – contains the short gastric vessels to the spleen.
- Gastrophrenic ligament – small peritoneal fold that joins the stomach to the diaphragm to the left of the oesophagus.

Duodenum

Although anatomically part of the small intestine, the duodenum (the named is derived from its length being roughly equal to the breadth of 12 human fingers) is closely related to surgery of the stomach and pancreas. It is the shortest and widest part of the small intestine, has no mesentery and is only partially covered by peritoneum, its posterior aspect being fixed by fascia to the posterior abdominal wall. It forms an eccentric curve 28 cm long facing the left. Proximally it joins the stomach at the pylorus and distally the small intestine at the duodenojejunal junction, which is marked by a peritoneal fold known as the ligament of Treitz. It is divided into four portions: first (pars superior, first portion, duodenal bulb); second, descending portion or pars descendens varies from 7 to 10 cm in length and contains the duodenal papilla; third or horizontal portion (pars horizontalis, preaortic); and the fourth ascending portion (pars ascendens), which is short, averaging 2.5 cm in length. The duodenal bulb passes backwards from the pylorus before turning down to form the second part. The fourth parts bends forwards at the duodenojejunal junction. The superior relation to the duodenal curve is the gallbladder, the fundus of which touches the duodenal bulb. On the right side and posteriorly are the inferior vena cava, the right renal vessels, the renal pelvis/upper ureter of the right kidney and the aorta. Anteriorly, the second part is crossed by the transverse colon to which it is attached by loose areolar tissue, whereas the third part is crossed by the superior mesenteric vessels and the root of the small bowel mesentery. The head of the pancreas nestles inside the duodenal curve. In the groove between the duodenum and the pancreas runs the gastroduodenal artery, which arises from the common hepatic and descends behind the duodenal bulb to reach the groove.

The duodenal mucosa contains *Brunner's* glands, which secrete highly alkaline mucus that acts as a protective mechanism to the mucosa from the acid chyme delivered into the duodenum by the stomach. Usually the Brunner epithelium stops just beyond the duodenal papilla and never reaches the duodenojejunal junction.

Blood supply of the stomach and duodenum

Stomach

The stomach is supplied by the left gastric, right gastric, right gastroepiploic and left gastroepiploic arteries; thus, directly or indirectly, its blood supply is from the coeliac axis. The left gastric artery (origin from the coeliac axis or aorta) gives off an ascending oesophageal branch and then runs down between the two layers of the lesser omentum close to the lesser curvature to form an anastomotic arcade with the right gastric artery (origin from the hepatic artery). This arcade gives off delicate branches to the lesser curve but most of its bigger branches pierce the seromuscular coat anteriorly and posteriorly to join the submucosal vascular plexus of the stomach. Likewise, the right gastroepiploic (origin from the gastroduodenal artery) forms an arcade along the greater curvature and joins up with the left gastroepiploic (origin from the splenic artery). All the branches from the gastroepiploic arcade pierce the seromuscular layer to join the submucosal vascular plexus of the stomach with no direct branches to the greater curvature.

Extensive arterioarterial and arteriovenous connections are present within the gastric submucosal vascular plexus. The nutritional blood supply to the stomach (with the exception of the lesser curvature) is derived from this plexus. This accounts for the viability of the stomach when only one artery (right gastroepiploic) is retained during gastric tube reconstruction after oesophagectomy. It also underlies the increased safety of tubulization of the stomach, which entails removal of the lesser curve and adjacent stomach over reconstruction with the use of the intact stomach. The other benefit of tubulization is increased length. The venous drainage of the stomach parallels roughly the arterial supply.

Duodenum

The duodenal blood supply is through the duodenopancreatic arcades, which supply the duodenum and pancreas and form an important collateral route between the coeliac and superior mesenteric territories. The duodenopancreatic arcades are formed by the gastroduodenal artery (origin hepatic artery) and the anterior and posterior inferior pancreatic arteries (originating from the superior mesenteric artery). The gastroduodenal artery soon after its origin behind the duodenal bulb gives off the posterosuperior pancreaticoduodenal (or retroduodenal) artery, which curves round the lower common bile duct in its descent to the posterior aspect of the head of the pancreas and the duodenum. The gastroduodenal artery then continues in the groove between the duodenum and the pancreas and divides into the right gastroepiploic and anterior superior pancreaticoduodenal artery. The latter together with the retroduodenal artery anastomoses with the anterior and posterior inferior pancreaticoduodenal arteries derived from the superior mesenteric artery. This explains the difficulty in devascularizing the duodenum in bleeding duodenal ulcers. The collateral circulation between the coeliac and superior mesenteric arteries through the duodenopancreatic arcades also accounts for the unpredictable results of ligation of the common hepatic artery.

Nerve supply

The sympathetic supply is through the splanchnic nerves (T5/6–T9/10) with the preganglionic efferent fibres ending in the coeliac plexus. The postganglionic fibres then travel in the periarterial plexuses along the arteries to the stomach and duodenum. The sympathetic fibres subserve visceral sensation and pain. The parasympathetic supply is from the vagal nerves. There is considerable variation in the anatomical distribution of the vagal branches to the stomach and duodenum, which is not helped by the confusing eponymous nomenclature and lack of precise knowledge regarding the origin of some of the branches. Classically, the anterior vagus has the following branches:

- Hepatic branches – constant. They travel up towards the liver in the pars flaccid of the lesser omentum

- The pyloric nerve of McCrea – inconstant nerve to the pyloric region.
- Anterior gastric division or nerve of Latarget – constant antral branches which are preserved in highly selective vagotomy.

The posterior vagal trunk gives off the following branches:

- The posterior gastric division – posterior nerve of Latarget – smaller but essentially a mirror image of the corresponding anterior nerve
- The coeliac division to the coeliac plexus.

The proximal branches to the fundus have a variable origin from the nerves of Latarget, from the main vagal trunks at or above the hiatus and even from the oesophageal nerve plexus in the mediastinum. One of these nerves arising from the anterior trunk close to the oesophagogastric junction is known as the nerve of Grassi and is held responsible for some of the recurrences after vagotomy, although other proximal gastric branches are equally important is this respect.

In addition, there are gastroepiploic nerves which travel along the related vessels in the greater omentum and are said to innervate the parietal cell mass alongside the greater curve. There is no doubt regarding the existence of these nerves as they can be demonstrated in thin patients, but their origin and function has not been established, although some regard them as important in ulcer recurrence after highly selective vagotomy.

Most of the nerve supply to the duodenum is from the coeliac plexus.

Ultrasound of gastric mucosal layers and anatomy of the gastric mucosal glands

Endoscopic ultrasound (EUS) has enabled the acquisition of *in vivo* data from human subjects on the wall thicknesses of the stomach and other sections of the alimentary tract (needed in radiation dosimetry). Five layers of differing echo patterns are outlined EUS by of the stomach:

- superficial mucosa
- deep mucosa
- submucosa
- muscularis externa
- serosa/adventitia.

In a study of human patients, the thicknesses for stomach mucosa ranged from 1030 ± 130 to 1640 ± 80 m. The total stomach wall thicknesses varied from 2.80 ± 0.12 to 4.23 ± 0.03 mm.

The gastric mucosa, which is heaped up in rugae in the fasting state, is dotted with deep pits into which open the gastric glands, which vary in their morphology in accordance with their location in the stomach: cardiac glands at the cardia, fundic glands at the fundus and antropyloric glands. Different cell types are found at different levels (Figure 23.1) from the opening of the gland into the gastric pits: isthmus, body and base of gland.

- Mucous glands are located at the isthmus (neck) of the cardiac, fundic and antropyloric glands – secrete alkaline clear mucus which lines the surface of the stomach as a protective layer.
- Parietal (oxyntic) cells located in the body of the glands (mainly antropyloric) – secrete hydrochloric acid (HCl) and intrinsic factor (IF).

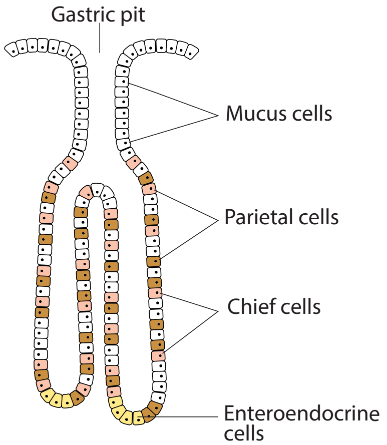

Figure 23.1 Schematic to illustrate the relation between the gastric pits and the gastric glands (cardia, fundic, antropyloric).

- Chief (peptic, zymogenic) cells located at the base of fundic glands only – secrete pepsinogens.
- Ghrelin endocrine cells located at the base of the fundic glands only – secrete ghrelin which stimulates release of growth hormone (see section Gastric physiology).
- Enteroendocrine cells also known as amine precursor uptake decarboxylase located at the base of all glands – secrete gastrin, histamine, endorphins, cholecystokinin (CCK), somatostatin.

Gastrin is released by the G-cells in response to distension of the antrum by ingested digested food (chyme). It stimulates the secretion of HCl from the parietal cells, and pepsinogen from the chief cells also increases gastric motility. Gastrin secretion is inhibited by a low pH (<4.0) and by somatostatin.

CCK induces contraction and thus emptying of the gallbladder after meals (especially fatty), decreases gastric emptying and induces the postprandial release of pancreatic juice which is alkaline and thus neutralizes the acid chyme entering the duodenum from the stomach.

Lymph node drainage

The drainage of lymph from the stomach is very complex and arranged in tiers and lymph node stations in the supracolic compartment and defined by the Japanese Society for Research in Gastric Cancer into 20 numbered stations which form the basis of modern curative resections for gastric cancer. The details of the lymph node stations and the various types of radical resections are outlined later on in this chapter (see Gastric cancer).

Gastric physiology

The most important physiological function of the stomach is to act as a receptacle (capacity 0.5–1.0 L) for ingested food, which is partially digested and hydrolysed by acid and pepsin, milled into semifluid chyme in the antropyloric region and then delivered in regulated aliquots in the postprandial period (gastric emptying). To enable the ingestion of an adequate amount of food, the stomach (particularly the fundus) possesses the property of adaptive relaxation or accommodation, which enables it to enlarge its capacity without a significant rise in the intraluminal pressure. The adaptive relaxation is mediated by stretch reflexes and vagal afferents and is therefore greatly impaired after vagotomy. It is also reduced to varying extents after partial gastrectomy and fundoplication. Loss of adaptive relaxation is manifested clinically as early satiety and can be caused by disease (usually malignant) that infiltrates the wall of the stomach The stomach is able to absorb most acidic drugs by passive diffusion of their lipid undissociated form, e.g. aspirin, other non-steroidal anti-inflammatory drugs (NSAIDs), ethanol, thiopental, secobarbital and antipyrine, whereas all substances which are almost completely ionized in acid solution are not. Ironically, some of the readily absorbed substances (NSAIDs, ethanol) are also known to cause gastric irritation and their overuse is commonly associated with development of gastritis and gastric ulcers.

The mucosa lining the body and fundus (proximal stomach) contains parietal (oxyntic), chief (zymogen secreting) and ghrelin-secreting G-cells (fundus only), whereas the mucosa lining the more muscular antropyloric segment secretes predominantly an alkaline mucus but contains specialized endocrine (G) cells that release gastrin in a co-ordinated fashion under the influence of gastrin-releasing peptide (GRP). The parietal cells secrete hydrochloric acid (HCl) and IF (necessary for the absorption of vitamin B_{12}) in the terminal ileum, whereas the chief cells are responsible for the production and secretion of pepsinogens that are then converted to active pepsins by HCl.

The motility of the stomach is a highly organized event controlled by the enteric nervous system. The initial adaptive relaxation after eating is followed by an increased activity of the antropyloric segment (antral mill), the contractions of which together with the acid/pepsin digestion convert the food into semifluid chyme before onward controlled passage into the duodenum via the pyloric sphincter. Normal gastric secretion consists of three interconnected phases: *cephalic, gastric* and *intestinal*. The *cephalic phase* follows stimulation of the vagal centres in the hypothalamus from the psychosensory input: expectation, sight, smell and chewing of food. The effect is mediated by direct cholinergic stimulation of the parietal cell mass and by cholinergic potentiation of other stimuli including histamine release. The *gastric phase* has two components. The first is consequent on intragastric stimulation by stretch receptors and chemoreceptors in the body that activate local and vasovagal reflexes evoking acid secretion. The second is the release of gastrin from the antrum by stimulation of stretch receptors and activation of antral chemoreceptors by peptides and amino acids released from the food acting via GRP. The *intestinal phase* is initiated by the entry of chyme into the duodenum when bile, pancreatic juice and various hormones are released. A delicate feedback inhibition occurs whereby acid and fat in the duodenum inhibit further gastric secretion by the release of secretin and CCK.

Peripheral mechanisms of gastric acid secretion

The secretion of acid is an important function of the human stomach, as by killing bacteria it provides a first-line defence against enteric infection. Gastric acid is also essential for the conversion of inactive pepsinogens to pepsins which initiate the digestion of dietary protein. Gastric acid is secreted by the human stomach constantly but the secretion rate varies, being low in the fasting state but sufficient to maintain the intragastric pH below 2.0. The secretion rate is highest with eating when the smell and taste of food stimulate the parietal cells mass via the vagal nerves. Additionally, the protein of ingested food stimulates the G-cells situated at the antral region to release gastrin, which circulates and stimulates the parietal cells in the body to secrete HCl. There are protective mechanisms which prevent excessive acidity of the stomach and duodenum. These include the release of somatostatin by D-cells within the antral mucosa, which exerts a paracrine inhibition of gastrin by the G-cells.

Gastric acid secretion is stimulated by acetylcholine, gastrin and histamine. Special receptors for these secretagogues are present on the surface of the gastric mucosal cells. The H_2 receptor (for histamine) is the most efficacious receptor in stimulating gastric secretion and has been cloned and shown to belong to the same family as the -adrenergic receptors. Its blockade by H_2-receptor antagonists (cimetidine, ranitidine, etc.) used to form the basis for acid suppression in the treatment of duodenal ulcer disease and reflux oesophagitis but has largely been replaced in clinical practice by proton pump inhibitors (PPIs).

Acetylcholine is released from the postganglionic neurones of the vagal sympathetic system and this is referred to as neurocrine secretion. Gastrin is released from the specialized G-cells into the bloodstream and exerts a hormonal action. Histamine is released from three sites (mast cells, enterochromaffin-like cells and nerves) into the interstitial fluid of the gastric mucosa and thus acts by a paracrine action.

The main inhibitor of gastric secretion is somatostatin, which is released from the D-cells and exerts a continuous inhibitory paracrine effect on the parietal cells of the fundus and on the G-cells of the antrum. Various hormones, such as secretin, CCK, vasoactive intestinal polypeptide (VIP), etc., inhibit gastric secretion through the release of somatostatin. More recent studies have shown that increased vagal cholinergic activity results in both direct stimulation of acid secretion and indirect stimulation by suppression of somatostatin restraint. This process is referred to as disinhibition. Other substances that inhibit gastric secretion include neurotensin, substance P and high concentrations of alcohol.

The acid pump

Irrespective of the chemical messenger (histamine, acetylcholine, gastrin) the ability of the parietal cells to secrete acid is dependent on the integrity of the enzyme H^+, K^+-adenosine triphosphatase (ATPase), which is also known as the acid pump. The system exchanges the H^+ from the intracellular water for extracellular K^+ present in the lumen of the canaliculus. Reversible inhibition of the ATPase pump can be achieved by PPIs, e.g. omeprazole. PPIs are inactive when administered but in the highly acid environment of the acid secretory canaliculus of the parietal cells, omeprazole is converted to cationic sulphenamide, which reacts covalently with groups in the outside of the pump producing long-lasting total but reversible inhibition of acid secretion. PPIs have largely replaced H_2 blockers in the treatment of peptic ulcer disease and reflux oesophagitis. However, with prolonged administration PPIs may cause a significant hypergastrinaemia. In experimental animals prolonged administration of PPIs results in the development of benign tumours of the enterochromaffin cells. The significance of this to prolonged therapy in the human remains uncertain although in practice only short or intermittent (on demand) PPI therapy is used.

Gastric secretion of pepsinogens

Pepsins are aspartate proteinases and are synthesized and secreted by the chief cells as prozymogens. The three important pepsins are pepsin I, pepsin II (gastricsin) and pepsin III (chymosin). Their main physiological role is acid-dependent digestion of dietary proteins within the stomach. The released peptides and amino acids mediate gastrin release, and through this mechanism the food-dependent gastric secretion of both acid and pepsins. Although pepsins may be involved in the pathophysiology of gastritis, peptic ulceration and gastro-oesophageal reflux disease, the exact mechanisms are still poorly defined, although digestion of the collagen IV component of the basement membrane, with delayed healing of any mucosal injury, may be operative.

Physiology of the gastric fundus

The primary function of the gastric fundus is to receive and store food. In the basal (fasting) state, the fundus is contracted, its resting tone being determined by a balance between excitatory cholinergic and inhibitory nitrergic drive. In humans activation of 5-HT_1receptors (by sumatriptan) relaxes the fundus. This relaxation is reversibly blocked by inhibition of nitric oxide synthase, confirming the nitrergic pathway. Variations in the tone of the gastric fundus alter the reservoir volume of the stomach during eating, thus enabling receptive relaxation. Additionally, gastric emptying is influenced by changes in the tone of the gastric fundus. Receptive relaxation during eating is largely mediated through activation of a nitrergic pathway. Efferent vagal preganglionic fibres synapse on both cholinergic excitatory and non-adrenergic non-cholinergic (NANC) inhibitory intrinsic neurones within the myenteric plexus of the fundus wall. The precise nature of the specific neurotransmitter released by the NANC neurones responsible for gastric relaxation is still uncertain, although on the basis of several experimental studies is thought to be nitrous oxide or VIP since both induce NANC-mediated relaxation of the fundus.

Growth hormone and ghrelin

Growth hormone (GH) has a complex regulation with two antagonistic hypothalamic hormones: growth hormone-releasing hormone and somatostatin, as well as the liver-derived hormone insulin-like growth factor (IGF)-I. Its secretion is influenced by metabolic signals (plasma levels of glucose, amino acids, free fatty acids, keto-acids) and the energy balance/nutritional state. Physiologically, GH has a dual action: somatic growth and the regulation of general metabolism.

The discovery of ghrelin followed the synthesis of artificial analogues referred to as growth hormone secretagogues (GHSs), including the highly potent GH-releasing hexapeptide, which stimulate the release of GH through their action on specific receptors in the pituitary gland. Following the cloning of the GHS receptor, this ligand was used to screen different tissue extracts. The highest expression of GHS receptor-activating factor, now known as the hormone ghrelin, is found in the gastric fundus where the ghrelin cells are located close to the capillaries and have no contact with the lumen of the oxyntic glands, indicating their endocrine nature. In most animals and in humans, the circulating ghrelin (normal plasma level range, 200–600 ng/L) originates largely from gastric fundal secretion. However, the majority of plasma ghrelin is not biologically active, as it is deamidated. Current radioimmunoassays measure total ghrelin. Through its release of GH, ghrelin is actively involved in the control of energy balance and the regulation of food intake.

The regulation of ghrelin secretion is controlled by food intake, vagal activity and various hormones. Somatostatin, cortistatin, thyroid hormones and insulin reduce gastric ghrelin secretion, whereas CCK and gastrin stimulate secretion (Figure 23.2). Human ghrelin is known to cross the blood–brain barrier and ghrelin administration activates fos and Egr-1 proteins in neurones of the arcuate, paraventricular and dorsomedial nuclei, and the area postrema of the hypothalamus. There is however controversy as to whether ghrelin acts by direct activation of central nervous system receptors or indirectly through activation of vagal nerve fibres. The latter mechanism has been suggested by the results of several animal studies, in which vagotomy was demonstrated to abolish ghrelin-induced feeding and GH secretion.

In humans, ghrelin administration (by either intravenous or direct infusion via the intracerebroventricular route) releases GH. Hence it is likely that gastric ghrelin may be involved in the physiological regulation of GH regulation secretion. Ghrelin administration in humans induces a sensation of hunger, an action which is opposite to that of the hormone leptin (derived from white adipose tissue). Ghrelin levels

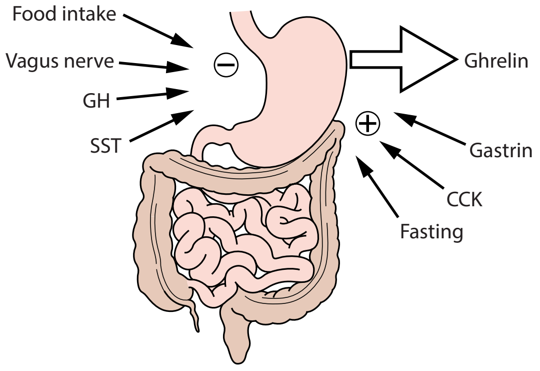

Figure 23.2 Regulation of gastric-derived ghrelin. GH, growth hormone; SST, somatostatin; CCK, cholecystokinin.

are decreased in obese patients and elevated in malnutrition states from any cause. Weight gain in malnourished patients is accompanied by a gradual reduction in the plasma ghrelin levels to normal. The plasma ghrelin levels are decreased after feeding in a reciprocal pattern with insulin, and in the fasting state, ghrelin levels are in phase with leptin. It seems therefore that the preprandial ghrelin rise may have a role in initiating meal consumption in humans. Obese patients who lose weight exhibit an increase in plasma ghrelin. This has been suggested as the reason for failure of low-calorie diets in the treatment of morbid obesity. In contrast, patients who have undergone bariatric surgery for morbid obesity have reduced ghrelin levels, thought to result from absence of direct food stimulation on the gastric fundus. It also probably explains why gastric bypass surgery is more effective in the long term than other bariatric operations. Additionally patients treated with gastric bypass usually experience reduced appetite after the operation. Physiologically, it is now thought that ghrelin anticipates the initiation of meals and releases GH. In malnutrition/catabolic states, the raised ghrelin levels through increased secretion of GH induces increased appetite and food intake, increased gastric emptying and food assimilation necessary for increased nutrient assimilation for restoration of muscle bulk and fat reserves. These actions are opposite to those of leptin, which reduces food intake and fat reserves.

Gastroduodenal mucosal defence mechanisms

The important defence mechanisms that protect the gastroduodenal mucosa against a variety of insults including drugs such as ethanol and NSAIDs are:

- surface mucous gel
- bicarbonate secretion
- reactive hyperaemia
- epidermal growth factors (EGFs)
- polyamines and ornithine carboxylase.

The outer surface of the gastric mucosa is covered by a mucous gel, which is hydrophobic. This property is dependent on phospholipid-containing vesicles, myelinated structures and a phospholipid band in the deeper layers of the mucous gel covering the luminal surface of the mucosa. The gastric mucosal cells extract bicarbonate from the mucosal blood and secrete it into the gastric lumen across the apical plasma membrane. Bicarbonate also reaches the gastric lumen by tracking between the gastric cells (paracellularly). This constant bicarbonate flux is reduced by smoking, certain drugs (e.g. cyclo-oxygenase inhibitors) and somatostatin. Enhanced secretion of bicarbonate is induced by prostaglandins and theophylline. When acid or other noxious agents enter the gastric mucosal cells, sensory neurones are stimulated, which then cause the release of vasodilatory neuropeptides (calcitonin gene-related peptides), nitric acid and prostaglandins with a resultant hyperaemia. This increased blood flow permits the neutralization of the back-diffusing acid before significant damage occurs. If the surface epithelium is damaged, the increased bicarbonate load brought to the mucosa by the reactive hyperaemia spills out and is trapped within the surface mucus, cellular debris and fibrin, forming a mucoid cap that covers the injured area, thereby providing a protective microenvironment with a stable pH 5–6, despite the high luminal acidity of the stomach.

EGF, which is produced by the salivary glands and Brunner's glands under physiological conditions, is concerned both with mucosal defence against injury and in the repair of established mucosal damage. Deficient secretion of EGF in patients with rheumatoid arthritis and Sicca syndrome is thought to be responsible for the enhanced susceptibility to NSAID-induced erosive disease exhibited by these patients. When ulceration develops anywhere in the gastrointestinal tract, special cells derived from the crypts adjacent to the ulceration site appear and secrete abundant amounts of EGF. This together with the synthesis of polyamines (required for cell growth and differentiation) by the enzyme *ornithine carboxylase* and other growth peptides is responsible for the reparative process.

Changes in the gastric mucosa induced by infection with *Helicobacter pylori*

In view of the importance of *Helicobacter pylori* infection in the aetiology of various benign and malignant disorders of the stomach, the hormonal, acid secretory changes leading to various morphological changes of the gastric mucosa induced by persistent infection by this organism are of importance in understanding the pathogenesis of these *H. pylori*-related disorders. It is now believed that *H. pylori* infection is usually contracted in childhood, causing acute abdominal pain due to severe inflammation of the antrum and body of the stomach associated with hypochlorhydria due to inhibition of the parietal cells. The infection then enters a chronic stage which persists throughout life, unless discovered because of a specific related disorder and eradicated by appropriate treatment. Undiagnosed, the chronic infection leads to morphological changes in the gastric mucosa. The effects on gastric secretion are determined by the extent to which the chronic gastritis affects the mucosa of the antrum or body of the stomach. Increased acid secretion in subjects with antral predominant disease is mainly due to *H. pylori* gastritis stimulating increased release of the hormone gastrin, which stimulates the parietal cells of the body of the stomach to secrete acid without the normal feedback restraint by antral somatostatin as these D-cells are destroyed or depleted by the antral gastritis. In subjects with a large parietal cell mass this leads to the development of duodenal ulceration.

When the chronic infection is predominantly located in the body of the stomach, hypochlorhydria ensues, with an increased risk of enteric infections due to the loss of the gastric acid barrier. Patients with chronic *H. pylori* body gastritis and hypochlorhydria or achlorhydria have in addition an increased risk of gastric cancer especially if the gastritis progresses to mucosal atrophy and intestinal metaplasia. The exact mechanism by which the hypochlorhydria associated with *H. pylori* body gastritis leads to the greatly increased risk of gastric cancer remains unclear, although one hypothesis concerns the production of potentially carcinogenic nitrosoamines following bacterial colonization of the stomach when the intragastric pH rises above pH 4.0, as various bacteria can produce carcinogenic nitrosamines from dietary nitrite and secondary amines.

In sharp contrast, the hypochlorhydria associated with chronic *H. pylori* body gastritis is now considered to have a beneficial effect in protecting subjects from acid-related upper gastrointestinal disorders, especially gastro-oesophageal reflux disease. This is based on the documented observation that the fall in prevalence of *H. pylori* in Western countries has been accompanied by a rise in prevalence of gastro-oesophageal reflux disease and increased incidence of Barrett's columnar cell metaplasia, dysplasia and junctional gastro-oesophageal cancer.

The important changes induced by chronic *H. pylori* infection in the gastric mucosa are summarized as follows:

- cell proliferation and apoptosis
- duodenal ulcer – antral-predominant disease
- increase in mucosa-associated lymphoid tissue (MALT) and MALT lymphomas
- gastritis, intestinal metaplasia, atrophy, gastric carcinoma – body-predominant disease.

Several clinical studies have established that eradication of chronic *H. pylori* infection by the appropriate therapy is followed within a period of 5 years by regression of intestinal metaplasia in the antrum and certainly no progression of the disease. Eradication therapy is therefore regarded as an effective prophylactic measure in patients at risk. In a seminal study from Japan involving patients with early gastric cancer, eradication following endoscopic resection significantly reduced the incidence of second cancers.

Physiological consequence of gastrectomy and gastric bypass

It is important to distinguish between the *physiological consequences* of gastric surgery (gastrectomy and gastric bypass) which occur in all patients and require supplements for their prevention and the adverse sequelae which occur in some but not all patients with varying severity and are collectively known as *postgastric surgery syndromes*. These often result in significant impairment of the quality of life of the affected patients and invariably pose problems in management. They are considered later in the chapter.

By and large gastric bypass and gastrectomy (total/subtotal) share the same physiological consequences although there are minor differences between the two. Loss of weight is invariable after total/subtotal gastrectomy and occurs in all patients after gastric bypass provided these patients adhere to the prescribed diet and undertake regular exercise. Weight loss after gastrectomy is marked with the development of malnutrition in patients who experience significant postcibal symptoms. In these patients, the resulting diminished dietary intake is the major factor and far outweighs others, such as malabsorption and decreased transit times. Mild steatorrhoea occurs in 70% of patients after gastrectomy, but severe steatorrhoea is rare (as distinct from gastric bypass patients) and is usually encountered in patients who develop bacterial overgrowth. Anaemia is a frequent adverse consequence of both gastrectomy and vagotomy with drainage, and its incidence increases with the duration of follow-up. Iron-deficiency anaemia accounts for the majority with an incidence of 60% in males and 75% in females at 10–20 years after gastric surgery. The higher incidence in females is due to the regular monthly menstrual losses. The exact pathogenesis of iron-deficiency anaemia remains unclear. Malabsorption of iron is likely to play a role, but several other factors have been incriminated: shift to trivalent ferric iron at high pH, loss of a gastric juice factor facilitating iron absorption, increased binding of dietary iron to proteins, diminished hydrolysis of iron–protein complexes in food and chronic blood loss from gastritis and erosions. Whatever the exact cause, sufficient oral iron can be absorbed even after total gastrectomy to restore the serum iron level to normal, and if prophylactic iron supplementation is administered (300 mg q.i.d.), the development of postgastrectomy iron-deficiency anaemia is prevented.

Vitamin B_{12} malabsorption is invariable after total gastrectomy, and unless replacement therapy is initiated megaloblastic anaemia develops within 3–4 years when the body stores of the vitamin become depleted. Although malabsorption of vitamin B_{12} is well documented after partial gastrectomy and gastric bypass surgery for morbid obesity, frank megaloblastic anaemia is rare. The main factor responsible in these patients is the lack of a sufficiently acid environment that is normally required to release vitamin B_{12} bound to food. Although IF secretion is reduced after partial gastrectomy, vagotomy and drainage and gastric bypass surgery, the residual secretion appears to be adequate in physiological terms in the majority but not all patients.

Postgastrectomy bone disease is less frequently encountered nowadays. Although osteomalacia accounts for the majority, cases with features of both osteoporosis and osteomalacia are well documented. The aetiology is multifactorial. Diminished dietary intake of calcium and vitamin D is important as is malabsorption. Postgastrectomy bone disease is usually encountered in elderly patients many years after total, subtotal and polygastrectomy as there is a latent period of many years. There is also an established female preponderance. The biochemical features (raised alkaline phosphatase and serum calcium) and radiological changes (refraction) predate the onset of symptoms, which include generalized bone pain, stress fractures and weakness from the associated myopathy.

Clinical features

Dyspepsia

The function of the stomach and duodenum is concerned with the initiation of the process of digestion. This is achieved by a combination of mechanical fragmentation and acid/peptic digestion of foodstuffs with an orderly delivery of the resulting acid chyme into the duodenum, where further chemical digestion in an alkaline medium continues. In health we are unaware of these activities, which are the result of co-ordinated secretory and motor functions by neural and hormonal mechanisms. Gastroduodenal disease disturbs many of these physiological mechanisms and produces varied symptoms described clinically under the embracing term of *dyspepsia*. Dyspeptic symptoms are however extremely common in the general population with reported prevalence rates varying from 14% to 44%, but show marked regional differences. It has been estimated that only 25% of patients with dyspepsia seek medical attention and in these flexible endoscopy is normal in a substantial but varying extent: 25–76%. One of the many reasons for this problem has been defining what constitutes dyspepsia in the general population. Several international working parties and consensus conferences have addressed this issue with some measure of, but not total, agreement on the constituent symptoms, severity grades and the appropriateness of endoscopy.

An agreed international definition of dyspepsia is 'episodic or persistent abdominal symptoms, often related to the intake of food, which patients or physicians believe to be due to disorders of the proximal portion of the digestive tract'. The symptoms included in this generic definition of dyspepsia agreed at the Maastricht Consensus Conference (1997) are:

- pain or discomfort in the upper abdomen
- nausea and vomiting
- early satiety
- epigastric fullness and regurgitation.

Heartburn and dysphagia are not considered dyspeptic symptoms by the Maastricht consensus statement and this is now agreed internationally.

There are two broad categories of dyspepsia: organic and non-organic. Organic dyspepsia is produced by organic disease, e.g. peptic ulceration, oesophagitis, gastric carcinoma, etc., whereas non-organic dyspepsia is restricted to symptoms occurring in patients without any demonstrable focal lesion or pathology in the upper gastrointestinal tract. The prevalence of organic dyspepsia (symptoms and abnormal endoscopic changes) increases with age with a distinct threshold around 40–45 years. In particular, gastric cancer is rare below the age of 40 years.

Four subgroups of dyspeptic patients are recognized. These are based on the predominant symptoms and generally reflect the most likely aetiology of the symptoms:

- ulcer-like
- reflux-like
- dysmotility-like
- non-specific.

Although this grouping is clinically useful, the results of several prospective studies have demonstrated unequivocally that the symptoms alone are not able to differentiate between organic and non-organic causes of disease. In essence, conventional history taking is not reliably predictive of the underlying cause of the dyspepsia in the individual patient. The important practical issue in the management of patients with dyspepsia relates to which patients should be investigated by upper gastrointestinal endoscopy before treatment. In practice, there are a number of clinical variables that influence this decision, although practice tends to vary between centres. Thus patients with the following features generally have non-organic disease and are thus likely to be endoscopy negative:

- age < 45 years
- patients who are *H. pylori* negative
- patients without a history of NSAID usage
- patients without alarm/sinister symptoms: loss of appetite, weight loss and bleeding/anaemia.

Specific symptoms of surgical importance

Altered motility (primary or following gastric surgery) can result in rapid emptying of the stomach (dumping), delayed emptying (from gastroparesis) or abnormal reflux of duodenal contents into the stomach (enterogastric reflux). The symptom complex produced is varied but is determined by the functional abnormality. In some cases, the functional abnormality may in turn cause organic disease, e.g. gastritis from enterogastric efflux.

Loss of appetite, weight loss, recent-onset dyspepsia, constant upper abdominal pain and evidence of bleeding (overt or occult) have to be regarded as *alarm* or *sinister* symptoms, and thus require urgent investigation by endoscopy particularly if the patient is over 40 years of age. Weight loss is common, if not universal, in patients with postgastric surgery symptoms and is largely the result of reduced dietary intake, as in many of these patients the symptoms are precipitated by food or the patient is only able to eat small meals because of early satiety due to either reduced gastric reservoir or loss of the adaptive gastric relaxation after meals. Loss of appetite associated with early satiety/abdominal discomfort in a patient without previous gastric surgery is highly suspicious of an infiltrating gastric neoplasm and predates obstructive symptoms (vomiting). In most Western countries, pyloric obstruction with vomiting of ingested food not mixed with bile is very rarely caused by benign disease. In young female patients loss of appetite and weight is commonly caused by psychological disorders including anorexia nervosa.

Sudden, acute, severe constant epigastric pain accompanied by abdominal signs of peritoneal irritation implies a breach in the integrity of the gastric/duodenal wall, most commonly by peptic ulceration. Constant chronic back pain is indicative of a posterior ulcerating lesion (benign or malignant) penetrating the pancreas. In the case of duodenal ulcer, when this involves the head/neck of the pancreas, erosion of the gastroduodenal artery as it runs in the groove between the two organs can result in severe upper gastrointestinal haemorrhage.

Investigation of patients with gastric disorders

Endoscopy

The development of modern flexible fibreoptic endoscopes has allowed accurate diagnosis of both acute and chronic gastroduodenal disease, and in many instances altered its management. Undoubtedly, the experienced endoscopist has an accuracy rate superior to that of the radiologist. Its value in the bleeding patient is well established and, nowadays, it is axiomatic that all patients admitted with acute upper gastrointestinal bleeding require an upper gastrointestinal endoscopy within 24 hours of admission, and, when indicated, therapeutic control of the bleeding is achieved by this approach in the first instance.

The management of gastroduodenal disorders has changed radically with the recognition of the important pathogenetic role of infection with *H. pylori* and related organisms. This is reflected in the recommendation that testing for *H. pylori* should constitute the initial step in the management of patients below 45 years with dyspepsia and, if positive, eradication therapy commenced – *the test and treat strategy*, according to which endoscopy is avoided in patients who are rendered symptom free by this treatment. This approach has translated into considerable savings in endoscopy-related costs. This strategy has had other advantages. It has lowered the *H. pylori* prevalence and hence the risk of *H. pylori*-related disease including gastric cancer and reduced the endoscopic workload in most Western countries including the UK. However, this strategy is not without its problems. In the first instance, none of the tests for *H. pylori* are totally sensitive (10–20% false-negative rates). The *test and treat strategy* results in overtreatment of patients who may not require eradication, e.g. patients with reflux oesophagitis whose symptoms can be worsened by eradication and may miss significant diseases, e.g. Barrett's columnar cell change, gastric ulcer or worse still gastric neoplasm. In addition, it incurs a low morbidity related to the side effects of antibiotics and the emergence of resistant strains.

The *test and scope strategy* establishes the diagnosis before treatment, permits biopsy of organic disease and excludes gastric neoplasia. Furthermore, it reduces the anxiety of patients and avoids overtreatment. It is cost effective in Europe where the endoscopy costs (under 500 euros) are significantly lower than in the USA. The morbidity of upper gastrointestinal endoscopy is low but it is considered an unpleasant experience by most patients. In the current state of knowledge, the *test and scope strategy* is preferable, certainly in European countries. To a large extent, the validity of the alternative *test and treat strategy* relates to the prevalence of *H. pylori* in the community. In most Western countries, this has declined substantially during the past two decades and now is of the order of 10%, whereas high prevalence rates (40–70%) are still encountered in underprivileged countries. If the *test and treat policy* is adopted on the basis of high community prevalence, endoscopy should be done in dyspeptic patients who are either *H. pylori* negative or have alarm symptoms irrespective of their *H. pylori* status.

In light of the rather confusing situation, the European Panel on the Appropriateness of Gastrointestinal Endoscopy (EPAGE) considers upper gastrointestinal endoscopy to be *necessary* in the following:

- in individuals >45 years testing positive for *H. pylori*, with persistent symptoms despite eradication treatment
- in individuals >45 years, never previously investigated, *H. pylori* negative and no NSAID intake, with persistent symptoms despite acid suppression treatment
- in individuals >45 years with a previous history of gastric ulcer, no *H. pylori* testing or *H. pylori* negative, with persistent symptoms despite acid-suppression drug therapy.

Upper gastrointestinal endoscopy is a safe technique. Full facilities for resuscitation should always be available, and pulse oximetry is nowadays considered essential during the procedure. Sedation should always be kept to the minimum, particularly in patients who may have hypovolaemia or hypoxaemia. Diazepam or midazolam in small incremental doses is usually adequate. Fortral should not be used, as with any opiate it may depress respiration significantly, and it also delays gastric emptying, thus increasing the risk for subsequent regurgitation and aspiration. In addition, Fortral can cause pulmonary hypertension, which can be significant in patients recovering from haemorrhagic shock. Spasmolytic agents, such as Buscopan, are sometimes useful to allow visualization of the antrum, passage of the endoscope through into the duodenum and duodenoscopy.

Radiology

Barium meal examination is commonly used in investigating the stomach and duodenum. Although gross lesions are usually seen, the technique does have major limitations. Subtle mucosal changes of gastritis and of early mucosal cancer can only be detected if a meticulous double-contrast technique is used in which the stomach is filled with air and the mucosal lining coated with a thin film of barium. Even with these precautions, endoscopy gives superior results. A barium meal examination is notoriously unreliable in the assessment of patients with acute upper gastrointestinal bleeding. The presence of clot within the stomach produces a variety of bizarre appearances. Even when a lesion can be identified, contrast radiology cannot demonstrate whether this has been or is responsible for the bleeding. For these reasons, endoscopy is the preferred investigation in the bleeding patient. Despite these limitations, barium meal remains a valuable investigation in specific situations. A normal radiological appearance should not be accepted however in any patient with continuing dyspepsia and an additional endoscopy should be performed without delay. Barium swallow/meal is invaluable in outlining the exact topography of upper gastrointestinal cancer.

Endoscopic ultrasonography

Ultrasound examination of the stomach can be performed with either external or endoluminal probes. It is used to measure gastric wall thickness, to assess the extent of intramural involvement of the stomach wall by tumour and to establish enlargement of the perigastric lymph nodes. The normal stomach wall thickness measured by ultrasound (internal to external) is 5–6 mm. An endoscopy with biopsy is indicated when the ultrasound gastric wall thickness exceeds 5 mm.

High-frequency flexible endoscopic ultrasonography (EUS) is now well established in routine practice and distinguishes five layers of the stomach wall: superficial mucosa, deep mucosa, submucosa, muscularis externa and serosa/adventitia (Figure 23.3). It provides the most sensitive modality for the accurate staging of gastric tumours, being superior in this respect to all other imaging tests. In the stomach, EUS is particularly useful in:

- the pretreatment staging of early gastric cancer in detecting absence, superficial and deep involvement of the submucosa

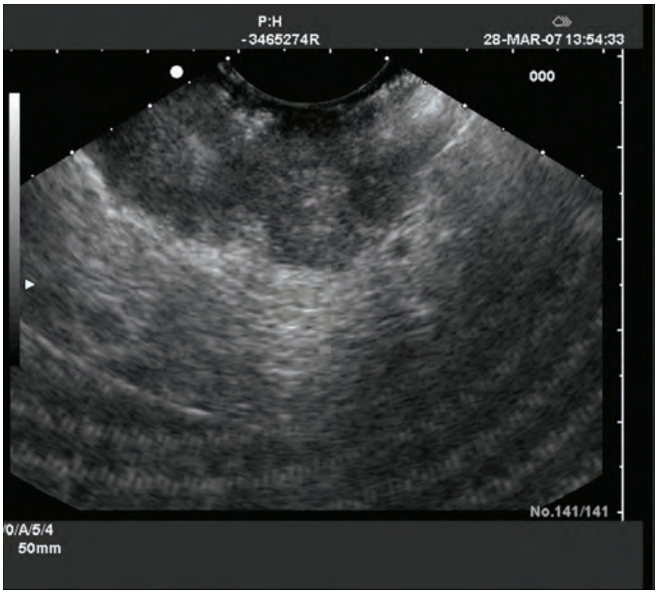

Figure 23.3 Endosonography of a gastric cancer.

- the staging and follow-up of MALT lymphomas
- the diagnosis of stromal (mesenchymal) tumours.

EUS is the established diagnostic modality of choice in local (T) staging of gastric cancer. The alternatives are multidetector row CT (MDCT) and MRI. A recent systematic review compared the relative performance of the three imaging modalities. The overall diagnostic accuracy of T staging for EUS, MDCT and MRI was similar, varying among 65–92.1%, 77.1–88.9% and 71.4–82.6%, respectively. The sensitivity for detection of serosal involvement for EUS, MDCT and MRI was also not statistically different: 77.8–100%, 82.8–100% and 89.5–93.1%, for EUS, MDCT and MRI, respectively, with corresponding specificities for the detection of serosal involvement of 67.9–100%, 80–96.8% and 91.4–100%. Thus although all three modalities give similar results in T staging and in assessing serosal involvement, EUS remains the first-choice imaging modality in preoperative T staging of gastric cancer.

Deep involvement of the submucosa in early gastric cancer (EGC) is associated with a significant increased risk of lymph node involvement. Thus whereas EGCs limited to the mucosa have a 3% incidence of regional node involvement, this increases to 20% with deep involvement of the submucosa, thereby precluding any form of local endoscopic treatment. EUS is also capable of identifying advanced gastric cancer (involvement of the muscularis propria) and infiltration of adjacent organs, but is unreliable in detecting lymph node involvement (as opposed to enlargement) and peritoneal deposits.

EUS has an overall diagnostic accuracy for gastric non-Hodgkin's lymphoma, approximating 95%. It is also reliable in assessing depth of invasion (85% accuracy) and, to a lesser extent (60%), in detecting metastatic spread to the perigastric lymph nodes. The characteristic echo pattern consists of an extended hypoechoic thickening of the second and third EUS layers with preservation of the identity of all the layers. A similar picture is obtained in linitis plastica except that the hypoechoic thickening is more longitudinally extensive and involves the entire circumference of the stomach. In patients with MALT lymphomas associated with *H. pylori* infection, if the lesion is confined to the second or third layer on EUS staging (deep mucosa or submucosa), eradication of the infection results in remission in 85% of cases. In contrast if the EUS staging shows deeper infiltration, eradication of the *H. pylori* infection has no effect on the tumour and indicates the need for chemotherapy or surgery.

Mesenchymal (stromal) tumours appear as hypoechoic masses continuous with the fourth (muscularis externa) and fifth (serosa/adventitia) layers. The EUS features suggestive of malignancy are tumour size >4 cm, irregular extraluminal border, echogenic foci and cystic spaces. If all these features are absent, the stromal tumour can be predicted as benign. However, a confident diagnosis of malignancy should not be made on EUS findings alone.

Multidetector row CT

There is a confusing array of different names in use for this imaging technology: multidetector row CT (MDCT), multidetector CT (MDCT), multidetector array helical CT, multichannel CT and multislice CT (MSCT). The number of simultaneous measurements along the length of the patient's long axis is referred to as the number of 'slices', e.g. 64-slice MDCT. Aside from the extremely high resolution, MDCT enables volumetric three-dimensional (3D) visualization and is used routinely in the preoperative staging of gastric cancer with or without contrast enhancement.

Studies comparing two-dimensional (2D) vs 3D MDCT imaging for gastric cancer indicate improved T staging of gastric with the latter (92% vs 77%). However, the overall accuracy rate for N staging is not improved by 3D volume visualization. The overall detection rate for gastric cancer by MDCT averages 90%, with detection rates for advanced gastric cancer approaching 100% and 85% for early gastric cancer. MDCT-based virtual gastroscopy is used in some centres for the characterization of both advanced and early gastric cancers. In a volumetric MDCT study from Japan on the depth of invasion involving scanning of 41 patients after drinking 600 mL of water and injection of non-ionic contrast agent, the overall sensitivity, specificity and accuracy rate of MDCT in determining the invasion of serosa were 85%, 96% and 92%, respectively.

2D MDCT is the standard test in most hospitals that is used in the preoperative staging and assessment of operability of patients with gastric cancer. Some centres use routinely hydro-MDCT. This technique involves the ingestion of water or dilute contrast (600–1000 mL) followed by scanning with the patient in the prone position (Figure 23.4). Hydro-MDCT allows documentation of the extent of mural involvement, extragastric extension and involvement of the retrogastric organs such as the pancreas. MDCT also enables detection of lymph node enlargement especially of the coeliac/para-aortic lymph nodes.

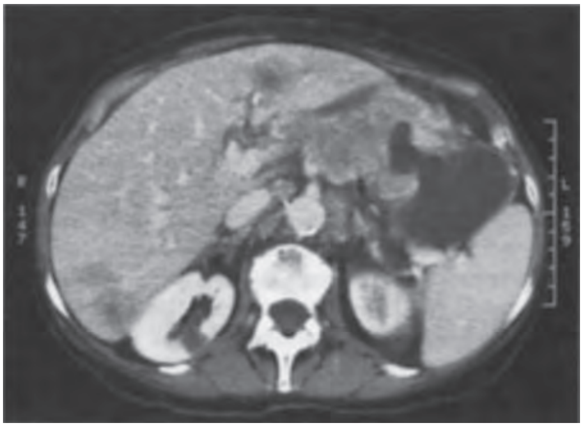

Figure 23.4 Hydro-multidetector row CT in a patient with advanced gastric cancer showing an advanced T3 tumour with local extragastric spread.

By contrast CT is not as reliable as other modalities in the staging of primary gastric lymphomas in terms of both extent of mural invasion and regional node involvement. It is also poor at distinguishing low- from high-grade disease. Hence, other modalities especially high field (3.0 T) MRI and EUS are preferred.

Magnetic resonance imaging

Despite, the considerable advances in MRI (3–7 T systems) with advanced software capable of 3D reconstruction, dynamic imaging, etc., MRI is not currently the gold standard (currently CT and EUS) in the preoperative staging of gastric cancer and there have been few published comparative studies between MDCT and MRI in the staging of advanced gastric cancer (invading the muscularis propria). One such study, prospective in nature, involved examinations in 26 patients with biopsy-confirmed disease. Contrast-enhanced MDCT and non-enhanced MRI with a 1.0 T machine using various sequences were obtained in each patient following injection of antiperistaltic drug and ingestion of 1.0 L of tap water. The images obtained by the two modalities were analysed by two radiologists. Diagnostic accuracy of each staging by MDCT or MRI was evaluated by comparison with the pathological results obtained from the resected specimen (histological staging). In this study MRI was slightly but significantly superior to CT in T staging, although it had a tendency to overstage the pathologica T2 cancers. With MRI, both the positive predictive value for T2 stage and sensitivity for T3 stage reached 100%. Regarding the N staging, CT was slightly superior to MRI (73% vs 65%; $p > 0.05$). However, both the two modalities tended to understage the N staging. At the time of writing, there are no published series of MRI staging of gastric cancer with 3.0 T machines, which provide a significantly higher resolution. The prediction is that high-field MRI systems will take over from MDCT in time, especially as they do not expose the patients to ionizing radiation.

Positron emission tomography CT

This medical imaging system combines positron emission tomography (PET) with MDCT to enable functional (metabolic activity) imaging with 2D/3D anatomical imaging of the disease as the two images are superposed (co-registered) (Figure 23.5). The combined systems share common software for the 2D/3D reconstruction. PET is a functional nuclear medicine imaging system which detects pairs of gamma rays emitted by a positron-emitting radionuclide administered to the patient before the imaging. The radionuclide most commonly used is a metabolite of glucose, ^{18}F-fludeoxyglucose (^{18}F-FDG or FDG). This contains the positron-emitting radioisotope fluorine-18 at the 2 hydroxyl ($^{-}$OH) group of the glucose molecule. The 2 hydroxyl group ($^{-}$OH) in glucose enables the metabolism by glycolysis of this nutrient. Hence although ^{18}F-FDG is taken up by active metabolizing cells, it is not capable of being metabolized and furthermore cannot exit the cell, disappearing only from the cellular tumour mass with radioactive decay. Thus, it provides imaging of living actively metabolizing tumour cells. Although the radioactivity elimination half-life of ^{18}F-FDG is the same as that of fluorine-18 (110 minutes) clinical reports on its use have shown that only 80–85% of the fluorine-18 activity is eliminated with a half-life of 110 minutes, as the rest is eliminated rapidly by the kidneys soon after injection (half-life of 16 minutes). This is important as the urine of a patient undergoing PET remains radioactive for several hours after the examination and adequate precautions are needed to eliminate the risk of contamination of bed linen, etc. One of the practical limitations of both PET and PET-CT relates to the production and transport of the radiopharmaceutical needed for PET

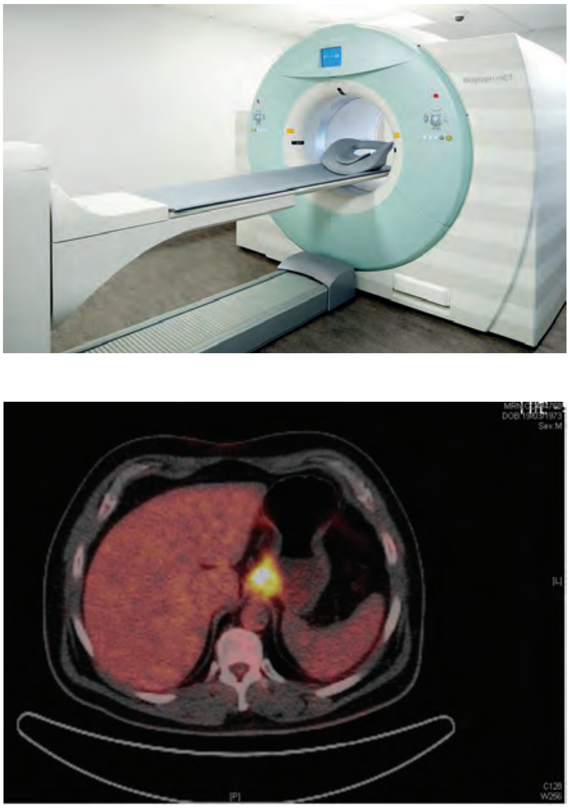

Figure 23.5 (a) Positron emission tomography (PET)-CT system; (b) positive PET scan.

imaging as these are extremely short lived and the hospital has to be within easy access to a cyclotron which is used for their production. PET-MRI systems have been introduced in recent years and may well replace PET-CT systems, especially with the advent of high-field MRI scanners.

To date, there have been few published series on the use of PET-CT in gastric cancer. However, early reports suggest its usefulness and superiority over MDCT alone in the diagnosis of recurrence after surgery for gastric cancers. In one series from Korea on 88 patients, PET/CT detected 40 locoregional lesions, 29 retroperitoneal and pelvic lesions, 25 seeding and 12 distant metastases. CT with contrast enhancement detected 28 locoregional lesions, 20 retroperitoneal and pelvic lesions, 27 seeding and 12 distant metastases. However, false-positive results were observed with PET–CT scanning in 23 patients (20%).

Other investigations

In most cases the morphological assessment of the stomach and duodenum by contrast, the various imaging modalities and endoscopy give sufficient information for further management decisions to be made. In selected cases, it may be necessary to obtain a functional evaluation of the gastroduodenal region. This can be achieved by gastric secretory testing, measurement of gastric emptying and enterogastric reflux, and determination of the plasma concentration of the antral hormone, gastrin.

Gastric secretory tests

Because of the association of duodenal ulceration with hypersecretion of acid, measurement of gastric acid output has held a fascination for many surgeons. In practice, however, measurement of acid secretion has little clinical relevance in the management of patients with upper gastrointestinal disorders unless Zollinger–Ellison syndrome is suspected. Thus nowadays and especially with the drastic decline in the use of vagotomy for the treatment of duodenal ulceration, acid secretory studies are carried out largely for research purposes.

Basal and maximal acid output

Basal secretion is usually measured over 1 hour. Maximal secretion is best stimulated with the synthetic gastrin analogue, pentagastrin, which is administered by intramuscular injection in a dose of 6 g/kg (10 pg/kg in the postvagotomy patient). Secretion is then followed for 1 hour and the maximal response (peak 15 minutes ×4) calculated. There are many pitfalls in acid secretory tests. The overlap between normal and disease is considerable, and the results obtained vary with body weight and sex. Typical values in preoperative and postoperative patients are shown in Table 23.1. The only clinical indication for acid secretory studies nowadays is in the diagnosis of pernicious anaemia and Zollinger–Ellison syndrome.

In the postoperative patient, maximal acid output is reduced by 70% or more after gastrectomy, and by 50–70% by vagotomy. A postoperative maximal acid response of 20 mmol/h is a fairly reliable indicator of a persisting hypersecretory state (incomplete vagotomy).

The measurement of basal acid output after gastric surgery has particular relevance to the question of ulcer recurrence caused by a pancreatic gastrin-producing tumour (Zollinger–Ellison syndrome). If hypergastrinaemia exists, the 'basal secretion' is already being stimulated and the characteristic findings will be of a high basal secretion, which does not increase much further on maximal stimulation. If basal secretion is greater than 10 mmol/h, and this represents more than 60% of the maximal response, a gastrinoma should be suspected. Proof of this requires measurement of plasma gastrin concentration.

The insulin test

After complete denervation of the parietal cell mass, acid output is reduced by 50% or more. Incomplete denervation will not achieve this, and the risk for a recurrent ulcer is increased. Nowadays, an assessment of the adequacy of vagotomy is indicated only in *H. pylori*-negative patients who develop recurrent ulceration after this procedure. The insulin test, originally described by Hollander, depends upon the fact that insulin-induced hypoglycaemia stimulates hypothalamic nuclei which induce a parasympathetic response. If vagal innervation of the parietal cell mass persists, acid will be secreted in response to the hypoglycaemia. This test is performed by giving an intravenous injection of soluble insulin (0.2 U/kg) after the basal secretion has been collected in four 15 minute aliquots. Secretion is then collected for a further 2 hours. If the acid concentration in any 15 minute sample after insulin is 20 mmol/L greater than in the basal period, the test is regarded as positive. If no free acid is secreted basally, then a postinsulin concentration of more than 10 mmol/L is taken as positive. Subsequent to Hollander's original description, the interpretation of the test has been modified in many ways. The modification most commonly used is to categorize a positive response as *early* (during the first hour) or *late* (second hour).

A positive insulin test indicates residual vagal innervations of the parietal cell mass. An *early* positive response usually implies fairly generous residual innervations and the actual amount of acid secreted (i.e. volume as well as concentration) is quite large. If a patient with recurrent ulcer has an *early* positive response to

Table 23.1 Typical values of basal and maximally stimulated acid secretion

	Acid output (mmol/h*)	
	Basal secretion	Maximal secretion
Normal	2	20–30
Preoperative duodenal ulcer	>5	>35
Postvagotomy	<2	10–20
Postgastrectomy	1	<10

*These values are approximations only. Secretion increases with increasing body weight and decreases progressively with age. Females secrete about two-thirds the amount of acid secreted by males.

insulin and a maximal acid output of 20 mmol/h or more, then incomplete vagotomy is the cause. A *late* positive response may not be so significant, particularly if the acid output in response to insulin and pentagastrin is small. Cephalic stimulation can also be produced by sham feeding (chew and spit). The gastric secretory response to sham feeding is used in some centres instead of the insulin test, as it is safer and just as reliable. One of the problems with the insulin test is that many asymptomatic patients can show a positive response. Furthermore, when serial tests have been performed after vagotomy, it has been shown that negative responses in the first few months after operation can revert to positive later on. Thus the insulin test must be interpreted with caution, and considered only in the context of all other clinical, endoscopic and secretory information. The deliberate production of hypoglycaemia is not without problems, and the test should not be carried out in patients with significant cardiac disease, cerebrovascular disease or epilepsy.

Gastric emptying

Measurement of gastric emptying is indicated in patients with symptoms indicative of dysmotility-type dyspepsia. The two conditions which may arise spontaneously (consequent on systemic disease) or develop after surgery on the upper gastrointestinal tract are:

- gastroparesis – early satiety, fullness and epigastric retention with vomiting
- rapid gastric empting with early vasomotor dumping.

In surgical practice, the majority of these patients have postgastric surgery symptoms and are investigated with a view to possible remedial surgery. It seems likely that future sufferers are more likely to be patients who have undergone bariatric gastric bypass surgery. Delayed gastric emptying can also be encountered after fundoplication (open or laparoscopic) for gastro-oesophageal reflux disease, especially patients who have been subjected to redo procedures for recurrence of reflux or for some other complication related to the fundoplication. Delayed gastric empting can also be the result of primary dysmotility disorders including the rare *hollow visceral myopathy*, which affects the entire gastrointestinal tract, and the much more common visceral neuropathy, which may complicate longstanding diabetes mellitus.

A variety of radionuclide meals are used for studying gastric emptying in patients with symptoms suggestive of gastroparesis or vasomotor dumping. The patient drinks or ingests the radionuclide-labelled meal and the radioactivity in the stomach is then monitored with an external gamma camera, thus obtaining radioactivity–time curves. The most useful index is the $T_{1/2}$, which is the half-emptying time, i.e. the time taken for half of the ingested meal to leave the stomach. Assessment of both liquid and solid gastric emptying (on separate occasions) is necessary to document the pattern of abnormal gastric emptying in the individual patient. Thus in many postgastrectomy patients, liquid emptying is fast but solid emptying is delayed (Figure 23.6). Rapid gastric emptying of liquids is often associated with a much shorter small bowel transit time. Useful qualitative information can be obtained using a 'physiological' food and barium meal if the more sophisticated isotope techniques are not available.

Test for enterogastric reflux

Measurement of gastroduodenal reflux can assist in the management of patients with bile vomiting and bile gastritis. In the latter case, demonstration of increased quantities of duodenal contents, including bile refluxing into the stomach, may suggest that reoperation for bile diversion may improve the gastritis and the patient's symptoms. Enterogastric bile reflux is best quantified by combining biliary excretion scintigraphy (HIDA scan) with CCK or preferably a milk meal (as a source of fat) – the *milk-HIDA test* (Figure 23.7).

Plasma gastrin

The peptide hormone gastrin is elaborated in specific endocrine G-cells in the gastric antrum and, to a lesser extent, the duodenum. Gastrin secretion occurs in response to distension

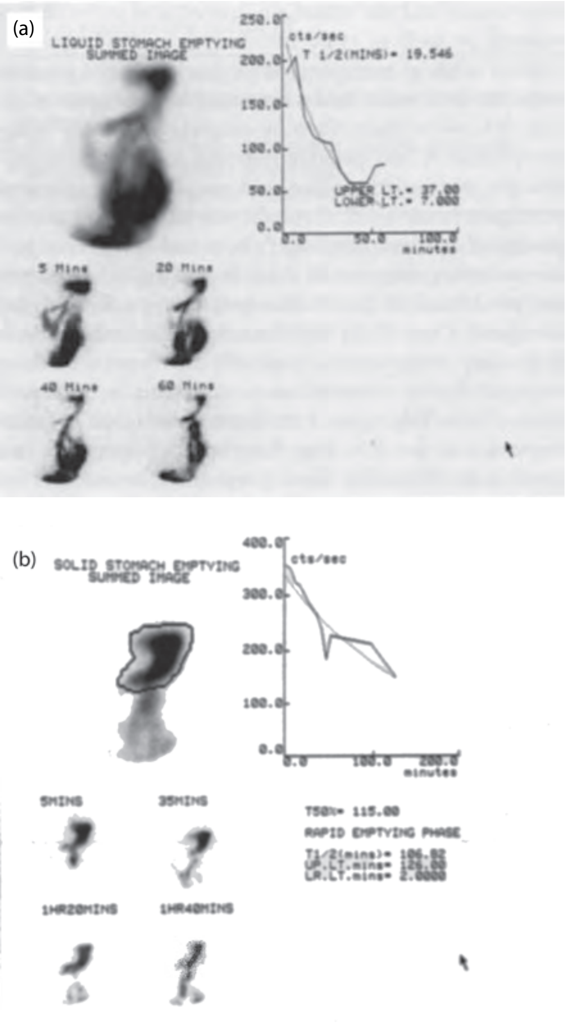

Figure 23.6 Isotope gastric emptying in a patient with vasomotor dumping after truncal vagotomy and drainage: (a) liquid meal showing fast emptying; (b) solid meal demonstrating slow emptying.

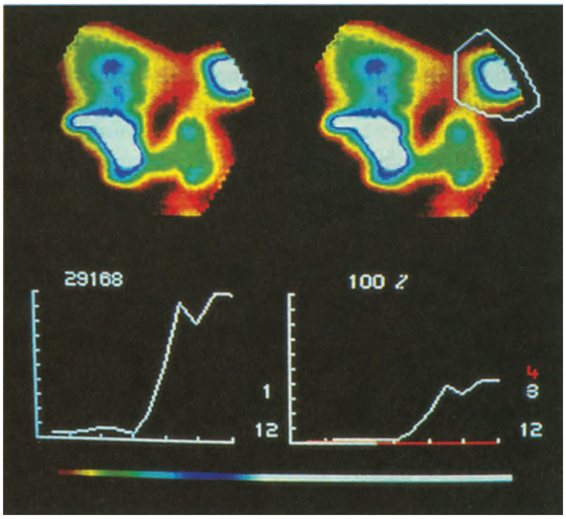

Figure 23.7 Extensive reflux of bile into the gastric remnant in a patient with severe bile gastritis and vomiting after Pólya gastrectomy.

of the antrum in the presence of food, particularly protein. When the pH in the antrum falls, gastrin release is inhibited by somatostatin (produced by the D-cells), such that this negative control feedback prevents prolonged gastric hyperacidity in the normal state. The concentration of gastrin in the plasma can be measured by specific radioimmunoassay. This is indicated if clinical and/or gastric secretory features suggest the possibility of Zollinger–Ellison syndrome. The reported levels of plasma gastrin vary between laboratories, but values greater than 200 pg/mL are regarded as abnormally high. Values in excess of 1000 pg/mL are virtually diagnostic of a gastrinoma, provided that the patient is secreting acid. The reason for this proviso is that in any achlorhydric patient, e.g. one with pernicious anaemia, there is no fall in the antral pH to shut off gastrin secretion by somatostatin and hence a persistent hypergastrinaemia ensues, although this does not normally reach the high levels associated with a gastrinoma.

In some patients, the plasma gastrin concentration will be found to be elevated but not sufficiently for the diagnosis of Zollinger–Ellison syndrome to be confirmed. There are various causes of hypergastrinaemia (Box 23.1). Many of these can be excluded readily on clinical grounds, but difficulty may be experienced in distinguishing a gastrinoma from antral G-cell hyperplasia, retained excluded antrum or merely an exaggeration of the usual rise in gastrin that follows acid reduction by vagotomy. Three stimulatory tests are useful in this respect: protein meal, calcium stimulation test and secretin challenge test (Figure 23.8).

BOX 23.1 Causes of hypergastrinaemia

Primary autonomous hypersecretion
- Tumour (gastrinoma) – Zollinger–Ellison syndrome
- Antral G-cell hyperplasia

Increased stimulation
- Hypercalcaemia

Decreased inhibition
- Hypo- or achlorhydria – pernicious anaemia, post vagotomy
- Retained and excluded gastric antrum
- Small bowel resection

Decreased removal
- Renal failure
- Small bowel resection

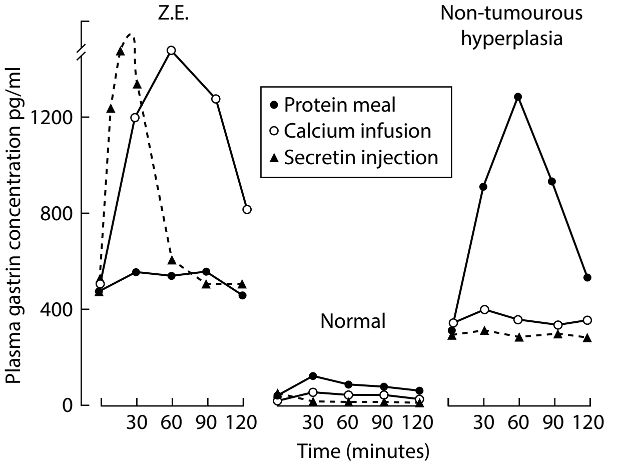

Figure 23.8 The use of provocative gastrin stimulation tests to differentiate between the hypergastrinaemia of the Zollinger–Ellison (ZE) syndrome and that due to antral G-cell hyperplasia.

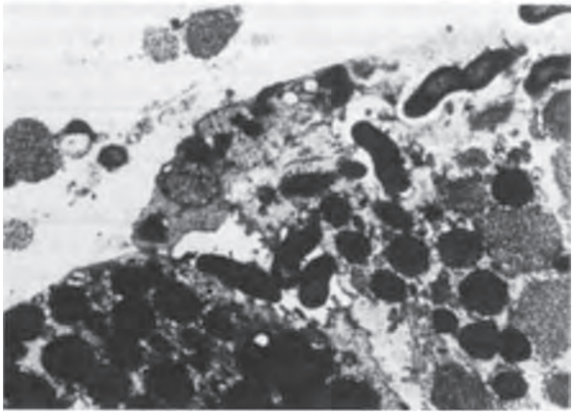

Figure 23.9 *Helicobacter pylori* in a gastric mucosal biopsy.

Helicobacter pylori infection

Gastroduodenal disease

H. pylori, previously known as *Campylobacter pylori*, is a spiral-shaped organism (Figure 23.9) of great aetiological importance in certain gastroduodenal disorders. The infection is acquired by oral ingestion. Transmission by inadequately cleaned and disinfected endoscopes is now well documented. There is also evidence of transmission between cohabiting parties as spouses/partners of duodenal ulcer patients have a higher seroprevalence of *H. pylori* infection than controls. The organism is often identified in children complaining of acute abdominal pain. Indeed, population studies indicate that the infection is usually acquired in childhood, and thereafter the acquisition rate slows down exponentially with age. A high rate of infection is documented among endoscopy staff (endoscopist and nurse working in endoscopy units), with prevalence rates as high as 75–80% compared with 20–65% background infectivity rates (varies considerably in different countries). Indeed in most Western countries *H. pylori* infection is fast disappearing, but infection rates remain high in developing countries.

Pathology

Within the stomach, *H. pylori* localizes on the epithelial surface beneath the viscid mucous layer, where it exerts its pathological effects via the elaboration of various enzymes and toxins. The initial acute inflammation persists as a chronic inflammation which predominantly affects either the antrum or the body of the stomach with different consequences in terms of disease: antral disease causes duodenal ulcers in patients with a large parietal mass, whereas body-predominant disease causes gastritis, gastric atrophy and gastric cancer.

The gastric mucous barrier is disturbed by the production by *H. pylori* of *endopeptidase*, which has a powerful mucolytic action, and by the generation of large amounts of ammonia with an increase in the epithelial pH. This alters the mucosal charge gradient, cellular permeability and epithelial Na^+, K^+–ATPase activity, leading to back diffusion of H^+. The adhesion of the organism to the surface of the gastric epithelial cells is mediated by a specific substance, *adhesin*, which also causes haemagglutination of erythrocytes *in vitro*. In addition to surface attachment, the organism can invade the gastric epithelial cells. *H. pylori* produces two cytotoxins. One of these induces vacuolization of the affected cells. This *vacuolizing toxin* is much more commonly encountered in isolates from patients with duodenal ulceration than those with gastritis and no ulceration. The clinical relevance of the other toxin, which is a weak haemolysin, remains unknown. The other adverse effects of *H. pylori* infection include reduced epithelial cell turn over (impaired healing), reduction of surface hydrophobicity and increased lipolytic activity, release of chemotactic factors for neutrophils and monocytes and degranulation of eosinophils with release of cytotoxic cationic proteins, increased apoptosis, activation of the classical complement pathway and stimulation of the G-cells with increased release of gastrin as a result of the high surface pH consequent on the locally produced NH_3.

Not all patients with *H. pylori* infections develop gastroduodenal disease. Aside from host factors, the virulence and the genetic type of the organism, age of the host and environmental factors (smoking, diet especially the protective effect of dietary fruit and vegetables) are important and determine the development of specific gastroduodenal disease, depending on the predominant site of the infection – antrum or body – and its incidence. *H. pylori* exhibits marked genetic variation and hence the presence of virulent and less virulent strains.

Virulence is associated with the *cag* pathogenicity island (PAI) (a segment of DNA) which has 40 genes, one of which is the *cytotoxin-associated gene A (cagA)* that codes for the protein CgA that is highly antigenic and hence can be detected by antibody tests. The PAI is associated with the vacuolating toxin and hence mucosal damage and inflammation. Longstanding inflammation then leads to atrophy and intestinal metaplasia. The *H. pylori* antigens also induce the appearances of MALT follicles in the gastric submucosa. Hence the entire spectrum of gastroduodenal disease caused by *H. pylori* is gastroduodenitis, duodenal and gastric ulcers, atrophic gastritis and gastric cancer, and MALT gastric lymphomas.

What is interesting is that the PAI including the *cagA* gene does not produce the vacuolating toxin. This is coded by another gene (*vacA*) that is located in the genome of *H. pylori* outside the PAI. However, only organisms that possess the PAI can secrete the vacuolating toxin. Whereas infections with virulent *CagA*-positive organisms cause serious gastroduodenal disease, paradoxically they protect the host from the development of reflux oesophagitis and probably Barrett's columnar metaplasia and carcinoma of the gastro-oesophageal junction. Indeed the marked fall in the incidence of *H. pylori* infections in Western countries has been linked with the marked rise in the incidence of these junctional cancers over the past 20 years.

Extradigestive disease

There are several mechanisms whereby gastric infection with *H. pylori* can contribute to the development of extradigestive disease:

- immunological responses to *H. pylori* antigens
- constant production of proinflammatory substances: cytokines, eicosanoids, acute-phase proteins
- mimicry between bacterial and host antigens
- reduced folate and iron absorption.

This has generated past and continued research interest into the possible aetiological association between *H. pylori* infection and a variety of extradigestive disorders (Box 23.2).

The reported studies in patients with ischaemic heart disease have tended to confirm this association, but with an extremely wide variation on the estimates of the degree of risk of infected patients. One of these reviews has indicated that infected patients carry a low (10–20%) excess risk. The association between

BOX 23.2 Extradigestive disorders with possible association with *H. pylori* infection

- Ischaemic heart disease
- Ischaemic cerebrovascular disorders, including carotid artery stenosis
- Functional vascular disorders: Raynaud's phenomenon and idiopathic migraine
- Immunological disease: Henoch–Schönlein purpura, Sjögren syndrome, autoimmune thrombocytopenia
- Extragastric MALT lymphomas
- Sideropenic anaemia: possible iron malabsorption
- Skin disorders: idiopathic chronic urticaria, acne rosacea and alopecia areata
- Hepatobiliary disease: cirrhosis, cholesterol stones. Chronic cholecystitis (other *Helicobacter* species, e.g. *H. bilis*, *H. pullorum*)

H. pylori infection and carotid artery stenosis is based on reports that show significantly more severe stenosis in infected than in non-infected patients suffering from this condition. The hypothesis suggested for the role of *H. pylori* infection in atherosclerosis, aside from the chronic inflammatory cascade, is folate malabsorption by the infected stomach. Low serum folate is a well-documented risk factor for ischaemic vascular disease.

Helicobacter heilmannii infections

This organism, previously known as *Gastrospirillum hominis*, can also infect the stomach, although it is much less commonly encountered in clinical practice and is reported to be present in 0.08–1% of endoscopies. Infection produces a gastritis that differs from that caused by *H. pylori* in several respects. In the first instance, the mononuclear infiltrate is mild, the inflammation is usually inactive, the bacterial mucosal load is low and the degenerative/regenerative lesions in the surface gastric epithelium are focal and mild. Contrary to *H. pylori*, the bacteria do not adhere to the surface epithelium. Nonetheless, infection with *H. heilmannii* can cause peptic ulcer disease, gastric cancer and gastric MALT lymphomas. Thus when present the condition requires eradication therapy.

Tests for *Helicobacter pylori* infection

The most commonly performed are the *rapid urease tests*. These are carried out on endoscopic biopsies and use test kits such as CLO, Hfast, Pyloritec, etc., and provide a result within 3 hours of the endoscopy. The sensitivity and specificity of these tests at the final reading are similar at 90% and 100%, respectively. Therapy with PPIs at the time of endoscopy significantly reduces the sensitivity of antral and corpus biopsies for detection of infection by rapid urease tests and histology. Thus, if PPI therapy cannot be discontinued, the *rapid urease test* should not be read before 24 hours after biopsy, and, in addition, a serological test should be performed.

Other tests include culture in a microaerobic environment, the polymerase chain reaction, histology of antrum and corpus (Giemsa or Warthin–Starry silver stain), the ^{13}C breath test and serology for the detection of *H. pylori*-specific antibodies [immunoglobulin (Ig) C]. The modern immunological test kits are based on purified antigen preparations and use the enzyme-linked immunosorbent assay.

There is little to choose between the various tests in terms of sensitivity and specificity (Table 23.2) and in practice the choice of test depends on the clinical situation. In symptomatic patients undergoing endoscopy, a biopsy-based test is the appropriate one (*rapid urease*, histology, culture) and the accuracy is increased if more than one test is performed. In asymptomatic patients a serological test is first performed, and if this is positive confirmation is achieved by the ^{13}C breath test. This test is also indicated in patients with recurrent symptoms after previous eradication, even if the endoscopy is normal. Serological tests within 6–12 months of eradication are unreliable. It is recommended that the outcome of any eradication treatment needs to be confirmed by a non-invasive test 4–8 weeks after the end of treatment, and the best test for this purpose is the ^{13}C breath test.

Table 23.2 Comparative sensitivity and specificity of the various tests used for the diagnosis of *Helicobacter pylori* infections

Test	Sensitivity (%)	Specificity (%
Rapid urease tests	90	100
Culture	98	100
Polymerase chain reaction	97	100
Histology of antrum and corpus	98	99
^{13}C breath test	100	100
Serology	98	88

Acute gastroduodenal disorders

The various surgical disorders of the stomach and duodenum are discussed later in this chapter. Many of these diseases present with varying degrees of urgency, such as perforation, bleeding or stenosis. The general management of these situations is discussed here.

Perforation

Free perforation into the general peritoneal cavity is a catastrophic event, the signs and symptoms of which do not usually cause diagnostic problems. When perforation of a chronic peptic ulcer occurs, there will often have been an increase in the severity of the dyspepsia for a few days prior to the perforation. When an acute ulcer perforates, there may be no premonitory symptoms, particularly in younger patients. The pathology of steroid-induced perforations is not fully understood. For instance, perforation is much more common in patients with rheumatoid arthritis on steroids than in patients with ulcerative colitis. This may be a reflection of the primary disease process, or, alternatively, may be a feature of the concomitant use of other drugs. The use of NSAIDs has been shown to be associated with an increased risk of both perforation and acute bleeding.

Acute perforations also accompany situations of stress, such as burns, multiple injuries and sepsis. It can also occur in patients receiving intensive chemotherapy and radiotherapy for malignant disease. Such perforations may be duodenal, pyloric or gastric. Perforation of malignant gastric ulcers is common and although most perforated gastric ulcers will be benign, biopsy is necessary if the ulcer is not removed.

The moment of perforation is often identified by the patient as sudden excruciating epigastric pain. The subsequent symptoms depend in part on the degree of peritoneal soiling and whether the perforation becomes sealed by the greater omentum. Otherwise, the pain becomes generalized. In addition, the patient may experience referred shoulder pain caused by diaphragmatic irritation. Sometimes, the spread of the gastroduodenal contents is maximal along the right paracolic gutter, such that the intensity of the pain becomes localized in the right iliac fossa, thus simulating acute appendicitis. Significant vomiting is uncommon unless the diagnosis is delayed and a paralytic ileus becomes established. Occasionally in elderly or seriously ill people (usually in intensive care), the perforation does not develop as a dramatic episode and there is a more gradual development of generalized peritonitis with fewer intense symptoms and signs.

The physical signs accompanying perforation will again depend upon the degree and rate of peritoneal soiling. Tenderness, with guarding, may vary from being localized to the upper abdomen to being generalized. If contamination of the general peritoneal cavity has occurred, there will be marked (board-like) rigidity, rebound tenderness and a silent abdomen. Abdominal distension is a late feature and reflects the onset of paralytic ileus and occurs because of subsidence of the reflex spasm of the anterior abdominal musculature. In elderly, immunosuppressed and seriously ill patients, this may be the only significant clinical finding. A variable degree of peripheral circulatory failure may be present, with tachycardia, hypotension, a cold periphery and a decreased urinary output. Respiration will be shallow and grunting.

Diagnosis

The key to the diagnosis, suspected from the symptoms and signs, is the plain abdominal or chest radiograph taken in the erect position. The lateral decubitus position may be used instead in a very ill patient. Although free peritoneal gas may come from any of the alimentary hollow organs, in practice the finding of subdiaphragmatic air usually on the right side is virtually pathognomonic of gastroduodenal perforation. Radiological features of an ileus may be present in more advanced cases. If a pneumoperitoneum is not evident radiologically, the diagnostic problem concerns the differentiation between a sealed perforation with minimal localized soiling and acute pancreatitis. In some instances of the former, identification may not be important if the clinical state of the patient is stable or improving. Otherwise, differentiation between a sealed perforation and acute pancreatitis is obtained by contrast radiology and estimation of serum amylase. Although moderate elevation of the serum amylase may be present in 10–20% of perforated ulcers, it is uncommon for this to exceed 700 Somogyi units unless renal function is impaired as a result of the hypovolaemia. If doubt persists, a diagnostic peritoneal tap or lavage may help. The amylase content will usually be very high in either condition, but it should be possible to differentiate between gastroduodenal contents and the brownish fluid of acute pancreatitis. An alternative approach is diagnostic laparoscopy, but this requires a general anaesthetic. If this goes ahead and the findings are those of a sealed duodenal ulcer, no attempt should be made to disrupt the omental seal. Aspiration of any fluid and saline irrigation is all that is required.

Management

Initial treatment should be directed towards correction of hypovolaemia and any electrolyte deficit/imbalance. Oliguria and poor peripheral perfusion are contraindications to immediate operative treatment, and their correction should take precedence even over radiological studies. If necessary, resuscitation should be monitored with measurement of central venous pressure and urine output from an indwelling urinary catheter. Colloids can be used for resuscitation, but crystalloids in the form of balanced electrolyte solutions are equally effective. Oxygen via a mask is recommended in shocked patients. Pain relief should be given immediately even before the physical examination. Intramuscular pethidine is usually very effective, and a small dose can be given intravenously if absorption from a poorly perfused periphery is suspected in the presence of hypovolaemia. Nasogastric intubation with intermittent aspiration is instituted next. Antibiotics are not recommended routinely since the initial peritonitis is chemical. However, if the presentation is late or surgical treatment is delayed beyond 8 hours from the onset of symptoms, or if the patient has chronic respiratory problems, the use of a broad-spectrum antibiotic (usually a second-generation cephalosporin) is justified.

Operative or conservative management

There is no doubt that some patients with perforated peptic ulcers can be managed conservatively (non-operatively) with a successful outcome with the understanding that these patients will be investigated by upper gastrointestinal endoscopy on recovery from the acute illness. A policy of nasogastric suction, intravenous fluids, antibiotics and analgesics will allow many perforations to seal spontaneously and the ileus to resolve. An H_2-blocker or more recently a PPI (esomeprazole, pantoprazole, etc.) administered intravenously is used by some to lower gastric secretion, gastric pH and juice volume. The problem with the conservative approach, which is usually reserved for poor-risk elderly patients, is a high incidence of residual abscess formation, particularly in the subphrenic regions, which will subsequently require drainage, although this may be carried out percutaneously under radiological guidance, thus obviating surgical intervention.

An operative approach (closure of the perforation and peritoneal lavage) is therefore strongly recommended in the vast majority of patients. This may be performed through an open surgical or laparoscopic approach. Several retrospective studies and two randomized controlled trials have confirmed that the clinical outcomes of patients in terms of survival and morbidity between the two approaches are identical. However, the laparoscopic approach has several disadvantages, including less postoperative pain with reduction in the analgesic intake and faster recovery.

Open surgical treatment

This is usually performed through an upper midline incision and consists of closure of the perforation with interrupted sutures (small duodenal perforation) or an omental patch (large duodenal perforation or gross friable oedematous perforation). For perforated gastric ulcers (other than juxta-pyloric) excision of the ulcer with interrupted suture closure of the resulting defect is a far better alternative than four-quadrant biopsy with closure of the ulcer, in terms of procuring the biopsy material essential in all such cases to exclude gastric malignancy. Biopsy of these ulcers is essential, as 10% of perforated gastric ulcers are due to malignant disease (carcinoma or lymphomas). A case for partial gastrectomy with wide margins and beyond the perforated area can be made if the patient's condition is good. However, most would prefer ulcer excision and suture closure in the first instance and relying on histology to decide on the definitive radical therapy should the patient have gastric cancer.

Closure of the perforation is followed by aspiration of all the purulent fluid in the various compartments, including the pelvis, and irrigation with warm saline fluid (3 L). Insertion of drains is of doubtful benefit and is not generally recommended, unless difficulties are encountered with closure of the perforation. There is controversy regarding the additional definitive surgical treatment in these patients at the time of emergency surgery for closure of the perforation. In practice nowadays, this consideration arises only in those patients with a long history of peptic ulceration and in whom the perforation is early (within 6–8 hours) and whose *H. pylori* status is not known. This constitutes a rare group in modern surgical practice. If a definitive surgical treatment is considered necessary by the surgeon for any reason, this should consist of a highly selective vagotomy rather than a truncal vagotomy and drainage. Partial gastrectomy is only considered for perforated gastric ulcer situated in the body of the stomach, in which case the resection should include the ulcer. Restoration of continuity using a gastroduodenal anastomosis (Billroth I) is preferable to a Pólya gastrectomy (Billroth II) in these cases as it is less likely to cause major postgastrectomy symptoms.

Laparoscopic surgical treatment

It is important to stress that the laparoscopic approach starts as an inspection to confirm the diagnosis and to determine whether the perforation is free or sealed. In the latter eventuality, the purulent exudates are aspirated completely, and then the region of the perforation is inspected for several minutes. If there is no duodenal leakage, the natural sealing by the omentum should not be disturbed and the surgeon, following the insertion of a drain down to the sealed perforation, should proceed with warm saline irrigation with copious amounts of fluid. An effective manoeuvre during this stage is to shake the patient from side to side through the drapes to dislodge any pocketed purulent exudates from the paracolic gutters and pelvis. The management of a free perforation is the same as described with the open approach. In all other respects, the laparoscopic management is identical to that used in the open surgical approach.

Following closure of the perforated peptic ulcer, two important factors determine future management:

- the *H. pylori* status
- the requirement of the patients for NSAIDs.

All these patients require testing for *H. pylori*, and if positive eradication therapy is instituted. Some advocate eradication therapy in all patients who have sustained a perforated duodenal ulcer, but this management policy is not recommended in regions of low *H. pylori* infection prevalence. If the patient has been taking and requires continued NSAID medication, consideration should be given to a selective cyclo-oxygenase-2 inhibitor. If this proves ineffective, the addition of a PPI may reduce the future risk of recurrent ulceration.

Pyloric stenosis (gastric outlet obstruction)

Pyloric stenosis is, in fact, rarely due to stenosis at the pylorus. More commonly, the site of obstruction is on one side or other of the pylorus – either the first part of the duodenum at the site of chronic scarring from duodenal ulceration or in the antrum consequent on scarring from a benign peptic ulcer of cancer. True pyloric stenosis can arise from a pyloric channel ulcer or, very rarely, from a congenital web or adult hypertrophic pyloric stenosis. Other stenotic complications of peptic ulcer disease include hourglass and teapot deformities (gastric ulcer). All complications result in varying degrees of outlet obstruction. The stenotic complications arise from repeated cycles of ulceration and healing, with resultant dense fibrosis, deformity and narrowing. Some instances of pyloric stenosis are, however, caused by inflammatory oedema surrounding an active ulcer, and these often resolve with medical conservative treatment.

Considerable hypertrophy occurs in response to outlet obstruction. Sometimes, difficulty is encountered in distinguishing between benign gastric outlet obstruction and obstructing antral gastric cancer. This requires repeated endoscopy with biopsy, which always clarifies the exact diagnosis. In practical terms, the common causes of gastric outlet obstruction are:

- chronic duodenal ulceration with fibrosis
- antral gastric carcinoma
- carcinoma of the head of the pancreas.

Rare causes of gastric outlet obstruction

Rare causes of delayed gastric emptying include a variety of benign tumours, lymphomas, Crohn disease, duodenal haematoma (blunt trauma), adult pyloric hypertrophy, annular pancreas, mucosal diaphragm and Wilkie disease.

Adult pyloric hypertrophy

Thickening of the circular muscle of the pylorus sufficient to produce outlet obstruction can occur in adults. The relationship to congenital pyloric stenosis is unclear, although about 25% of such adult patients give a history dating back to childhood. At operation, a focal or generalized thickening of the pylorus is found. There is nearly always a degree of fibrosis so that pyloroplasty rather than pyloromyotomy is the usual corrective procedure of choice.

Mucosal diaphragm

Symptoms due to incomplete diaphragm are often not apparent until middle age. Presumably, muscular hypertrophy of the stomach muscular wall is capable of overcoming the obstruction until this time. The diaphragm consists of mucosa and submucosa and may be located in the antrum, pylorus or duodenum. It represents failure of recanalization of the embryonic foregut at this point. Gastric ulcers are sometimes found in association with this lesion. Excision of the diaphragm, with or without pyloroplasty, is all that is needed for relief of the obstruction.

Megaduodenum

Rarely, a dilated stomach is found without an organic obstruction with the dilatation extending into the duodenum to a variable extent. Such cases have been well documented as being associated with degeneration of the myenteric nerve plexus. This may be part of *Chagas disease*, but often the exact cause of the degeneration is not known. Gastrojejunostomy is usually beneficial in the short term, although progression of the degeneration to other parts of the gastrointestinal tract may occur.

Annular pancreas

Many instances of annular pancreas present in adult life with symptoms of pyloric stenosis and there is an established association of this congenital anomaly with Down syndrome and other congenital abnormalities. Annular pancreas is thought to arise because the free end of the ventral pancreas becomes fixed during embryonic development and as it migrates around to the right posteriorly to join the dorsal analogue it then encircles the duodenum (Figure 23.10). Morphologically, the condition consists of a ring of pancreatic tissue which partially or totally encircles the second part of the duodenum. The commonest presenting symptom in adult patients (usually between 20 and 40 years) is colicky upper abdominal pain (86%). Other symptoms include postprandial fullness, nausea, vomiting, weight loss and episodes of gastrointestinal bleeding. The precipitating cause may be an attack of pancreatitis. Symptomatic cases may be treated with any of the following, depending on the extent of the duodenal pathology at operation: duodenoduodenostomy, duodenojejunostomy or gastrojejunostomy.

Arteriomesenteric compression (Wilkie disease)

In this condition, the fourth part of the duodenum is compressed between the superior mesenteric vessels which cross it anteriorly such that the duodenum is compressed by the aorta behind. Acute weight loss and immobilization in a plaster cast are cited as predisposing factors to this rare condition. The symptoms are of high small bowel obstruction following a long period of insidious symptoms consisting of cramp-like epigastric pain often misdiagnosed as peptic ulcer disease. In chronic cases, megaduodenum with gastric stasis develops. However, it is important to stress that, in some patients diagnosed with *Wilkie disease*, obstruction is caused by other disease, the most important being tumours (lymphoma or carcinoma) at the duodenojejunal junction. Thus a thorough investigation is needed in all cases to establish the definitive diagnosis. Surgical treatment of Wilkie disease is either by duodenoduodenostomy (which may be difficult) or duodenojejunostomy (often easier technically) or gastrojejunostomy, which requires vagotomy or long-term acid secretory suppression.

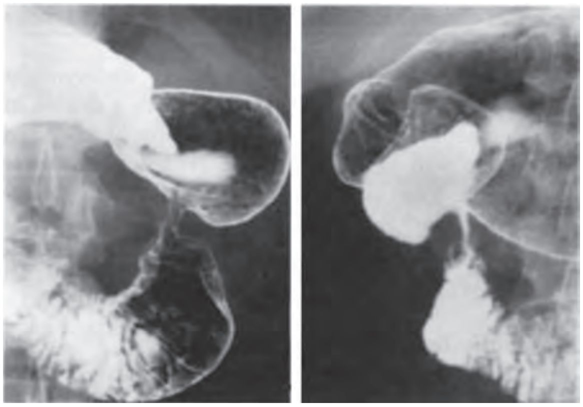

Figure 23.10 Barium meal in an adult male patient with annular pancreas who presented with intermittent episodes of vomiting after meals.

Clinical features of gastric outlet obstruction

Pyloric stenosis due to a duodenal ulcer usually occurs in a patient with longstanding symptoms of ulceration. A short preceding history with little in the way of typical ulcer pain suggests that the obstruction may be malignant. In most Western countries, the majority of gastric outlet obstruction is caused by distal gastric or proximal pancreatic cancer. In the typical case of benign pyloric stenosis, the patient experiences yet another exacerbation of the ulcer symptoms. As the obstruction develops, however, the character of the pain may change to become more cramp-like with a persistent upper abdominal discomfort. Vomiting and anorexia supervene. As vomiting increases, pain may become less of a feature. The typical vomiting of pyloric stenosis is effortless and projectile and the vomitus is characterized by an absence of bile and the presence of partially digested food eaten hours or days previously. With repeated vomiting and failure to eat, the patient often becomes constipated, although, in some cases, diarrhoea may develop.

Examination will usually show an underweight patient who is dehydrated and often with a degree of iron-deficiency anaemia. In such relatively advanced cases, there will always be evidence of gastric stasis in the form of a succussion splash. Visible peristalsis may be apparent passing across the upper abdomen from left to right, and the dilated stomach may actually be palpable.

Metabolic features

Prolonged vomiting of gastric juice and contents will result in a characteristic series of electrolyte disturbances. Initially, the major loss is fluid rich in hydrogen and chloride ions so that the dehydration is accompanied by hypochloraemic alkalosis. At this stage, the serum sodium is usually normal and the hypokalaemia may not be obvious. The more marked metabolic changes which inevitably accompany unrelieved gastric outlet obstruction result from a combination of continued losses and secondary changes in renal function. In the early stages, the urine is characterized by low chloride content and is appropriately alkaline because of enhanced bicarbonate excretion. This tends to compensate for the metabolic alkalosis, but it does so at the expense of sodium loss. If the gastric losses continue, the patient becomes progressively more dehydrated and hyponatraemic. In an attempt to conserve the circulating blood volume, sodium is retained by the kidneys and hydrogen ions and potassium are excreted in exchange. At this late stage, therefore, the patient with a metabolic alkalosis will have, paradoxically, acid urine. This further increases the severity of the alkalosis and the hypokalaemia. As a secondary effect of the alkalosis, the concentration of plasma ionized calcium may fall such that disturbances of the conscious level and tetany may be apparent.

Management

Gastric outlet obstruction due to chronic duodenal ulcer is treated by truncal vagotomy and gastroenterostomy. Other benign causes not associated with avid hypersecretion are managed with gastroenterostomy alone. Hourglass deformity and the teapot stenosis, which are complications of gastric ulcer disease, are best managed by gastrectomy if the patient's condition permits.

The priority in management of advanced cases of pyloric stenosis is correction of the fluid and electrolyte disturbances. Blood transfusion may be needed. This will often become apparent as dehydration is corrected and the spuriously high haemoglobin value falls to its actual level. Rehydration should be achieved by saline infusions with potassium supplement as indicated by electrolyte determinations. Provision of adequate sodium allows the excretion of alkaline urine so that the alkalosis is corrected. Success is indicated by clinical improvement in the state of hydration, by an increase in the urine output, a fall in the blood urea and haematocrit, and restoration to normal of the serum electrolytes.

Gastric lavage should be performed with a wide bore tube using saline for irrigation. This should be performed twice daily initially and until the returning fluid is quite clear of particulate matter. The patient should not be allowed to eat, but fluids may be given, and milky drinks or elemental diets should be encouraged. One benefit of bed rest, rehydration, lavage and milk drinks is that an ulcer will begin to heal and with subsidence of inflammatory changes, the obstruction will begin to remit especially with the administration of a PPI intravenously. Such improvement is often apparent even when the cause of obstruction is a malignancy. There must be no undue rush over this stage of management, which will often take a week to 10 days. The objective is to get the patient into the best possible condition for surgery, and it is a mistake to accept less than this ideal. During this time, the patient will also benefit from chest physiotherapy. In nutritionally compromised patients, provision of adequate nutrition often requires intravenous feeding. It may be difficult to make a firm diagnosis of the cause of the pyloric stenosis by contrast radiology. Even when the stomach has been well prepared, radiological studies may merely confirm gastric outlet obstruction and fail to reveal its cause. Flexible endoscopy with biopsy will establish the exact diagnosis and is indicated once the stomach is cleansed.

Sometimes pyloric stenosis first manifests itself when active ulcer disease within the duodenum has burnt itself out. A non-operative approach is justified in these cases, particularly in elderly or unfit patients. Balloon dilatation of the stenosed area, via an endoscope, can relieve the obstruction. Although this may need to be repeated at intervals of a few weeks for a period, this approach can obviate the need for surgery. Alternatively the endoscopic insertion of a metallic stent can be used, especially if dilation is followed by restenosis and recurrence of obstructive symptoms.

Volvulus

Gastric volvulus is rare and in terms of aetiology is classified into *type 1* (idiopathic) and *type 2*, which is either congenital or acquired. Type 1 is by far the commonest and constitutes two-thirds of the reported cases. It is thought to result from abnormal laxity of the gastrosplenic, gastrophrenic and gastrohepatic ligaments, and, indeed, cases associated with a wandering spleen have been reported. Although it usually presents in adults, cases of type 1 gastric volvulus are well documented in children. Type 2, which accounts for one-third of all cases, is associated with congenital or acquired abnormalities which result in undue mobility of the stomach anchorage, particularly at the hiatus and pylorus, such that these points of tethering become stretched and weakened. The most common cause for this in adults is hiatal hernia, particularly of the paraoesophageal type, although it may complicate all large hiatal hernias irrespective of type and indeed even diaphragmatic hernias. Rare causes of type 2 gastric volvulus include connective tissue disorders, which cause laxity of the fascial tissues (e.g. *Ehlers–Danlos syndrome*), and bulky benign gastric tumours, causing lengthening of the connective tissue attachment of the stomach.

In anatomical terms, volvulus of the stomach can occur along two axes – *mesentericoaxial* or *organoaxial* (Figure 23.11). In all types of gastric volvulus, the presentation may be acute or chronic with symptoms of recurrent episodes of epigastric pain and vomiting (Figure 23.12). Acute volvulus, more common with the organoaxial variety, presents as sudden severe pain in the epigastric or left upper quadrant region with ineffectual

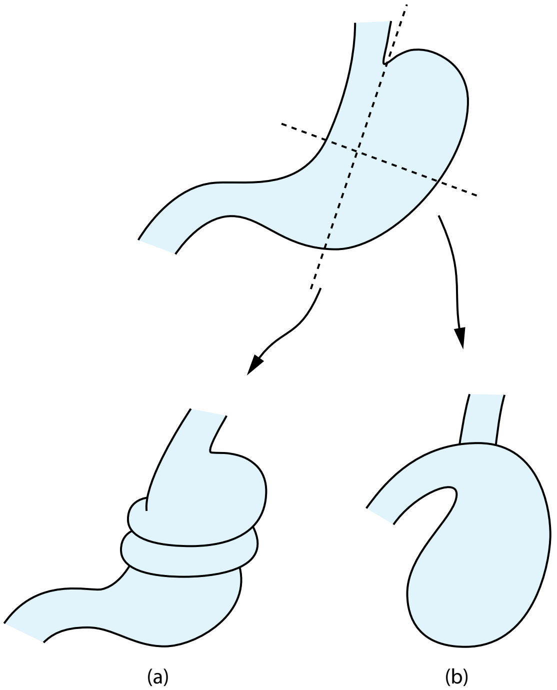

Figure 23.11 Schematic representation of the two types of gastric volvulus: (a) organoaxial; (b) mesentericoaxial.

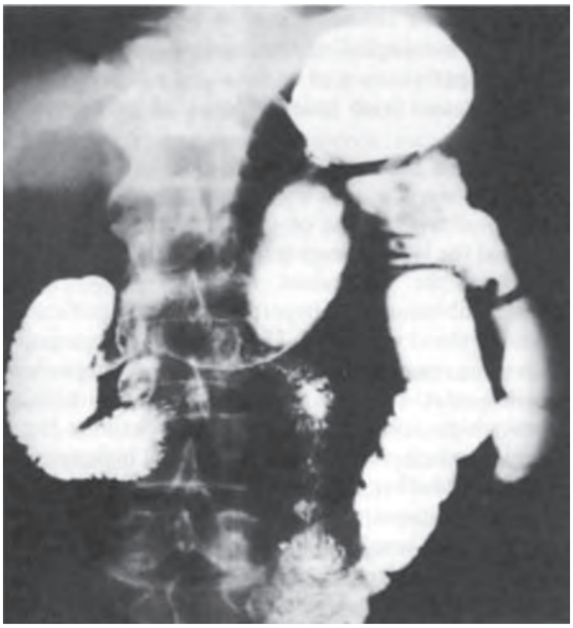

Figure 23.12 Contrast study in a patient with chronic mesentericoaxial volvulus.

retching. When the volvulus is intrathoracic, the pain is located in the chest and radiates to the neck, shoulder, arms and back, simulating acute myocardial infarction. A few patients may present with haematemesis secondary to gastric wall ischaemia. Distension, upper abdominal tenderness and signs of shock develop rapidly in these acute cases, and urgent surgical intervention is indicated if strangulation and perforation are to be avoided. With this clinical background, the inability to pass a nasogastric tube into the stomach is diagnostic in 70% of patients.

Endoscopic reduction should be attempted but only in the absence of clinical signs of strangulation. The flexible endoscope is negotiated through the twist into the stomach, where deflation and untwisting occur. If successful, the patient is managed conservatively, especially if the general condition is poor and in the presence of comorbid disease. Otherwise urgent surgery is indicated. At operation, the volvulus is untwisted to restore tissue perfusion and, if the stomach walls are viable, the stomach is fixed by a gastropexy with the insertion of a percutaneous endoscopic gastrostomy tube. Partial or complete resection may be necessary in cases of delayed diagnosis with established gastric gangrene.

Haematemesis and melaena

Patients presenting with acute upper gastrointestinal haemorrhage still pose management problems, and despite the advances in medical treatment, including diagnostic and interventional endoscopy, the overall mortality from acute upper gastrointestinal bleeding has not changed appreciably during the past two decades and probably averages 20%, although there is sufficient evidence from good prospective and retrospective reports that, with the appropriate management strategy, the hospital mortality of these patients can be reduced to 5%.

Aetiology

The causes of upper gastrointestinal haemorrhage are discussed in Chapter 5. The vast majority (>90%) are caused by chronic peptic ulceration, NSAID-induced bleeding and oesophagogastric varices. On occasions the source of an upper gastrointestinal bleed may remain unknown. If the presenting problem is melaena alone and no blood is found in the stomach or duodenum on repeat endoscopy, then attention should turn to the small bowel and the colon, and certainly capsule small bowel endoscopy is indicated as this in now the investigative procedure of choice and has replaced all other tests for the diagnosis of obscure bleeding from the small intestine. If small bowel capsule endoscopy proves non-productive, emergency mesenteric angiography is indicated. In any case, there is no indication for emergency laparotomy for undiagnosed gastrointestinal bleeding in modern surgical practice.

Chronic peptic ulcers

Despite more effective medical treatment, bleeding from duodenal and gastric ulcers still remains one of the common causes of life-threatening upper gastrointestinal haemorrhage. Some consider the bleeding caused by NSAIDs to be largely due to exacerbation of chronic peptic ulcer disease, especially gastric ulcers in elderly women. The problem inherent to bleeding peptic ulcers is their tendency to rebleed after spontaneous or therapeutic arrest. This propensity to recurrent haemorrhage has been attributed to the acid environment of the stomach and the proximal duodenum that impairs platelet aggregation and blood coagulation and to the digestion of clots by pepsin. In an interesting study on human volunteers, intraduodenal infusion of blood resulted in decreased pentagastrin-stimulated acid and pepsin secretion, suggesting a natural protective mechanism.

NSAID-induced bleeding

Aspirin and non-aspirin NSAID usage in elderly people is widespread in the general population, and population-based studies document annual prevalence rates as high as 60%. A meta-analysis of 16 studies has shown that NSAID users have a threefold risk of gastrointestinal haemorrhage, surgery and death compared with non-users. The risk from bleeding is greatest:

- in the first few months of treatment
- in the elderly (> 65 years)
- in patients with concomitant steroid use
- in patients with a previous history of gastrointestinal events.

The incidence of bleeding and perforation according to the Nottingham study is 1:6000 and 133 000 prescriptions respectively. Of all the NSAIDs known to cause bleeding or perforation (indometacin, naproxen, etc.), aspirin produces the most damage. There is some evidence that the newer NSAIDs, e.g. nabumetone, which are selective inhibitors of cyclo-oxygenase-2, are less damaging to the gastroduodenal mucosa and hence significantly less ulcerogenic, but they appear to be less effective in relieving pain. The other problem with NSAIDs concerns the development of non-specific ulceration of the upper small intestinal mucosa in 8–9% of users. These can bleed and perforate.

Dieulafoy's lesion (exulceratio simplex, cirsoid aneurysm)

This condition was first described in 1898 by a French surgeon. It consists of a nodule containing an arteriole which protrudes through a mucosal defect and is typically located within 6 cm of the oesophagogastric junction on the lesser curvature. Extragastric Dieulafoy's lesion may occur in other parts of the gastrointestinal tract: oesophagus, duodenum (usually periampullary), small bowel, colon and rectum. The condition is nowadays thought to be caused by an abnormally large-calibre tortuous submucosal artery which erodes the overlying gastric mucosa by the repeated incessant arterial pulsations.

Dieulafoy's lesion is an uncommon cause of recurrent gastrointestinal bleeding and accounts for 1% of all cases of acute, often massive, upper and lower non-variceal gastrointestinal bleeding. The diagnosis is difficult and is usually made after repeated endoscopies. The most common presentation is with recurrent, often massive, haematemesis associated with melaena (51%) or haematemesis alone (28%) and, least commonly, melaena alone (18%) without any accompanying dyspeptic symptoms.

Therapeutic endoscopy is the treatment of choice with electrocoagulation, sclerotherapy, heater probe, laser photocoagulation, epinephrine injection, haemoclipping and banding, depending on the local availability and expertise. Endoscopic therapy is successful in achieving permanent haemostasis in the majority (85–90%) of cases. Rebleeding after treatment is initially treated by further endoscopic therapy but some 5% ultimately require surgical treatment (gastrotomy with suture ligation). Bleeding from extragastric Dieulafoy lesions can be treated by angiographic therapeutic Gelfoam embolization.

Portal hypertensive gastropathy

This condition can cause acute or chronic repeated gastrointestinal blood loss. Up to 65% of patients with portal hypertension from cirrhosis will develop portal hypertensive gastropathy (PHG) but equally it occurs in patients with non-cirrhotic portal hypertension (presinusoidal). PHG is usually associated with the presence of oesophageal and/or gastric varices. The pathogenesis of PHG is not fully understood but regulation of gastric nitric oxide, prostaglandins, tumour necrosis factor (TNF)- and EGF production may be involved. The reported data on seroprevalence of *H. pylori* and PHG are conflicting and currently there is no clear correlation between *H. pylori* infection and aetiology, stage of cirrhosis and presence/severity of PHG. Additionally, there is no clear correlation between PHG and the severity of the cirrhosis and degree of portal hypertension. The histological appearances of PHG consist of mucosal and submucosal vascular dilatation with little evidence of inflammatory changes.

The diagnosis of PHG is made by endoscopy. In mild PHG, the gastric mucosa often looks reddened and oedematous with a faintly mosaic pattern. With established disease, the endoscopic appearances predominantly affect the fundus, but no region is exempt and the condition may be generalized. The mucosa often has a marked mosaic-like pattern (Figure 23.13) and may exhibit red point lesions, cherry red spots, and black-brown spots. Treatment of PHG is by beta-blockers, which reduce the frequency of bleeding episodes. Removal of all risk factors known to cause gastric injury, e.g. alcohol, aspirin and NSAIDs, is important for success of medical therapy. If this fails, surgical decompression of the portal system, or nowadays by radiologically guided transjugular intrahepatic stenting and liver transplantation (in cirrhotic patients), will effectively resolve this condition.

Gastric antral vascular ectasia or watermelon stomach

This is a related disorder but must be distinguished from PHG. The exact pathogenesis of gastric antral vascular ectasia (GAVE) syndrome remains unclear, although one hypothesis attributes the cause to repeated trauma and ischaemia from antroduodenal prolapse. The classical endoscopic features of GAVE syndrome consist of hyperaemic antral folds with dilated, tortuous vessels extending radially from the pylorus, producing a watermelon appearance accounting for the alternative name. Ectatic submucosal capillaries, microvascular fibrin thrombosis and fibromuscular hyperplasia in the lamina propria constitute the distinctive histological features. Although the majority (70%) of patients with GAVE syndrome do not have cirrhosis or portal hypertension, cases associated with cirrhotic and non-cirrhotic portal hypertension do occur and must be differentiated from PHG; whereas PHG generally responds to a reduction in portal pressures, GAVE associated with portal hypertension does not. Cases of GAVE associated with other disorders including end-stage chronic renal disease are documented

GAVE presents with upper gastrointestinal haemorrhage. The bleeding is often recurrent, requiring multiple transfusions. Treatment options include endoscopic therapy and surgery, which is performed only if endoscopic therapy fails. Flexible endoscopic therapy (electrocoagulation, sclerotherapy, laser coagulation) constitutes the first line of management and is effective in the majority, although it often has to be repeated.

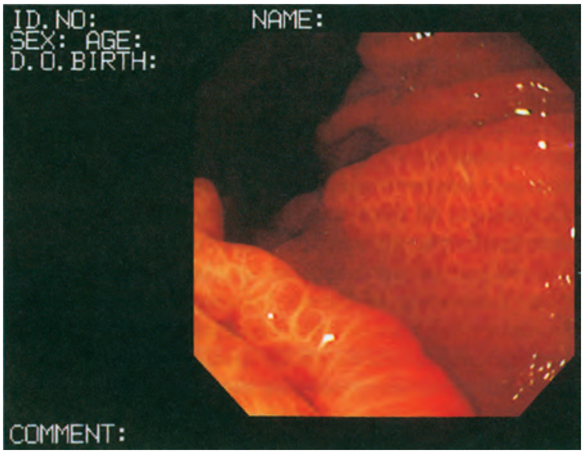

Figure 23.13 Mosaic-like appearance of portal hypertensive gastropathy. (Courtesy of Professor John F Dillon, Dundee, UK.)

Surgical treatment consists of distal gastrectomy (open or laparoscopic) and is always curative but accompanied by a reported high postoperative mortality.

Tumours

Gastrointestinal haemorrhage may be caused by both benign and malignant tumours. Acute haemorrhage is, however, more commonly associated with benign lesions, such as neurofibromatosis, smooth muscle tumours and gastrointestinal stromal tumours (GISTs). Malignant tumours (carcinoma and lymphomas) more usually cause chronic blood loss with the development of iron-deficiency anaemia, although massive bleeding may be precipitated by combination chemotherapy.

Chemotherapy

Life-threatening bleeding or perforation from necrosis of the tumour may complicate chemotherapy for gastrointestinal tumours, especially lymphomas. The bleeding is aggravated by the frequent thrombocytopenia induced by the treatment. In addition to haematological support, surgical intervention with resection of the tumour (if possible) is indicated to save life.

Stress ulceration

There has been a substantial decrease in the incidence of stress ulceration in intensive care units and this has been attributed to improved methods of supportive care. Stress ulceration causing acute bleeding is treated conservatively in the first instance by intravenous PPI and sucralfate together with blood transfusion. Sucralfate is administered via a nasogastric tube after aspiration to remove blood in aliquots of 60 mL repeated every 2–4 hours. Surgical treatment is only considered if conservative treatment fails, which is rare.

Aortoenteric fistula

This usually complicates aortic replacement with prosthetic grafts but may arise spontaneously. The aetiology is thought to be the result of graft infection. Small repeated warning haemorrhages usually precede the catastrophic bleeding, which when it occurs often leads to fatal exsanguinations, although prompt aggressive surgical intervention with ligature of the aorta, removal of the graft and axillofemoral bypass may save some of these patients.

Duodenal diverticulum

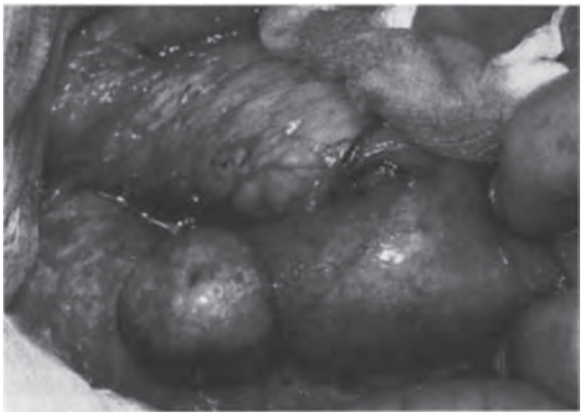

Figure 23.14 Duodenal diverticulum in a patient who failed to respond to conservative treatment and required open surgical intervention.

Although fairly common (Figure 23.14) and usually located in the ampullary region, bleeding from a duodenal diverticulum is rare (1% of cases). Acute haemorrhage may be caused by erosion of a major vessel, bleeding ectopic gastric mucosa, an intradiverticular polyp or local inflammatory process. Duodenal diverticula are managed conservatively unless complications (bleeding or perforation) arise. Aside from causing difficulties with cannulation of the bile/pancreatic duct during endogastric retrograde cholangopancreatography, a solitary duodenal diverticulum increases the risk of duodenal perforation in patients undergoing endoscopic sphincterotomy. The treatment of a bleeding duodenal diverticulum is conservative (endoscopic sclerotherapy or clip ligation) in the first instance, but surgical treatment may be required if endoscopic treatment fails or the bleeding recurs after successful control. At operation the procedure involves duodenotomy of the second part with eversion of the diverticulum (by sutures) and suture ligation of the bleeding vessel.

Management

The successful treatment of acute upper gastrointestinal haemorrhage demands aggressive treatment and a policy that is flexible enough to deal with the problems peculiar to the individual patient. There is good evidence that the best outcome is achieved by combined management between gastroenterologists and surgeons working as a team and in close co-operation from the time of admission of the patient. There are three phases in the management of the bleeding patient: resuscitation, diagnosis and definitive treatment (see Chapter 5).

Acute dilatation of the stomach

Acute dilatation of the stomach is a serious condition which may cause death by aspiration. Although encountered most commonly as a complication of upper abdominal surgery (especially splenectomy) and pelvic surgery, it occurs in other situations including orthopaedic patients immobilized in plaster casts. It is more common in malnourished and debilitated patients. Other predisposing factors include aerophagy (by apprehensive patients), excessive inadvertent distension of the stomach during endotracheal intubation and ventilation, administration of oxygen by nasal catheter, flexible endoscopy with vigorous insufflations of gas and the use of opiate analgesia. Contrary to expectations, acute dilatation of the stomach is rarely encountered in gastric outlet obstruction. The exact aetiology is unknown but is likely to be multifactorial. The stomach becomes atonic and this has been attributed to reflex inhibition of the myenteric neurones supplying the gastric musculature or failure of the gastric pacemaker.

Acute dilatation of the stomach is well documented in patients (usually young females) suffering from *anorexia nervosa* or *bulimia* (compulsive eating followed by self-induced vomiting), and instances of gastric necrosis and rupture of the stomach have been reported in these patients. The suggested mechanisms for acute dilatation in anorexia nervosa include muscular atrophy from starvation and neurogenic paralysis. In both conditions gastric necrosis supervenes when the intragastric pressure exceeds the gastric venous pressure.

The hugely dilated stomach, which may occupy the whole of the abdomen, is filled with dark blood-stained fluid. Evidence of hypovolaemia due to fluid and electrolyte sequestration is often present and the patient is frequently hypokalaemic. Premonitory symptoms include hiccups, vague feelings of unease in the epigastric region and small vomits which contain altered blood. A gastric succussion splash is diagnostic. The more dramatic presentation, which usually follows these signs and symptoms but which may arise *de novo,* is either severe pain mimicking myocardial infarction or severe collapse from hypovolaemia (simulating pulmonary embolism) or sudden marked vomiting of large amounts of foul-smelling fluid with inevitable aspiration and the development of acute respiratory distress syndrome – Mendelson syndrome.

The treatment of this emergency situation is by prompt decompression of the stomach by a large-bore nasogastric tube, preferably of the Salem sump suction variety, and correction of the hypovolaemia and electrolyte deficit by crystalloid solutions. Pulmonary aspiration is treated by bronchoscopic suction and lavage, antibiotics and steroids together with endotracheal intubation and ventilatory support in the intensive care unit. The mortality of acute gastric dilatation accompanied by pulmonary aspiration remains high. Early detection of the condition with appropriate intervention will prevent the vast majority of these deaths.

Nasogastric suction

Routine nasogastric suction by a Ryle's tube was introduced as a precaution against complications such as acute gastric dilatation in all patients undergoing abdominal surgery. This practice is now no longer recommended as a number of prospective controlled clinical trials have demonstrated (level 1 clinical evidence) that the routine use of nasogastric suction after elective surgery is accompanied by a higher incidence of postoperative infective complications, delays recovery, increases hospital stay, aside from causing considerable discomfort to the patient.

Although routine prophylactic nasogastric decompression has been abandoned in modern surgical practice, early therapeutic nasogastric suction is mandatory in all patients in whom the postoperative ileus persists beyond 24–48 hours after surgery. It is also indicated in acute abdominal conditions, e.g. intestinal obstruction, perforation, gastrointestinal bleeding, peritonitis, acute gastric dilatations, etc. Therapeutic nasogastric suction is best achieved by the use of the Salem sump suction tube rather than the cheaper but more popular single-lumen Ryle's tube. If a nasogastric tube is inserted, then continuous drainage with intermittent aspiration to establish continued patency is essential. There is never an indication to plug the tube, as this amounts to bad practice since, aside from causing patient discomfort, the tube is not contributing any possible benefit to the patient under these circumstances.

Peptic ulcer disease

Although there are differences in the clinical features between the two, it is customary to consider gastric and duodenal ulcers together as peptic ulcer disease.

Epidemiology

In the Western world, the incidence and prevalence of peptic ulcer disease and its complications increased from the beginning of the twentieth century to reach a peak in the period 1960–1970 and thereafter declined. During the same period, the incidence of peptic ulcer disease (especially duodenal ulcers) started to increase in other parts of the world, such as Kenya and South Africa, suggesting an increased exposure to environmental ulcerogens. Worldwide, duodenal ulcers are more common than gastric ulcers and there is a significantly higher incidence of duodenal ulcers in males of all age groups. In Africa and India, almost all ulcers are duodenal, and stenosis with obstruction is a frequent complication. In Europe, duodenal ulcers are two to four times as common as gastric ulcers but there are some regional variations, e.g. duodenal ulcers are twice as frequent in Scotland as in England. Duodenal ulceration is common in North America but gastric ulcer appears to be less common than in Europe. Although duodenal ulcers are prevalent in Australia, a relatively high incidence of gastric ulcers is encountered in younger females.

Aetiology

Aside from genetic factors (increased prevalence of duodenal ulcers in patients with blood group O who are non-secretors and in individuals with hyperpepsinogenaemia 1), dietary factors, drug ingestion (NSAIDs) and smoking are important. The last is associated both with an increased incidence of gastric and duodenal ulceration and with a higher relapse rate following successful healing. The most important cause is however infection with *H. pylori*, which is acquired in childhood. This pathogen is responsible for peptic ulceration (duodenal and gastric) though not all infected individuals develop ulcers. Duodenal ulcer, however, develops in all patients with antral predominant infection and who also have a large parietal cell mass, thus augmenting the hypersecretion of HCl. The risk of peptic ulceration is determined also by the severity of the gastritis. The vacuolizing toxin secreted by *H. pylori* is involved in the development of duodenal ulceration. Undoubtedly the infection by impairing the mucus–bicarbonate protective layer plays an important role in the chronicity of both duodenal and gastric ulcers and their tendency to relapse. The only permanent healing is achieved by eradication of the *H. pylori* infection. Strains of *H. pylori* with vacA signal sequence type S1A are associated with severe gastritis and duodenal ulcers, whereas vacA S2 strains cause a milder gastritis with little tendency to ulceration. There is also evidence that strains of *H. pylori* that produce cytotoxin and induce a neutrophil oxidative burst are associated with peptic ulcer disease.

Chemical ulcerogens include substances in food and drugs. Information on dietary ulcerogens is scanty apart from the association with excessive alcohol, smoking and coffee and Coca-Cola consumption in the West. Although chronic ingestion of hot spicy food is often incriminated, there is little epidemiological evidence to support this. By contrast there is some evidence on dietary protective factors, although the exact mechanism involved in not known. Dietary factors include high-fibre diets, increased consumption of essential fatty acids (-linolenic acid, which is a prostaglandin precursor) and fruit and green vegetables (particularly raw cabbage, Brussels sprouts and lentils).

The most important group of chemical ulcerogens is constituted by aspirin and other NSAIDs and steroids. They are the commonest cause of peptic ulceration in *H. pylori*-negative individuals. However, these drugs cannot be regarded as specific gastroduodenal ulcerogens since they also induce damage and ulceration of the small and large intestine. Other drugs that can cause both gastric and duodenal ulcers include cocaine and amphetamine (usually drug addicts). There are some important differences between ulcers caused by *H. pylori* and those caused by NSAIDs. These include:

- NSAID-associated ulcers are more likely to cause gastrointestinal haemorrhage; thus overall, 75% of patients with upper gastrointestinal bleeding from peptic ulcers are on NSAID medication
- gastric ulcers caused by *H. pylori* are rarely encountered on the greater curve (5%), being most commonly situated on the lesser curve (85%), whereas NSAID ulcers (in the absence of *H. pylori* infection) occur along the lesser and greater curvatures in 35% and 45% of patients, respectively.

H. pylori infection and NSAID usage is encountered in 20% of patients. Eradication of the infection does not appear to influence the healing and recurrence of peptic ulcers associated with chronic NSAID medication.

Role of acid and pepsin

The maxim 'no acid, no ulcer' is no longer tenable. Although 30–40% of duodenal ulcer patients exhibit acid hypersecretion and there are well-established syndromes of persistent gastric hypersecretion associated with intractable ulceration, the overlap between the acid secretory status of duodenal ulcer patients and controls is considerable and there are many normal individuals who hypersecrete acid (with large parietal cell mass) who do not develop ulcers in the absence of infection by *H. pylori*. Furthermore duodenal ulcers can develop in individuals with normal gastric acid output and almost all patients with gastric ulcers have normal or reduced acid secretion. Nonetheless, gastric acid is an important factor in the chronicity of the disease and acid suppression with antibiotic therapy is necessary for *H. pylori*-associated peptic ulcer disease.

The secretory characteristics of the usual duodenal ulcer patients (the norm) include an increased acid secretory capacity due to an enlarged parietal cell mass and enhanced maximal acid output in response to pentagastrin, increased gastrin response to food (protein) and insulin, increased sensitivity to gastrin and defective inhibition of acid secretion normally elicited by antral acidification, antral distension and intraduodenal fat. There is an increased concentration of pepsins in the gastric juice of patients with duodenal ulceration, especially pepsin I, which is the more mucolytic. The disruption of the mucus–bicarbonate layer by pepsin I exposes the underlying mucosa to injury by ulcerogens and impairs healing by removal of the protective mucous cap (blister effect).

Other factors

Enterogastric reflux of bile salts and lysolecithin with destruction of the mucus–bicarbonate layer and mucosal injury was first suggested by Capper as the cause of gastric ulceration. Although bile salts in particular can lead to back diffusion of acid following disruption of the mucous gel, this theory has never been conclusively proven. Similarly, antral stasis with delayed gastric emptying resulting in antral distension and increased gastrin release has been implicated in the development of pyloric channel and prepyloric ulcers. As a group, these gastric ulcers behave like duodenal ulcers and tend to be associated with hyperacidity as distinct from the more usual proximal gastric ulcers, which originate on a background of normal or hypoacidity and are accompanied by atrophic gastritis. Despite the extensive literature on the potential vascular cause of peptic ulcers as exemplified by instances of gastric ulceration after highly selective vagotomy and in association with mesenteric ischaemia, or experimental restriction of the blood supply to the stomach in animals, there has been no confirmation that focal vascular insufficiency is important in the pathogenesis of peptic ulcer disease.

Peptic ulcers occur at specific localized sites: antropyloric junction on the lesser curve, etc.; this has been interpreted as indicative of trauma resulting from the action of ulcerogens being specifically directed to these sites. Examples illustrative of this effect include the lesser curve location of gastric ulcers following reflux of duodenal contents and the occurrence of 'sump' ulcers following ingestion of ulcerogenic tablets which gravitate to the most dependent part of the stomach. The same mechanism has been proposed by Kirk for explaining the location of duodenal ulcers, i.e. the jets of gastric contents repeatedly hit the duodenal bulb in the same area causing focal ulceration.

Stress induces gastric hypersecretion and can lead to acute (stress) ulceration in patients. The stress may be purely psychological or result from major complicated disease (usually in intensive care patients) and after major burns (Curling's ulcer). Although psychological stress is usually an aggravating factor, it may be the primary cause in some patients. Rarely, duodenal ulcerations may be associated with other disorders, which include liver disease (particularly after shunt surgery for portal hypertension), persistent hypercalcaemia, renal failure and massive small bowel resection.

Clinical features

Chronic duodenal ulceration

This can occur at all age groups but the peak incidence is between 25 and 50 years. Whereas mortality caused by duodenal ulceration is low to negligible in this age range, the age-specific death rate (from complications of the disease) rises to 24 per

100 000 and 7 per 100 000 above 65 years in males and females respectively. This difference in mortality is due to the significantly higher incidence of duodenal ulceration in males with a male–female ratio of 2.0–4.0:1.0. Duodenal ulceration is a remitting disease characterized by periods of activity and quiescence. Exacerbations may be associated with periods of stress, dietary or alcoholic indiscretions and smoking. Early in the history of the disease, remissions may be associated with complete healing; but as the disease progresses, there is a tendency towards fibrous scarring so that evidence of past disease may be found on investigation even when the patient is free of symptoms. Typically, the epigastric pain is experienced during fasting or before meals (hunger pain) when the stomach is empty and there is nothing to buffer the acid secretion. Relief usually follows eating, ingestion of milk or alkali. Failure to produce relief, particularly if the pain radiates to the back, is suggestive of posterior ulcer penetration into the pancreas. The postprandial pain relief lasts for varying periods but usually averages several hours before it recurs and often occurs at night waking the patient up. Vomiting is not usually a feature of uncomplicated disease but may develop in severe exacerbation of an inflamed ulcer with surrounding gross oedema of the duodenal bulb or result from fibrosis causing organ outlet obstruction (pyloric/duodenal stenosis).

As the patients are constantly nibbling food to ward off painful indigestion, they are usually overweight. Other than this, the physical signs may amount to no more than diffuse epigastric tenderness, although this is sometimes well localized. Occult bleeding may produce iron-deficiency anaemia. The presence of a succussion splash indicates delayed gastric emptying.

Chronic gastric ulcer

Chronic ulceration of the stomach is less common than in the duodenum in most countries, the ratio of gastric to duodenal ulcers varying from 1:4 to 1:20. There are two quite distinct types of gastric ulcer: type I, which occurs in the body of the stomach along the lesser curve, and type II, which is referred to as the pyloric channel ulcer and includes prepyloric ulcers. The natural history, acid secretory profile and therapeutic response of type II ulcers are akin to those of duodenal ulceration. Type I chronic gastric ulcer may arise in a normal mucosa or on a mucosal background of atrophic gastritis. The disease is not associated with hyperacidity and, indeed, hypoacidity is frequently encountered, particularly in patients with atrophic gastritis. There is a male preponderance but this is not as marked as in duodenal ulceration and the peak incidence is encountered after middle age. The age-specific mortality from complicated gastric ulcer disease in patients above the age of 65 years is 57/100 000 and 41/100 000 in males and females respectively.

Gastric ulceration is most commonly encountered in late middle-aged and elderly patients. In Australia, an association with chronic ingestion of NSAIDs and the relatively high prevalence in younger females has been documented. The association with chronic ill health and lower socioeconomic class is not as obvious nowadays as it was in the past. The main clinical feature is pain, or, perhaps more commonly, a feeling of acute discomfort and fullness in the epigastrium. Unlike duodenal ulcer, the pain of gastric ulceration is not experienced during fasting when the stomach is empty. Indeed, the converse is true, as eating produces or exacerbates the pain. For this reason, patients suffering from the disease are afraid of eating and because of the reduced dietary intake they are usually underweight. It is important to stress that this symptom complex of indigestion immediately after meals and weight loss is indistinguishable from that produced by gastric cancer, and clinically it is impossible to differentiate between the two disorders unless the cancer is advanced and incurable. Nausea and vomiting are more common symptoms than in duodenal ulcers, even in the absence of outlet obstruction. Although periodicity with remissions and relapses is encountered, this is not as obvious as in duodenal ulceration.

Aside from weight loss, physical examination is not usually rewarding, with epigastric tenderness being the only fairly constant finding. Gastric ulcers may obstruct, perforate or bleed. Occasionally, a large inflammatory mass around an ulcer may be palpable, particularly if the patient has lost weight, but for all practical purposes, a palpable epigastric mass in a patient with this dyspeptic background should always indicate the probability of gastric cancer being the cause of the patient's symptoms.

Investigations

In most centres, upper gastrointestinal endoscopy has replaced double contrast barium meals because of the greater diagnostic accuracy. In patients with duodenal ulcer, the findings vary from a definite crater in the first part of the duodenum to severe duodenitis. Endoscopic biopsy of the antrum is necessary in all cases for establishing the *H. pylori* status, but the ulcer itself should not be biopsied as it is always benign and the biopsy may precipitate bleeding. Although double contrast barium meal carries a high diagnostic yield for gastric ulcer, and, if performed expertly, will differentiate benign gastric ulcer disease from early ulcerating cancer, endoscopy and multiple biopsies with brush cytology are mandatory in all patients with gastric ulceration. The *H. pylori* status is best determined on the endoscopic biopsies (histology). Furthermore, the endoscopy should be repeated after 2–3 months and if ulcer healing is not documented further biopsies are taken and surgical treatment is indicated even if the second biopsies are reported as benign.

Medical treatment of peptic ulcer disease

Modern evidence-based treatment of peptic ulcer disease is based on the aetiology of the disease in the individual patient in accordance with the following categories:

- *H. pylori*-positive duodenal or gastric ulcers
- *H. pylori*-negative duodenal or gastric ulcers
- ulcers caused by NSAID medication which may be *H. pylori* positive or negative.

Hence, the importance of testing for *H. pylori* infection in all patients. The National Institute for Health and Clinical Excellence (NICE), Guideline no. 17 (www.nice.org.uk/CG017) recommends use of the ^{13}C-urea breath test or a stool antigen test over serological tests, which have lower sensitivity and specificity (92% and 83%, respectively) than either breath testing (sensitivity 95%, specificity 96%) or the stool antigen test (sensitivity 95%, specificity 94%). The lower predictive value of serological tests (64% vs 88% for the ^{13}C-urea breath test and 84% for the stool antigen test) indicates an increased probability of false positives with serological testing such that a number of patients would be treated unnecessarily with antibiotics for eradication of the infection. The recommendation from NICE is that retesting after eradication treatment to confirm clearance of the infection should currently be performed by the ^{13}C-urea breath test as currently there is insufficient evidence to recommend the stool antigen test as a test of eradication.

Eradication therapy *for Helicobacter pylori*

All patients who test positive should receive a 7 day twice-daily course of eradication treatment consisting of a full-dose PPI, with either metronidazole (400 mg) + clarithromycin (250 mg) or amoxicillin (1 g) + clarithromycin (500 mg). This regimen is effective in 80–85% of patients. Other regimens such as PAC500 (PPI, amoxicillin, clarithromycin 500 mg) and PMC250 (PPI, metronidazole, clarithromycin 250 mg) achieve the same eradication rate.

However, PMC250 when used as a first-line therapy may induce resistance to both clarithromycin and metronidazole. Although 14 day courses have been reported to increase the eradication rate by 10% (to 95%) they do not appear to be cost effective according to NICE. In patients who require a second course of eradication therapy the antibiotic combination with the full dose PPI should not include any of the antibiotics used in the initial eradication attempt.

In patients using NSAIDs with peptic ulcer, *H. pylori* eradication does not increase healing compared with acid suppression therapy in patients using NSAIDs with a peptic ulcer. However, in patients on chronic NSAID medication without peptic ulcer disease, *H. pylori* eradication reduces the risk of a first occurrence of peptic ulcer. Furthermore in patients on NSAIDs with a history of previous peptic ulcer, *H. pylori* eradication reduces the risk of recurrence.

There is a core of peptic ulcer patients (10–15%) who are resistant to the normal eradication regimens (usually with infections by cagA strains). In these patients an alternative regime is used: PPI with triple therapy with tripotassium citratobismuthate (De-Nol tab) 120 mg q.d.s., metronidazole 400 mg t.d.s. and tetracycline 500 mg t.d.s. for 2 weeks.

Duodenal ulcer

Aside from general dietary measures, such as abstinence from alcohol, cessation of smoking and avoidance of hot spicy food, excessive coffee drinking and chocolate, management is based on PPI therapy, testing for *H. pylori* and cessation of NSAIDs. Whenever possible, NSAIDs should be stopped. Otherwise, they are changed to a cyclo-oxygenase (Cox)-2 inhibitor or paracetamol or low-dose ibuprofen. Initial treatment is with a full-dose PPI for 2 months followed immediately by a 1 week course of eradication therapy in *H. pylori*-positive patients. The PPI therapy induces healing of the duodenal ulcer in 70%, and although this is only increased by a further 5% by eradication, this dramatically reduces the ulcer recurrence rate. Thus studies have shown that at 3–12 months only 39% of patients treated with PPI alone are ulcer free, but this is increased by a further 52% by successful eradication of the infection.

Frequent relapses or failure to control the disease by on demand PPI therapy in *H. pylori*-negative patients should raise the possibility of rare causes of duodenal ulcers: gastrinoma, Crohn disease, etc.

Gastric ulcer

The medical management of gastric ulcer is similar. If the patient is on NSAIDs these should be stopped if possible or substituted as previously outlined. A full-dose PPI course is administered for 2 months and is followed by eradication treatment in *H. pylori*-positive patients. All patients with gastric ulcer require an endoscopy and retesting for *H. pylori* 6–8 weeks after the start of treatment. The main reason for the endoscopy is to establish healing or otherwise of the ulcer. If this has healed and the patient is *H. pylori* negative, low-dose maintenance treatment is individualized (low-dose PPI continuous or on demand). Patients who remain *H. pylori* positive after eradication need an endoscopy with biopsy. In patients in whom eradication is successful but the ulcer has not healed, PPI in high doses is continued for a further 4 weeks and then the patient is re-endoscoped. If the ulcer has not healed by then, it should be considered as malignant, biopsied and referred for surgical opinion.

It should be noted that *H. pylori* eradication therapy does not increase gastric ulcer healing in *H. pylori*-positive patients, when compared with acid suppression alone, but it reduces gastric ulcer recurrence. Thus studies have shown that, after 3–12 months, 45% of patients receiving acid suppression therapy alone are ulcer free. Eradication increases this by a further 32%.

Indications for surgical treatment of peptic ulcer disease

Elective surgery for duodenal ulcer disease has declined substantially during the past 30 years and is now largely restricted to the treatment of complicated or, even more rarely, uncomplicated disease that proves resistant to medical treatment (intractable disease). In this respect, the situation is changing in Western countries with the marked decline in the prevalence of *H. pylori* infection in the general population to around 8–10%. Furthermore, failure of eradication of *H. pylori* is an increasing problem and reliance on long-term acid suppression with PPIs has its problems and is costly. Laparoscopic elective peptic ulcer surgery offers a cost-effective alternative to long-term medication and is increasingly preferred to open surgery for both complicated and intractable duodenal ulcer disease.

Operations for duodenal ulcer

The aim of all operations for uncomplicated duodenal ulceration is to reduce acid secretion to such levels that the ulcer will heal permanently. In the majority of patients, the surgeon is faced with the choice of either gastric resection (to reduce the size of the parietal cell mass and remove the antrum and thus gastrin release) or vagal denervation of the stomach (to abolish the cephalic phase of secretion and reduce the sensitivity of the parietal cell mass to secretory stimuli), or a combination of the two. Although the purpose of the operation is to achieve permanent cure of the ulcer diathesis, this should not be the only consideration, as other factors are important in the decision-making process regarding the selection of the correct operation in the individual patient: operative morbidity and mortality, and the incidence of side effects need to be weighed carefully against success rate in terms of healing and ulcer recurrence rates.

The relative advantages and disadvantages of gastrectomy, vagotomy and drainage and highly selective vagotomy are summarized in Figure 23.15. Subtotal gastrectomy with gastrojejunal anastomosis is an excellent antiulcer operation, but its merits are seriously marred by the increased morbidity/mortality as well as the high incidence of troublesome side effects and nutritional sequelae. The initial hope that the operation of truncal vagotomy and drainage would avoid the alimentary sequelae and maintain good nutrition did not materialize and some surgeons are dissatisfied with this procedure. Truncal vagotomy and antrectomy possesses the advantage of a dual attack on the acid secretory mechanisms and, as a result, carries the lowest recurrent ulcer risk. Unfortunately, it incurs the disadvantages of both resection and vagotomy. Truncal vagotomy and antrectomy is probably the operation of choice for intractable and resistant ulcers including pyloric channel and prepyloric ulcers, as these are attended by high ulcer recurrence rates.

Vagotomy procedures

The alternatives to truncal vagotomy and drainage (by gastrojejunostomy or pyloroplasty) are bilateral selective vagotomy with drainage, highly selective vagotomy (parietal cell, proximal gastric, selective proximal gastric vagotomy), posterior truncal vagotomy and anterior seromyotomy (Taylor procedure), and posterior truncal vagotomy and anterior highly selective vagotomy (Hill procedure).

Bilateral selective vagotomy confines the denervation to the stomach and preserves the vagal branches to the liver (hepatic plexus). The operation requires additional gastric drainage as the antrum is denervated. Gastric stasis and ulceration have been documented in patients in whom drainage had been omitted. Although bilateral selective vagotomy does reduce the incidence of diarrhoea and achieves adequate gastric denervation, the overall clinical results obtained by this operation have been no better than those of truncal vagotomy with drainage, and, for this reason, the operation has been largely abandoned.

Undoubtedly highly selective vagotomy (HSV) is the most physiological procedure since it denervates the parietal cell mass but leaves the antral mill (antropyloric segment) innervated and therefore obviates the need for a drainage procedure. Herein lies the distinct advantage of this operation as the avoidance of drainage leads to virtual abolition of the alimentary side effects, although diarrhoea can still occur, albeit extremely rarely. The drawback of HSV is the higher incidence of recurrent ulceration documented by some long-term reports (20–30%). These reports have, however, included cases for which HSV is nowadays considered unsuitable. Thus HSV should not be performed in patients with pyloric channel ulcers (including prepyloric), in patients with stenosis (previously these were managed with HSV and pyloric dilatation) and in patients with bleeding ulcers. HSV is easily performed by the laparoscopic approach.

Alternatives to HSV include the Taylor procedure (posterior truncal vagotomy and anterior seromyotomy) and the Hill procedure (posterior truncal vagotomy and anterior highly selective vagotomy). Several reports and one clinical trial have demonstrated that the Taylor procedure gives equivalent results to the classical HSV in the short term but there are no long-term reported series. There have been no large series or clinical trials with the Hill procedure, although on *a priori* grounds it should achieve equivalent results. Both the Taylor and the Hill operations can easily be performed laparoscopically and there are several such reports on the laparoscopic Taylor operation.

Drainage procedure

Truncal vagotomy and bilateral selective vagotomy necessitate a drainage procedure. This can be achieved by either a

	Subtotal gastrectomy	Vagotomy and drainage	Highly selective vagotomy
Mortality	2%	1%	0.5%
Recurrence rate	2–3%	5–8%	5–30%
Side effects	+++	++	±

Figure 23.15 The relative advantages and disadvantages of the various procedures used for chronic duodenal ulceration. The mortality and ulcer recurrence data are average values only. Choice of the 'best operation' for the individual patient involves a careful balance of these three factors.

gastrojejunostomy (anterior or posterior) or a pyloroplasty (Heineke–Mikulicz or Finney). Most surgeons would prefer the posterior short loop to the anterior (longer) gastrojejunostomy although there are no comparative trials. With Heineke–Mikulicz pyloroplasty, the pylorus is incised longitudinally and then sutured transversely, whereas the Finney procedure consists of an anastomosis between the duodenum and the antrum through an inverted U-shaped incision. There is not much to choose between these two in the absence of duodenal scarring, in which case the Finney pyloroplasty is preferable.

Controlled clinical studies comparing gastrojejunostomy vs pyloroplasty have not indicated any obvious superiority between these two forms of drainage, but there are some important practical considerations. Bile vomiting is slightly commoner after gastrojejunostomy but this is offset by a slightly higher incidence of dumping after pyloroplasty. Gastrojejunostomy is a safer option when the ulcer area is the seat of an inflammatory mass or when there is significant fibrous scarring. If a patient develops bile vomiting or dumping after vagotomy and drainage, it is easy to close the gastrojejunostomy. In contrast, reconstruction of the pylorus is more technically demanding and the results of remedial surgery less certain.

Operations for gastric ulcer

The objectives of gastric ulcer surgery are the removal of the ulcer, thus dealing with the problem of possible malignancy, and the prevention of further recurrence. Ideally, therefore, the ulcer should be removed as part of the gastrectomy specimen, but as an alternative local excision of the ulcer is combined with vagotomy. The standard treatment is the Billroth I gastrectomy. This resection includes the ulcer, the lesser curve and the antrum. Restoration of continuity by gastroduodenal anastomosis is seldom a problem as the duodenum is normal. Both the mortality and the ulcer recurrence rate following this operation are low (2%) and it is currently the gold standard procedure for the surgical treatment of gastric ulcer disease. Postoperative alimentary side effects can follow this operation but their frequency and severity are less than those encountered after Pólya gastrectomy or truncal vagotomy with drainage. Likewise, long-term nutritional problems are not usually marked or frequent after Billroth I gastrectomy.

The Pólya gastrectomy (also sometimes referred to as Billroth II) is less popular nowadays because of the associated higher incidence of postgastric surgery syndromes. The resection is more extensive and includes the first part of the duodenum with closure of the duodenal stump and an end-to-side gastrojejunostomy. This operation was popular in the past particularly for the emergency treatment of a bleeding pyloric channel and duodenal ulcers.

Nowadays, the main alternative to Billroth I gastrectomy in the treatment of gastric ulcer is vagotomy and drainage. This carries a lower operative mortality (1%). If this operation is preferred, it should be combined with local excision of the ulcer whenever possible. A full thickness biopsy is mandatory if ulcer excision is not possible because of its location. The recurrence rate after truncal vagotomy and drainage with excision of the gastric ulcer is high and averages 10–20% in the long term. Furthermore, the symptomatic results, in terms of alimentary problems, are no better than those after Billroth I gastrectomy, though better than after Pólya gastrectomy. There is therefore little justification in using this operation as the routine surgical treatment for uncomplicated type I gastric ulcer. It is, however, indicated in the poor-risk elderly patient. The reported experience of HSV with ulcer excision is limited but the results appear to approximate those achieved by truncal vagotomy and drainage, although one report documented an unacceptably high ulcer recurrence rate.

A special problem is posed by the high lesser curve ulcer situated at the cardio-oesophageal junction. The options here include a resection distal to the ulcer, leaving it *in situ* (Kelling–Madlener procedure) or, preferably, to excise all the lesser curve using the Pauchet type of gastrectomy where the new lesser curve is reconstituted without the use of clamps. Unfortunately, very high lesser curve ulcers are often encountered in elderly patients where the questions of malignancy and operative mortality are especially pertinent. Proximal or total gastrectomy is inadvisable in these patients and, whenever possible, medical therapy should be persisted with. An HSV with local excision of the ulcer merits consideration in elderly patients who prove refractory to medical treatment.

Some 30% of patients with lesser curve ulceration are said to have evidence of past or present duodenal ulceration. Such ulcers have been designated as type III. It is usually assumed that the duodenal ulcer precedes the gastric, but the precise relationship is not always clear. In theory, both delayed gastric emptying from pyloric stenosis or bile reflux through an incompetent diseased duodenal bulb could be responsible for the gastric ulcer.

Gastric ulcers coexisting with duodenal ulcer disease tend to be located fairly distally in the stomach, usually at or beyond the incisura. Levels of gastric acid secretion are normal or high but below levels found in patients with duodenal ulcer disease alone. Surgical treatment of combined ulcer disease is by the operation normally favoured by the surgeon for duodenal ulcer. The risk of gastric ulcer being malignant when it is associated with duodenal ulcer is small but, nonetheless, present. In one large series, gastric carcinoma was present in 8% of patients with gastric ulcer alone and 1.2% of patients with coexisting duodenal ulceration. All forms of gastric ulcer must be biopsied.

Laparoscopic elective ulcer surgery

All elective operations for peptic ulcer disease can and are being carried out laparoscopically with good results in terms of immediate outcome although there are no published long-term studies and thus data on completeness of vagotomy and ulcer recurrence rates compared with the conventional open approach are not available. What is established from the retrospective published series is that the immediate clinical outcome is the same in terms of ulcer healing and that the laparoscopic approach is attended by a low incidence of wound-related complications, reduced postoperative pain and period of ileus, resulting in a shorter hospital stay and accelerated recovery to full activity or work. Thus the laparoscopic approach seems ideal for the treatment of failures of medical therapy for both duodenal ulcer (usually HSV) and gastric ulcer (Billroth I gastrectomy). The laparoscopic approach is equally appropriate for the emergency treatment of complicated peptic ulcer disease, especially perforation. Indeed judging by the increasing number of published series and randomized clinical trials, laparoscopic treatment of perforated peptic ulcer disease is likely to replace the open approach as, aside from the general benefits of the minimal access approach, it is accompanied by a lower incidence of surgical site infections and wound-related complications.

Failures of gastric surgery

Unsatisfactory results follow ulcer surgery in 10–20% of patients. The reported incidence varies considerably and no doubt depends to some extent on the thoroughness and length of follow-up. Poor results may be due to recurrent ulceration, alimentary side effects leading to various postgastric surgery syndromes or adverse nutritional consequences. Thus the failures of gastrectomy are largely nutritional or due to postcibal or alimentary sequelae, and rarely caused by recurrent ulceration; with the opposite being the case after HSV. The poor results of truncal vagotomy with drainage may be due either to recurrent ulceration or to functional postcibal side effects.

Recurrent ulcer

Recurrence of type I gastric ulcer after an appropriate gastrectomy is rare, so the problem concerns mainly duodenal and pyloric channel ulcers (type II). Recurrent ulceration may appear in the stomach, the duodenum, or at the site of the gastrointestinal stoma (anastomotic ulcer). The overall rate depends on the procedure performed, the ulcer type and personal habits of the patient, e.g. smoking, alcohol, etc. Thus the highest recurrent ulcer rates are reported after HSV and the lowest after truncal vagotomy and antrectomy. Prepyloric ulcers exhibit a higher recurrence rate than duodenal ulcers. A Swedish study has demonstrated that continued smoking is an important factor and resulted in a recurrence rate of 24% as opposed to 7% in non-smokers after HSV. Several studies over the years have confirmed that the two most important factors are incomplete vagotomy (denervation of the parietal cell mass) and inadequate drainage (gastric hold-up) and these probably account for 80% of recurrences. It should be stressed, however, that these data on recurrent ulceration after surgical treatment predate the *H. pylori* era, and that it seems highly likely that many of these patients with recurrent ulcers harboured this infection. Thus the true recurrence after surgical treatment in *H. pylori*-negative patients is not known.

Table 23.3 Laboratory findings associated with recurrent ulcer after surgery

Test	Result
Helicobacter pylori breath test	Positive
Basal acid output	>4 mmol/h
Postoperative % reduction of basal acid output	<70%
Maximal acid output	>25 mmol/h
Insulin test	Positive
Sham feeding test	Positive
Basal serum group I pepsinogen	>100 ng/mL
Betazole-stimulated group I pepsinogen	>100% of basal

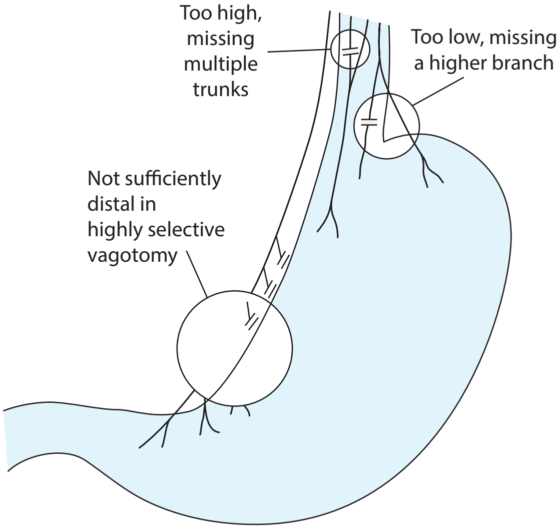
The laboratory tests needed in the assessment of patients with recurrent ulcer are shown in Table 23.3. In patients with recurrent ulcer after vagotomy with drainage or antrectomy, the basal serum pepsinogen I (PG I) levels are significantly higher than in patients without recurrence.

Furthermore, following injection of betazole, patients with recurrent ulcer exhibit a rise in the serum PG I level whereas those without (or with a complete vagotomy) demonstrate a paradoxical decrease in the serum level of PG I. Rare causes of recurrent ulceration include inadequate gastric resection, retained antrum, Zollinger–Ellison syndrome and hypercalcaemia.

Inadequate vagotomy

Failure to achieve complete denervation of the parietal cell mass is the commonest cause of recurrent ulceration. The incidence of incomplete vagotomy may be as high as 20% after truncal vagotomy, as judged by the results of the early postoperative insulin test. It is true that some of these positive results are only technically positive and may be the result of very small residual fibres, but some are due to a missed major vagal trunk, in which case recurrence is inevitable. Preoperative tests have been described which are reputed to improve visualization of the nerve fibres (leucomethylene blue) or permit a check on the completeness of the vagotomy by observing a failure of peristalsis or absence of acid secretion after electrical stimulation or after pentagastrin or histamine infusion (as shown by an intragastric dye such as Congo red or pH probe). In practice, these tests have not become established in routine practice. The most important prerequisites for successful (complete) vagotomy are an appreciation of the variable anatomy of the vagi, patience and meticulous technique.

Truncal vagotomy can be carried out at two levels: the hiatus or above (as advocated by Dragstedt), or at the cardia. At either level, it is possible to miss vagal fibres (Figure 23.16), although there is less likelihood to overlook a significant trunk if the vagotomy is carried now down on the oesophagus. The solution to the problem is to divide the anterior and posterior trunks at the hiatus initially. This will enable the oesophagus to be pulled down and the region of the cardia then becomes more accessible. The lower



Too high, missing multiple trunks
Too low, missing a higher branch
Not sufficiently distal in highly selective vagotomy

Figure 23.16 Causes of incomplete vagotomy.

abdominal oesophagus is then cleared methodically all the way round of all nerve fibres. With this length of abdominal oesophagus cleared, it is quite easy to inspect the region of the fundus and thus ensure against missing nerve fibres (of Grassi) to this region.

If complete denervation of the parietal cell mass is to be achieved, three aspects of the technique need special attention. Clearance of at least 5 cm of the lower abdominal oesophagus is mandatory. In addition, the denervation of the lesser curve must be extended distally enough – at least 2.5 cm from the oesophagogastric junction. In HSV, this means leaving only one recognizable anterior antral branch of the nerve of Latarget. Finally, the innervation of the fundus by the nerves of Grassi must be disrupted.

Antral stasis

This arises when there is duodenal fibrosis. Previously these cases were treated by pyloric dilatation during the HSV. Undoubtedly this has been one of the factors involved in ulcer recurrence after this procedure. Nowadays, it is recognized that these patients require a pyloroplasty. The nature of the vagotomy (HSV or truncal) then becomes a matter of individual choice. Another unsatisfactory practice is the performance of bilateral truncal vagotomy with pyloric stretch instead of drainage. The ulcer recurrence (usually pyloric channel) in these patients with time is unacceptably high.

Rare causes of ulcer recurrence

These include inadequate gastric resection, retained gastric antrum, the Zollinger–Ellison syndrome and hypercalcaemia (Figure 23.17).

Inadequate gastric resection

If gastrectomy is the procedure used for reducing acid secretion, a 75% resection is needed. A related consideration is the method of restoring continuity after resection. In terms of ulcer recurrence, it is generally believed that a gastrojejunal anastomosis (Billroth II, Pólya) is better than gastroduodenostomy, although it is difficult to substantiate this claim from the published literature. The difference in ulcer recurrence rates may be related to the extent of gastric resection since more stomach is likely to be retained in Billroth I operations to achieve a gastroduodenal anastomosis without tension.

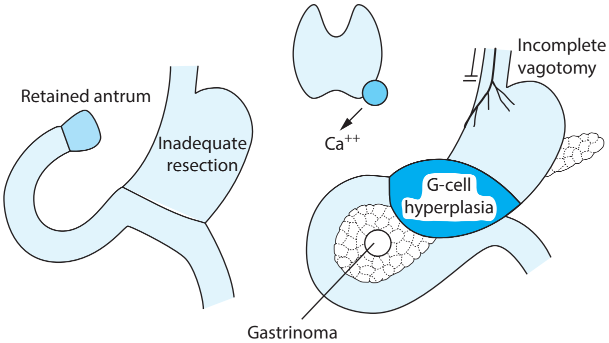


Figure 23.17 Rare causes of recurrent ulceration after surgical treatment of peptic ulcers.

Retained gastric antrum

If antral tissue (after gastric resection) is left in continuity with the duodenal stump, the antral G-cells now in a permanent alkaline environment will secrete gastrin continuously. Under this constant stimulus, the residual parietal cells will produce sufficient acid for stomal ulceration to develop. Whenever hypergastrinaemia is found after partial gastrectomy, the retained antrum syndrome must be considered. Differentiation of this condition from autonomous tumour production of gastrin is usually possible from the results of the secretin and calcium tests, but direct confirmation of retained antral tissue may be more difficult. Radioisotope scanning with pertechnetate may help. Treatment entails excision of the retained antral tissue.

Zollinger–Ellison syndrome (gastrinomas)

This was first described in 1955 in a classical surgical paper by Zollinger and Ellison before the isolation of gastrin by Gregory and Tracey in a 36 year old female patient with severe recurrent ulcer disease and multiple pancreatic tumours who was cured of her ulcer diathesis by a pancreaticoduodenectomy. It is now established that Zollinger–Ellison syndrome is a clinical syndrome with severe peptic ulcer disease often associated with erosive oesophagitis and sometimes diarrhoea caused by gastric acid hypersecretion secondary to a neuroendocrine tumour (NET) that secretes excessive amounts of gastrin. Zollinger–Ellison syndrome is now recognized to consist of two types – sporadic and hereditary–and is the presenting feature of *multiple endocrine neoplasia type 1* (MEN-1, Werner syndrome), which is described in Chapter 27. The definition of Zollinger–Ellison syndrome outlined above is important as some NETs although expressing gastrin are not functionally active. The term gastrinoma is nowadays reserved to a tumour secreting gastrin autonomously and thus causing the Zollinger–Ellison

BOX 23.3 Relative features of sporadic and hereditary Zollinger–Ellison syndrome

- Sporadic cases account for up to 75% of cases
- Clinical features of the two types are identical
- Zollinger–Ellison syndrome is the presenting feature in 40–60% of MEN-1
- Over 90% of tumours in Zollinger–Ellison syndrome with MEN-1 are located in all parts of the duodenum with highest incidence in first part, and often multiple and small (<10 cm) and thus difficult to detect
- In sporadic Zollinger–Ellison syndrome , the gastrinomas may be located in either the duodenum or pancreas - the latter are usually solitary and bigger, with the majority located in the head
- The prognosis of sporadic and MEN-1-associated duodenal gastrinomas is better than that of pancreatic gastrinomas, as the duodenal tumours progress slowly to liver metastasis

syndrome. The relative features of the sporadic and hereditary Zollinger–Ellison syndrome have been reported in detail and are summarized in Box 23.3.

In one of the largest registries of sporadic NETs of the pancreas (535) collected from the archives of the departments of pathology in Zurich, Switzerland, and Kiel, Germany, 24 patients (4.5%) suffered from sporadic pancreatic gastrinomas and Zollinger–Ellison syndrome. An additional 19 patients suffered from MEN-1 and Zollinger–Ellison syndrome. The latter group of patients showed exclusively duodenal gastrinomas, with no pancreatic tumours. The incidence of sporadic duodenal gastrin-producing tumours appears to be increasing, but this is likely to be due to improved diagnosis. In sharp contrast, pancreatic MEN-1-associated gastrinomas are very rare if one excludes the large subset of tumours with immunohistochemical expression of gastrin but without evidence of Zollinger–Ellison syndrome. These are now designated as *functionally inactive NETs expressing gastrin*, rather than gastrinomas. Sporadic gastrinomas account for 70% of gastrinomas and are malignant but usually of low grade in 40–85%. They occur in a region described as the *gastrinoma triangle* – the confluence of the cystic with the common bile duct superiorly, the second and third portions of the duodenum inferiorly, and the neck and body of the pancreas medially. Duodenal sporadic gastrinomas arise in the submucosa and may be multiple whereas sporadic pancreatic gastrinomas tend to be solitary. Although metastasis to lymph nodes occurs early, hepatic metastases occur late and only in 10% of patients. Primary gastrinomas may very rarely occur in other sites: body of the stomach, jejunum, peripancreatic lymph nodes, splenic hilum, root of the mesentery, omentum, liver, gallbladder, common bile duct, and the ovary. Primary lymph node gastrinomas (disputed by some and considered as deposits from a small undetectable primary duodenal gastrinoma) are said to be due to entrapment of neuroendocrine cells during development. Whatever the truth between these opposing views, apparently nodal disease without an obvious other tumour is encountered in 5–10% of sporadic Zollinger–Ellison syndrome.

Signs and symptoms of the sporadic and hereditary Zollinger–Ellison syndrome do not differ. The hypergastrinaemia by inducing continuous gastric acid hypersecretion leads to mucosal ulcerations in the oesophagus, stomach, duodenum and even jejunum. Some 20% of patients exhibit secretory diarrhoea alone or in combination with upper gastrointestinal ulceration. Abdominal pain is a frequent symptom (>75% of the patients). The important differences from the usual peptic ulcer disease include multiple ulcers, ulcers in atypical locations, persistence and/or difficult control of symptoms despite adequate antacid therapy and diarrhoea. All these unusual features should suggest the possibility of Zollinger–Ellison syndrome and the need for appropriate testing. Despite this, the mean interval from first symptoms to definite diagnosis is usually long, up to 4 or more years. This may be attributed to late presentation in some patients either with a mild form of peptic ulcer disease or with secretory diarrhoea.

The diagnosis is confirmed by serum gastrin assay, and a gastrin concentration >1000 pg/mL is diagnostic. However, the levels are lower in some 60% of patients and the issue is compounded by the high prevalence of patients on chronic PPI medication causing hypergastrinaemia. In these borderline cases, the secretin test is indicated. It is considered positive (diagnostic) if it increases the serum gastrin by more than 200 pg/mL. It is recommended that the PPI should be stopped for 1 week before a secretin test is performed, but as this may put the patient at risk from complications close observation is essential during this period.

Once the diagnosis is established the patient is immediately put on a high-dose PPI, which is nearly always effective. One large review of 80 patients confirmed that high-dose omeprazole (varying from 60 to 120 mg) daily provided satisfactory control in 90% of patients. The important practical issue is that the dose of PPI has to be individualized as the response to PPIs varies from patient to patient. Localization of the gastrinoma and imaging tests to stage the disease (MDCT, MRI, PET-CT) are used mainly to detect nodal involvement and hepatic metastases. Somatostatin receptor scintigraphy (SRS) with ^{111}In-labelled octreotide is used for the detection of gastrinomas as most of these tumours overexpress the somatostatin receptor subtype 2. Published reports show a high yield of SRS in the localization and staging of gastrinomas (80%), and SRS is regarded as being superior to other non-invasive imaging tests and contributes to patient management. The problem relates to its sensitivity, as this depends on the size and exact localization of the tumours. Thus small pancreatic lesions and lesions located in the duodenum may be missed.

The real controversy lies in the definitive treatment of Zollinger–Ellison syndrome and, in particular, the role of surgical treatment of the disease. There is little doubt that long-term PPI therapy is highly effective and safe especially as the disease, even when malignant, is compatible with long-term survival, and indeed the most important prognostic factor in the individual patient is the biological aggressiveness of the NET. Certainly, patients with gastrinoma associated with type 1 (MEN-1) are seldom if ever cured by non-Whipple operations, i.e. by removal (enucleation) of duodenal and pancreatic gastrinomas. Most surgical experts consider that surgery should be used in these patients to deal with malignant pancreatic or duodenal tumours, the malignant potential being indicated by the size of the tumour. According to this policy, tumours greater than 2 cm in size warrant excision. Cure rates as high as 50% have been reported after local excision of malignant gastrinomas. In this respect, wide duodenotomy is essential for improved tumour detection cure rates. In experienced hands, and in the absence of hepatic deposits, Whipple pancreaticoduodenectomy results in the highest probability of cure in both sporadic and hereditary type MEN-1 gastrinoma patients as it removes the entire gastrinoma triangle. However, this has to be balanced against the excellent long-term survival of these patients with lesser operations, especially in view of the increased operative mortality and long-term morbidity of the Whipple procedure. There is no indication for total gastrectomy nowadays as inoperable disease is controlled by various forms of drug therapy in addition to PPIs.

In one-third of the patients the tumour has already metastasized to the liver by the time of diagnosis. The palliative treatment options in these patients include chemotherapy, peptide radioreceptor therapy (PRRT) and biotherapy with somatostatin analogues and is indicated if there is evidence of disease progression. PRRT is based on the established fact that well-differentiated NETs overexpress somatostatin receptors which are targeted by this form of radionuclide therapy. There is emerging evidence that PRRT may be especially effective in gastrinomas and cases when sufficient downstaging by PRRT enabled subsequent resection are documented. Usually, however, this treatment is considered palliative and several reports have documented partial response or disease stabilization. Biotherapy with somatostatin analogues is also used in progressive symptomatic inoperable well-differentiated disease (G2), usually before recourse to chemotherapy with streptozotocin plus doxorubicin/5-fluorouracil (5FU). In poorly differentiated gastrinomas (G3) chemotherapy is usually with etoposide and cisplatin. Future therapeutic strategies are predicted to include angiogenesis inhibitors and kinase inhibitors targeting tumour-specific signalling cascades.

Antral G-cell hyperplasia (pseudo-Zollinger–Ellison syndrome or Zollinger–Ellison syndrome type 1)

This condition is referred to as Zollinger–Ellison syndrome type 1 to distinguish it from the classical Zollinger–Ellison syndrome associated with a gastrinoma and referred to as Zollinger–Ellison syndrome type 2 in this context. It is a very rare condition where the hypergastrinaemia results from an increased number of antral gastrin-secreting cells or from an exaggerated response to feeding (postprandial hypergastrinaemia without hyperplasia). The syndrome is therefore better referred to as antral G-cell hyperactivity or hyperfunction. The recommended treatment is antrectomy. Some doubt the existence of this syndrome and cite the absence of reported cases in recent years as evidence. The controversy is compounded further by the undoubted existence of rare cases of recurrent and intractable peptic ulceration in association with a pancreatic endocrine tumour that does not secrete gastrin although the nature of the factor has yet to be identified.

Hypercalcaemia

Primary hyperparathyroidism can, on rare occasions, cause peptic ulceration in the absence of a gastrinoma. These patients do not usually have hypergastrinaemia. In addition, hyperparathyroidism is, of course, part of the MEN-1 syndrome associated with Zollinger–Ellison syndrome, in which case the serum gastrin will be abnormally high. In practice, if hypercalcaemia is found in a patient with peptic ulcer, recurrent or otherwise, both parathormone and gastrin levels should be assayed. If primary hyperparathyroidism only is established by this testing and corrected surgically, the ulcer should heal. There is some evidence that this is more likely to occur if the patient has a parathyroid adenoma than hyperplasia. If MEN-1 Zollinger–Ellison syndrome is established treatment is that of gastrinoma takes precedence.

Management of patients with recurrent dyspepsia

The persistence of indigestion, or its return after a period of freedom from symptoms, suggests the possibility of recurrent ulceration. Other possibilities should not, however, be overlooked. These include unrelated pathology such as gastro-oesophageal reflux disease, gallstones and pancreatitis. On other occasions, the dyspepsia is caused by complications of ulcer surgery, e.g. enterogastric reflux or gastric stasis. It is not always easy to diagnose recurrent ulceration on clinical grounds alone. Sometimes, the character of the pain is similar to that experienced by the patient before operation, but on other occasions it is different in type, site or both. If vomiting is a feature, the presence of bile or food may suggest gastritis or stasis as the underlying cause of the patient's symptoms. Recurrent ulcers may present with bleeding or, less commonly, perforation with no accompanying dyspepsia. The rapid return of symptoms, haemorrhage or perforation, particularly in the younger patient should suggest the possibility of Zollinger–Ellison syndrome. Coexisting diarrhoea may be indicative of this condition or a gastrojejunocolic fistula, although simple postvagotomy diarrhoea is much more common than either of these two conditions. Gastrojejunocolic fistula is an extremely rare complication of benign ulcer disease nowadays and the vast majority of cases are neoplastic in origin.

Following gastric surgery, radiological contrast studies of the stomach and duodenum though occasionally useful are often not, and are difficult to interpret. Scarring of the duodenum will persist even if the ulcer has healed and the presence of a pyloroplasty makes radiological identification of a recurrent ulcer in this region virtually impossible. Endoscopy with assessment of the *H. pylori* status is the best method for the investigation of patients with recurrent dyspepsia and, especially, for the detection of ulcer recurrence. It may also provide additional information relating to adverse consequences of gastric surgery, particularly enterogastric bile reflux and gastritis. The diagnosis of recurrent ulceration may (rarely nowadays) be followed by investigation to assess the postoperative gastric acid secretion. These tests will provide information on the completeness or otherwise of the vagotomy and the persistence of acid hypersecretion which, if excessive, should raise the possibility of Zollinger–Ellison syndrome.

Estimation of serum gastrin is wise in all patients with recurrent ulcer. If hypergastrinaemia is detected, further investigations are required to exclude gastrinoma.

Not all recurrent ulcers require surgical treatment. Indeed the prevalent view is that the vast majority should be treated with a full 2 month course of PPI with eradication in those patients who test positive for *H. pylori* by the ^{13}C-urea breath test. The specific indications for surgical intervention include antral stasis associated with pyloric channel ulcers, incomplete vagotomy and retained antrum (following gastrectomy). Patients with incomplete vagotomy who are *H. pylori* negative are best treated with revagotomy and antrectomy.

BOX 23.4 Sequelae of gastric surgery

Recurrence of the disease

Nutritional and functional sequelae
- Weight loss, anaemia: iron deficiency and B_{12} deficiency
- Milk intolerance
- Bone disease
- Dumping syndromes
- Reactive hypoglycaemia
- Bile vomiting
- Diarrhoea
- Small stomach syndrome

Mechanical complications
- Afferent/efferent loop obstruction
- Jejunogastric intussusceptions
- Gastro-oesophageal reflux

Others
- Cholelithiasis
- Bezoar formation
- Gastric carcinoma

Sequelae of gastric surgery

Minor postprandial complaints are commonly experienced by patients after gastric operations. These usually improve with time and dietary adjustments. In a cohort of patients, however, variously estimated at 5–20%, the symptoms are severe, persistent and cause considerable disability, often drastically reducing the quality of life, and malnutrition. The problem may affect the quality of life so adversely that the patient commits suicide. This regrettable outcome was encountered in two patients in a series of 321 patients with postgastric surgery problems referred to the author for remedial treatment/surgery over a period of 30 years. It seems likely from recent reports that similar problems are being encountered in patients after gastric bypass, pancreatic biliary bypass and duodenal switch operations for morbid obesity.

The various postgastric surgery syndromes arise on a background of altered anatomy and physiology of the upper gastrointestinal tract, although the exact mechanisms responsible for some of the severe symptoms remain unclear. A useful classification of the sequelae of gastric surgery is shown in Box 23.4.

In the author's personal series, no particular personality type is at increased risk, but disabling symptoms after gastric surgery are more commonly encountered in the following:

- female sex
- operations for peptic ulceration in the young (below 30 years)
- extensive gastrectomy with duodenal diversion (Pólya).

Severe and persistent symptoms are rarely encountered after HSV if one excludes symptoms caused by recurrence of the ulcer. However, they occur with similar frequency to that reported after gastrectomy in patients who undergo truncal vagotomy with drainage or truncal vagotomy and antrectomy. The type of drainage procedure (pyloroplasty or gastrojejunostomy) does not affect the incidence of postprandial symptoms and other sequelae.

Nutritional consequences of gastric surgery

These consist of weight loss, anaemia and bone disease.

Weight loss

Loss of weight or failure to gain weight is very common after gastric surgery and tends to be more marked after extensive gastrectomy, particularly of the Pólya type. Often there is early satiety due to loss of adaptive relaxation and disturbances of ghrelin release. In practice, significant weight loss is usually encountered in patients who obtain a bad functional result and who experience severe postcibal symptoms such that they are afraid to eat. The resulting diminished calorie and protein intake is the major factor, although malabsorption of fat and nitrogen and decreased small bowel transit time may be operative, at least in some patients. Although mild steatorrhoea is common, severe fat malabsorption is rare unless there is a coexisting subclinical small bowel disease (e.g. gluten enteropathy) or gross bacterial overgrowth.

Anaemia

Iron-deficiency anaemia

Microcytic hypochromic anaemia is very common after vagotomy and drainage and gastric resections, especially in females. The incidence of this complication increases with time and approximates to 60% and 80% at 10–20 years in males and females respectively. The exact pathogenesis of the iron-deficiency anaemia is unclear but is probably multifactorial. The mechanisms thought to be important include:

- shift to trivalent ferric iron at high pH followed by polymerization
- loss of a gastric juice factor which normally facilitates the absorption of iron
- diminished splitting of iron–protein complexes by the reduced peptic activity of the gastric juice
- enhanced binding of dietary iron to specific proteins (e.g. gastroferrin).

In view of the high incidence of iron-deficiency anaemia after gastric surgery, prophylactic treatment with oral iron (300 mg q.d.s.) is nowadays recommended in all patients after gastrectomy and truncal vagotomy with drainage or antrectomy. This amount of daily iron supplementation allows sufficient absorption to restore serum iron levels to normal.

Macrocytic anaemia

This is the result of vitamin B_{12} deficiency. Malabsorption of this vitamin is invariable after total gastrectomy due to the loss of IF. However, megaloblastic anaemia takes several years to develop due to the large body stores of vitamin B_{12}.

These patients have an abnormal Schilling test and require 3 monthly injections of cyanocobalamin indefinitely. Subclinical deficiency of this vitamin is also encountered in some patients after partial gastrectomy and vagotomy with drainage or antrectomy, although frank megaloblastic anaemia is rare in these groups. The main factor responsible for the impaired absorption of dietary vitamin B_{12} in patients after partial gastrectomy and truncal vagotomy is the lack of acid environment which normally facilitates the release of vitamin B_{12} bound to ingested food. The reduced secretion of IF reported in some patients is considered to be less important in this group of patients in whom the Schilling test is normal. Treatment is with oral crystalline vitamin B_{12}, which is administered between meals. Malabsorption of vitamin B_{12} may also be the consequence of bacterial overgrowth and steatorrhoea. Folate deficiency is rare and is only encountered in patients after extensive or total gastrectomy. It results from an inadequate dietary intake,

Bone disease

This complication develops several years after gastric resection with duodenal exclusion (Pólya) as the duodenum is the major site of calcium absorption. The majority of patients are females who classically develop osteomalacia 10–20 years after the gastrectomy. In fact, in the vast majority of cases features of both osteomalacia (demineralization of bone) and osteoporosis (loss of bone substance) are present. The biochemical features (raised alkaline phosphatase and serum calcium) usually predate the clinical symptoms by several years. The clinical features of postgastrectomy bone disease include generalized bone pains, weakness due to an associated myopathy and the development of stress fractures most commonly in the vertebral column. Treatment should be prophylactic with oral calcium and vitamin supplements. The established condition may be treated with bisphosphonates.

The dumping syndrome

Considerable confusion has been generated by the inclusion of patients with reactive hypoglycaemia in the group and referred to as 'late dumping' to differentiate this condition from patients with vasomotor symptoms which occur soon after eating and in this erroneous classification are designated as 'early dumpers'. There is now general agreement that patients with symptoms due to reactive hypoglycaemia which occur 2–3 hours after a meal should not be included in the dumping syndrome.

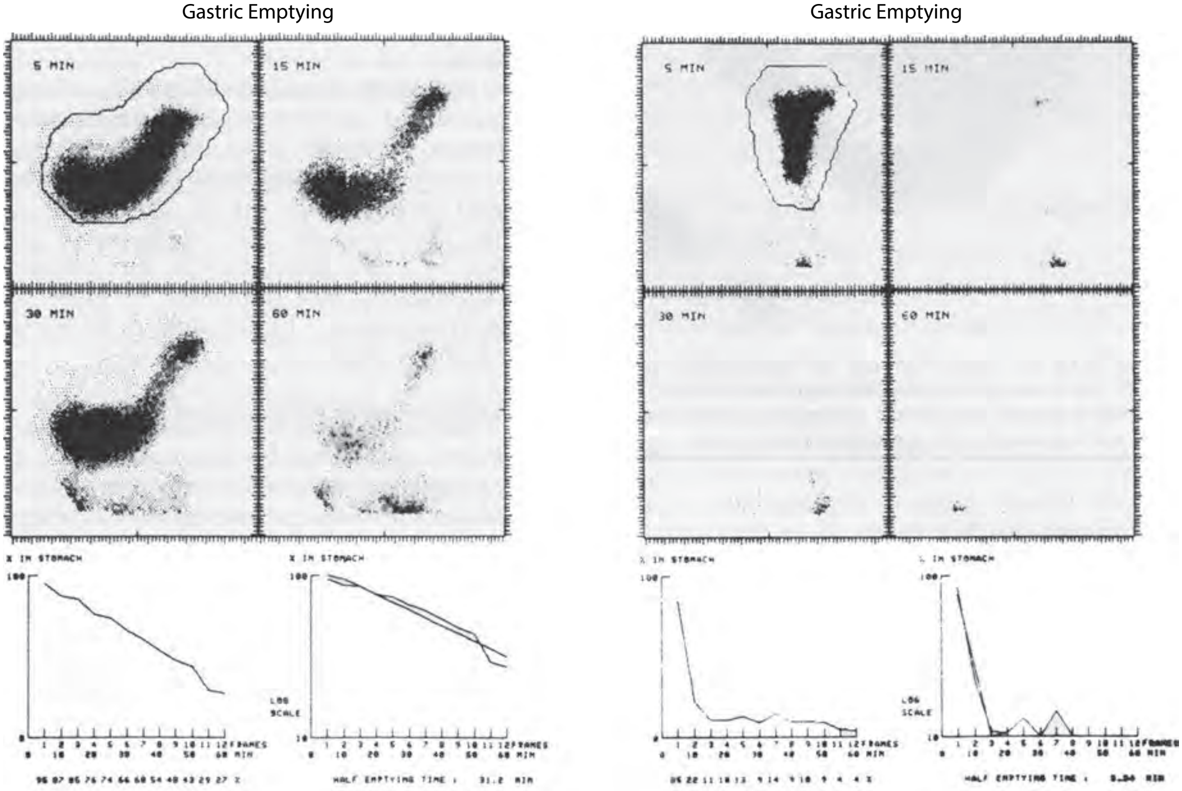
Although the term 'dumping' was introduced by Mix in 1922, the first description of the symptoms of vasomotor dumping syndrome had been reported previously by Hertz in 1913. The syndrome, which is one of the commonest sequelae of gastric surgery, consists of postprandial vasomotor (systemic) and gastrointestinal symptoms (Table 23.4). The dumping syndrome is associated with rapid gastric emptying (Figure 23.18), although some have postulated that the enterogastric reflux of bile is responsible for some of the symptoms. The fact is that both enterogastric reflux of bile and vasomotor dumping may occur in the same patient, and other than sharing the same aetiology (gastric surgery) there is no evidence that one syndrome causes the other.

The vasomotor symptoms and signs (palpitations, vasodilatation, hypotension and fainting/having to lie down, etc.) occur within minutes of eating and are principally caused by hypovolaemia, which is accompanied by diminished cardiac output and reduced peripheral resistance. The attacks are typically precipitated by high-carbohydrate meals. The hypovolaemia is secondary to a massive outpouring of fluid from the vascular compartment into the small bowel lumen as a consequence of the hyperosmolar nature of the intestinal contents resulting from the precipitous gastric emptying. Several vasoactive peptides have been held responsible as mediators of the vascular and gastrointestinal manifestations of the dumping syndrome. These include kinins, substance P, enteroglucagon, gastric inhibitory polypeptide and neurotensin. The gastrointestinal symptoms, which include diarrhoea, occur later during the course of a dumping attack and may be absent.

Patients with mild to moderate dumping symptoms are managed satisfactorily with dietary manipulations. These patients are advised to eat small, dry meals (no fluids before or during meals) rich in protein and fat but low in carbohydrates. Additives that slow gastric emptying, such as methoxy-pectin or bran,

Table 23.4 Manifestations of the dumping syndrome

Vasomotor (systemic)	Gastrointestinal
Weakness	Fullness and early satiety
Tiredness	Epigastric discomfort/heaviness
Dizziness	Nausea
Headache	Vomiting
Fainting/wanting to lie down	Distension
Feeling of warmth	Excessive borborygmi/distension
Dyspnoea	Diarrhoea
Sweating	



(a) (b)

Figure 23.18 Gastric emptying of an isotope-labelled meal: (a) normal single exponential emptying; (b) rapid initial gastric emptying in a patient with severe dumping symptoms.

are beneficial. However, remedial gastric surgery is required for patients with severe and persistent dumping (see below).

Reactive hypoglycaemia

This complication is relatively uncommon and has a reported incidence of 1–6% after gastric surgery. Reactive hypoglycaemia often exists with other symptoms, including vasomotor dumping and diarrhoea. The symptoms, which occur 2–3 hours after a meal, are due to hypoglycaemia and include sweating, tremor, difficulty in concentration and, rarely, fainting. The diagnosis is best confirmed by an extended oral glucose tolerance test, which demonstrates an initial hyperglycaemia. This triggers an exaggerated insulin release with elevated plasma insulin and enteroglucagon that precede the hypoglycaemia.

Reactive hypoglycaemia usually responds to dietary measures, including small low-carbohydrate, high-protein meals and very rarely requires remedial surgical treatment.

Bile vomiting

Vomiting of bile or bile-stained fluid before or after meals may be a manifestation of the following disorders:

- recurrent ulceration
- enterogastric reflux
- intermittent obstruction of the afferent or efferent loop of a gastrojejunostomy
- cardio-oesophageal incompetence.

Enterogastric reflux/reflux gastritis

Reflux of upper intestinal secretions (bile/pancreatic juice/succus entericus) into the stomach causes a reflux erosive gastritis and bile vomiting. The symptoms include epigastric pain, nausea and vomiting in the early postprandial period. The pain is usually of a burning nature, is aggravated by food and is not relieved by antacids. The attack usually culminates in the vomiting of bile-stained fluid 1–2 hours after a meal. Less commonly, the vomiting occurs in the early morning and is preceded by nocturnal burning pain. The erosive gastritis leads to chronic blood loss with the development of an iron-deficiency anaemia and, occasionally, to overt acute gastric haemorrhage.

The diagnosis is established by upper gastrointestinal endoscopy, which shows a diffuse gastritis with oedematous friable mucosa and superficial erosions, in addition to pooling of bile-stained fluid. Quantification of the enterogastric reflux is obtained by the modified EHIDA test. In this investigation, EHIDA is injected intravenously and is followed by external scintiscanning of the upper abdomen with a gamma camera. When the gallbladder is imaged by the isotope, contraction and emptying of the organ is achieved either with a milk meal (milk–EHIDA test) or by intravenous cholecystokinin (EHIDA–CCK test). The amount of enterogastric reflux is calculated as a percentage of the total abdominal radioactivity (Figure 23.19).

The symptoms of reflux gastritis and bile vomiting may be improved by the administration of bile salt-binding agents (cholestyramine, aluminium hydroxide, charcoal). However, conservative management along these lines often fails, when remedial surgical intervention becomes necessary. Prolonged enterogastric reflux can result in atrophic gastritis and intestinal metaplasia. It has been incriminated as a factor in the development of carcinoma of the stomach after gastric surgery, although evidence for this hypothesis remains lacking.

Extrinsic loop obstruction

This rare complication occurs after truncal vagotomy and gastrojejunostomy and usually affects the afferent loop. The predisposing factors to the development of afferent loop obstruction include antecolic anastomosis of long loops (exceeding 20 cm). The causes of extrinsic loop obstruction are:

- internal herniation
- kinking of the anastomosis
- adhesions
- volvulus
- stenosis
- jejunogastric intussusception
- development of carcinoma of the gastric remnant.

Obstruction of afferent or efferent loops is usually chronic and intermittent but may be acute.

The symptoms of chronic afferent loop obstruction include fullness, cramp-like pain and nausea within 1 hour of eating. The attack culminates in vomiting of copious amounts of bile-stained fluid which relieves the symptoms. The presentation of acute afferent loop obstruction is with severe colicky abdominal pain, nausea and vomiting, which is characteristically free of bile. Abdominal tenderness is present. The condition may be complicated by the development of acute pancreatitis, jaundice and necrosis with perforation.

Acute jejunogastric intussusception is a serious condition characterized by severe epigastric pain, vomiting, haematemesis, a palpable abdominal mass with high small bowel obstruction. Urgent surgical intervention is required because of the risk of strangulation and gangrene. The condition may be diagnosed preoperatively by a plain abdominal film which shows a soft-tissue epigastric mass surrounded by the gastric air bubble. Alternatively, emergency barium meal or endoscopy will establish the diagnosis.

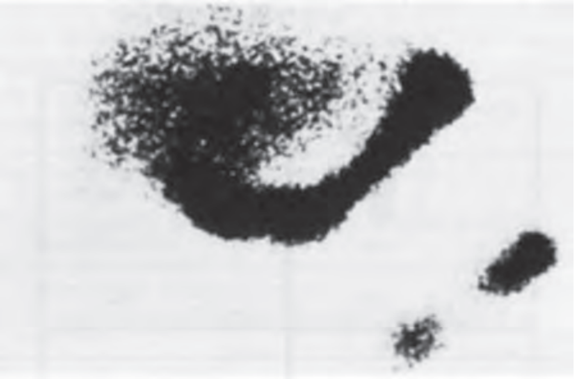


Figure 23.19 The milk–EHIDA test for enterogastric reflux. The patient experienced severe bile vomiting after vagotomy and pyloroplasty. Reflux of isotope (bile) into the stomach occurs in the fasting state but is considerably enhanced after the administration of milk (as a source of fatty meal).

Gastro-oesophageal reflux and oesophagitis

The situation regarding gastro-oesophageal reflux and surgery for duodenal ulcer is both confusing and controversial. In the first instance gastro-oesophageal reflux often accompanies duodenal ulcer and oesophagitis may, therefore, be present preoperatively. Transient dysphagia may occur after any type of vagotomy and this has been attributed to oedema of the lower abdominal oesophagus. It is now established that vagotomy itself does not affect the oesophageal high-pressure zone, but damage to the oesophageal attachments, particularly the phreno-oesophageal membrane during the mobilization of the oesophagus, may cause cardio-oesophageal incompetence. If this becomes subsequently associated with the development of enterogastric reflux of bile and pancreatic juice (neutral or alkaline reflux) a severe form of erosive oesophagitis develops. It is now documented that the eradication of *H. pylori* in patients with duodenal ulcer aggravates any underlying cardio-oesophageal incompetence and has been suggested as one of the factors accounting for the rising incidence of junctional cancers during the past 20 years.

Diarrhoea

The reported incidence of this complication varies widely, largely due to varying definitions. Three patterns of diarrhoea are encountered after gastric surgery:

- frequent loose motions
- intermittent episodes of short-lived diarrhoea
- severe intractable explosive diarrhoea.

Severe explosive diarrhoea is a serious, but rare disability, being encountered in 2% of patients after truncal vagotomy with drainage. It is often accompanied by dumping symptoms and is precipitated by food. Severe intractable diarrhoea is characterized by extreme urgency and often causes incontinence during an acute attack. Also the fluid motion is extremely foul smelling and this is often complained of by the partner and close family members.

Although often associated with rapid gastric emptying, the exact mechanism is unknown. Malabsorption of bile salts and/or fatty acids consequent on the intestinal vagal denervation has been implicated but never confirmed. The small bowel transit is markedly exaggerated in all patients.

A full malabsorption survey is necessary in all patients with severe diarrhoea as in a few patients this disability is secondary to a previously undiagnosed gastrointestinal disease (e.g. adult coeliac) or bacterial overgrowth consequent on a blind loop. Medical management is with a low animal fat diet, intestinal sedatives (codeine phosphate, loperamide) and bile salt-binding agents such as cholestyramine. Although temporary improvement can be obtained in this way, long-term benefit is rarely obtained with conservative measures and the patient either accepts and lives with the disability or asks for remedial surgical treatment.

In the past 10 years, cases of severe explosive diarrhoea have been reported after laparoscopic fundoplication especially of the anterior (Watson) type. The incidence after this operation is about 2%. The presumed aetiology is damage to the vagal nerve trunks. These patients should be treated conservatively for 2 years as a considerable number resolve by this time. Remedial surgery may be considered if the condition persists beyond 2 years.

Small stomach syndrome

This term is sometimes used for the early satiety complained of by many patients after vagotomy, which causes loss of the receptive relaxation of the stomach during eating. It is however, best reserved for those unfortunate patients, usually females, who cannot eat after gastrectomy and whose quality of life is miserable and whose nutrition can only be maintained by enteral or parenteral feeding. In essence, these patients, because of pain and myriad other symptoms, are unable to eat and in essence starve themselves. Thus the condition inevitably leads to protein calorie malnutrition and cachexia similar to that encountered in advanced malignancy. In the author's experience, small stomach syndrome is refractory to conservative management, although in some patients nutrition can be maintained by elemental diets administered via a Clinifeed tube and an IVAC pump or via a feeding jejunostomy in those who cannot tolerate nasoenteral feeding. Although many can be trained to use this in their homes and maintain a reasonable nutritional state in this way, their quality of life is extremely poor and it is no wonder that some commit suicide. The alternative to feeding jejunostomy is home hyperalimentation with intravenous nutrition. Aside from cost, this is best avoided in these patients because of the inordinately high complication rates associated with the indwelling intravenous line. If the patient is fit and middle aged, surgical intervention designed to reconstruct a gastric reservoir and restore duodenal continuity provides the best chance for improvement and ability to maintain nutrition with an oral diet although supplementation is often needed.

Other complications

These include the formation of gallstones and bezoars and the development of gastric carcinoma. Vagotomy causes dilatation of the gallbladder. However, although there are a number of reports indicating an increased risk of gallstone formation after both vagotomy and partial gastrectomy, there is no firm evidence that gastric surgery predisposes to cholelithiasis.

The factors implicated in the formation of bezoars after gastric surgery include hypoacidity, impaired proteolytic activity, inadequate mastication and loss of the antral pump. The majority of bezoars, which develop after gastric surgery, consist of undigested vegetable/fruit fibre debris (notably orange pith). Bezoars can cause chronic symptoms such as nausea, vomiting, abdominal discomfort, halitosis and early satiety. They can also lead to serious complications, e.g. small bowel obstruction, severe gastritis and ulceration, bleeding, perforation and malnutrition. Treatment is initially conservative by enzyme (cellulose) digestion or endoscopic fragmentation/removal. Surgical intervention is undertaken if medical/endoscopic therapy fails or because of development of a complication.

There is good evidence that previous gastric surgery (partial gastrectomy, gastrojejunostomy) predisposes to the development of gastric carcinoma in the stomach remnant. Vagotomy does not appear to be implicated in this complication. Although reflux gastritis with the development of intestinal metaplasia, particularly of the type III variety, and bacterial overgrowth with the formation of nitrosamines in the hypochlorhydric gastric remnant have been implicated, the exact mechanism for the development of invasive carcinoma remains unknown. Also it seems likely that many of these patients had *H. pylori* gastritis that was not recognized at the time. This is now thought to have contributed to the development of gastric carcinoma. There is a long latent period of 15–20 years but the risk, though definite, is small.

Remedial surgical treatment for postgastric surgery syndromes

General considerations

As the majority of symptoms improve with time, initial management should always be conservative and surgical treatment should not be considered before 18 months to 2 years of presentation and with no improvement on conservative management. Only patients with severe symptoms which persist beyond this time despite conservative management should be considered as candidates for remedial surgery, and, ideally, the patient should request the intervention. All these patients need to be investigated and assessed (nutritionally and fitness for surgery). In addition, a detailed history of the symptoms during 'bad days' is essential to establish the *dominant symptom/disability* – what troubles the patient most and would improve his or her quality of life if treatment were to be successful. Remedial surgery should be directed to amelioration of this dominant symptom with the proviso, which must be conveyed to the patient, that while the intended surgery may impart considerable benefit, a totally symptom-free outcome is rarely, if ever, obtained. Despite the classical descriptions of separate syndromes, most patients cannot be pigeonholed and, instead, have a mixture of symptoms, but a careful history will always determine the dominant symptom/disability and remedial surgery should be directed exclusively to correction of this symptom if the patient is to benefit from remedial surgery.

Dominant dumping symptoms

The easiest patients to manage surgically are those who experience severe dumping after truncal vagotomy with drainage. In these patients, the remedial surgery consists of either take down of the gastrojejunostomy or pyloric reconstruction (Figure 23.20) depending on the type of drainage used. Surprisingly, symptomatic gastric retention is rarely encountered, although postprandial fullness is common and the patient should be advised to avoid heavy bulky meals, lying down after meals and to eat the evening meal at least 3 hours before retiring to bed. In practice, prokinetic drugs do not help these patients.

For patients with dominant dumping symptoms after partial gastrectomy or vagotomy with antrectomy, the more technically demanding isoperistaltic jejunal interposition (10–15 cm) between the gastric remnant and the duodenum acts as an effective brake to slow the gastric emptying (Figure 23.21).

Bile vomiting as the dominant symptom

The commonest cause of this is enterogastric reflux. Excellent results are obtained in patients with vagotomy and gastrojejunostomy by take down of the latter. In contrast, pyloric reconstruction for bilious vomiting in these patients gives unsatisfactory results and should not be attempted. These patients are best served by an antrectomy and an isoperistaltic jejunal interposition (10–15 cm) between the proximal stomach and the duodenum. Severe bile vomiting due to enterogastric reflux after partial Billroth I gastrectomy may be treated by Roux-en-Y diversion. Although very effective in abolishing the bile vomiting, this procedure may lead to bacterial overgrowth, but this is not usually a major problem. An alternative approach is reconstruction with an isoperistaltic jejunal loop between the gastric remnant and the duodenum.

Dominant symptoms of the small stomach syndrome

This is the most difficult symptom complex to treat. These patients are usually grossly malnourished and require a period of parenteral nutrition before the remedial surgical treatment. The best procedure consists of completion gastrectomy and the creation of a jejunal reservoir with an isoperistaltic conduit between the oesophagus and the duodenum (Figure 23.22).

In these patients, the gastric stump is invariably inflamed and immotile and is therefore excised prior to commencement of the reconstruction. An improved outcome following this major reconstruction is reflected by the ability of the patient to sustain weight by a semisolid low-roughage diet and is encountered in 50–60% of patients. The problem has been the prediction of patients who are likely to benefit from such extensive remedial surgery. Obviously, psychological factors are important in this respect and the patient requires to be well motivated to overcome the disability. Too much stress cannot, however, be based on psychological assessment as the psychological state of the patient may be the result of the disability. Preoperative weight gain on enteral feeding is reported to be a good indicator of a positive clinical outcome after remedial surgery for the small stomach syndrome (Figure 23.23). In patients who do not improve after completion of gastrectomy and creation of a gastric reservoir, or those who are unfit for major surgery, nutrition can be maintained by surgically constructed feeding jejunostomy. This is physiologically better, safer and more cost effective than permanent home hyperalimentation with parenteral nutrition.

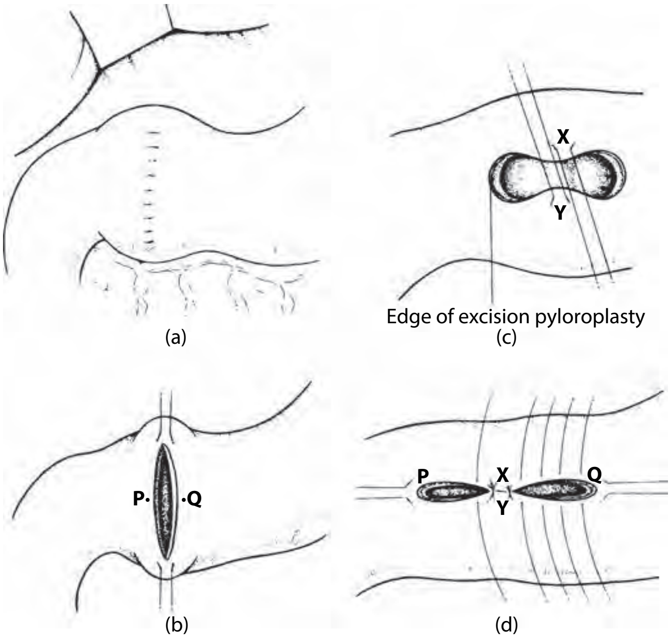

Figure 23.20 Pyloric reconstruction for dumping after Heineke–Mikulicz pyloropasty: (a) complete exposure of the pyloroplasty by freeing of adhesions; (b) insertion of stay sutures beyond both ends of the pyloroplasty scar which is carefully incised along its length; (c) precise restoration of the normal alignment of the pyloric muscular ring; (d) the realigned antropyloric segment is closed in a single layer with fine (3/0) carefully placed interrupted sutures.

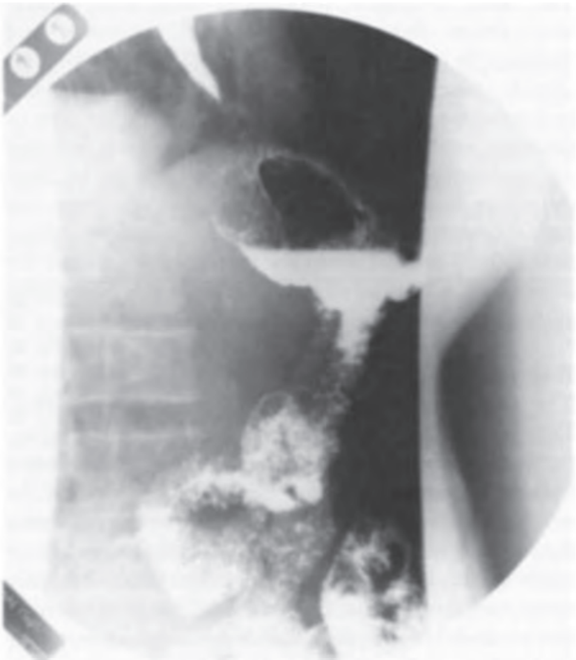

Figure 23.21 Contrast radiology of isoperistaltic jejunal interposition between the gastric remnant and the duodenum.

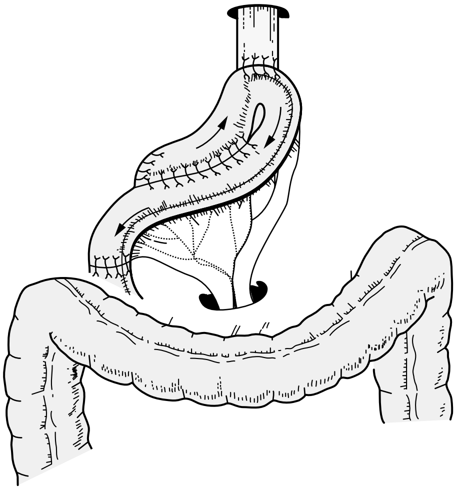

Figure 23.22 Jejunal pouch reconstruction with an isoperistaltic conduit for the small stomach syndrome. The useless gastric remnant is first removed before this reconstruction.

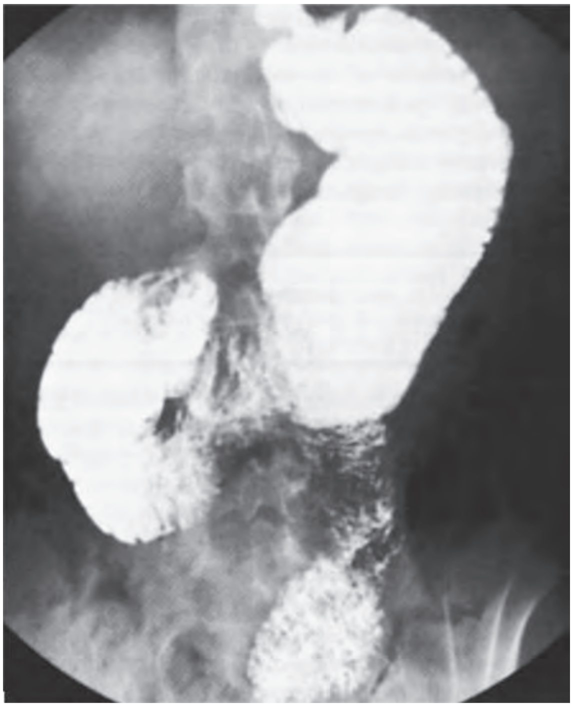

Figure 23.23 Barium contrast series in a patient with completion gastrectomy and reconstruction with a jejunal reservoir with an isoperistaltic conduit. The operation was performed for severe symptoms (small stomach syndrome) with good symptomatic result and weight gain on a semifluid oral diet.

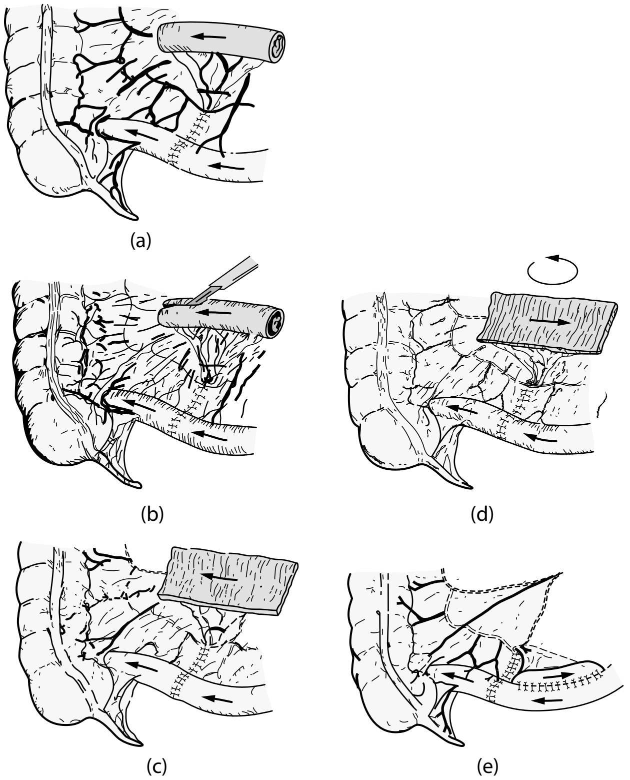

Figure 23.24 Reversed ileal onlay graft for severe explosive diarrhoea: (a) a 10–12 cm segment of ileum is isolated on an intact vascular pedicle some 30 cm proximal to the caecum; (b) continuity of the small bowel is restored by an enteroenteric anastomosis; (c) the isolated segment is split longitudinally along its antimesenteric border; (d) reversal of the flap; (e) suture of the reversed graft as an onlay to the adjacent ileum following an appropriate enterotomy, thereby creating a passive non-propulsive segment. (From Cuschieri, *Br J Surg* 1986;**73**:981, with permission).

Severe explosive diarrhoea

Although the use of reversed jejunal segments has been advocated, the outcome of these operations is poor due to the development of episodes of postprandial colic, intestinal obstruction, distension and bacterial overgrowth. The best results are obtained by the distal onlay ileal graft procedure, which is designed to create a passive non-propulsive segment of the small intestine some 30–60 cm from the ileocaecal junction (Figure 23.24). Some 50% of patients obtain significant benefit following this operation if they avoid fatty/dairy products. Some patients complain of postprandial colic after this operation with some abdominal distension. Revision (reduction of the length of the distal onlay graft) may be necessary if these symptoms persist.

Remedial surgery fails in half the patients and, in these, a temporary loop ileostomy can be offered. If the patient finds this acceptable after a trial period of 3 months, the ileostomy is made permanent, otherwise it is reversed.

Gastritis

There is considerable confusion regarding the nomenclature of inflammatory conditions of the gastric mucosa (gastritis). Clinical designations do not always conform with the specific histological patterns and, in some instances, vascular changes are present with minimal cellular inflammatory response (Box 23.5). The term *gastropathy* as opposed to gastritis is more appropriate to the latter conditions, typified by alcoholic gastritis.

In the past, there have been several clinical and histological classifications of gastritis producing a rather confusing picture to the clinician. In 1990, the Sydney system was introduced as a

BOX 23.5 Classification of gastritides

Common
- Non-atrophic gastritis (*H. pylori*)
- Atrophic gastritis type A (autoimmune)
- Atrophic gastritis type B (associated with *H. pylori* infection)
- Chemical/reactive gastritis
- Stress gastritis (seriously ill patients)

Rare
- Lymphocytic gastritis
- Granulomatous gastritis (tuberculosis, Crohn disease)
- Gastritic cystic polyposa
- Gastritis in immunosuppressed patients
- Eosinophilic gastritis
- Radiation gastritis
- Suppurative phlegmonous gastritis
- Emphysematous gastritis

basis for classification and this is now widely accepted and was updated at the international workshop in Houston in 1966; hence it is referred to as the Sydney–Houston classification. The system is based on the histological examination of at least four biopsies, two from the middle body and two from the antrum at least 2.0 cm proximal to the pylorus (anterior and posterior walls). The Houston update also recommends that additional biopsies from the lesser curvature and the angular notch are necessary especially for the early diagnosis of atrophic gastritis and intestinal metaplasia. The main change in the classification of gastritis outlined by the Houston update is the designation of two broad categories: *atrophic* and *non-atrophic*, although there is some disagreement on the validity of this subdivision as a mixed picture may be encountered (gland atrophy and metaplasia).

The new classification is based on five histological variables that are graded separately by the histopathologist as mild, moderate or severe:

- chronic inflammation – mononuclear infiltrates
- activity – acute polymorphonuclear infiltrates
- atrophy – loss of normal glands
- intestinal metaplasia
- extent of colonization of biopsies by *H. pylori* in non-metaplastic epithelium.

Extensive lymphoid follicle formation is indicative of *H. pylori* infection and may lead to the development of MALT lymphomas In general, the grade (mild to severe) of the colonization correlates with the severity of the mononuclear inflammation, the activity (polymorphonuclear inflammation), the mucus depletion, lymphoid follicle formation and the degenerative changes. In practice, the system results in the following categorization of the gastric mucosa:

- normal
- non-atrophic *H. pylori* gastritis
- atrophic gastritis – *H. pylori* positive (type B) or negative (type A)
- special forms of gastritis.

Patients with a histologically normal stomach by the Sydney–Houston classification have a normal functional mucosa with respect to the output of acid, pepsinogens, IF and peptide hormones, and these individuals have a low risk of peptic ulcer and gastric carcinoma. Ulcers when they occur are due to drug ingestion such as NSAIDs or steroids and rarely to Crohn disease or rarer still to the sporadic or hereditary forms of Zollinger–Ellison syndrome.

H. pylori and much more rarely *H. heilmannii* cause both non-atrophic and atrophic gastritis. *H. pylori* non-atrophic gastritis involves mainly the antrum and the duodenal bulb (bulbitis) and is strongly associated with the development of peptic ulcers with a cumulative risk of symptomatic peptic ulcer disease of 30% over a period of 10 years, the infection having been acquired in childhood.

Atrophic gastritis

Atrophic gastritis can occur in the absence of *H. pylori* infection (type A) or be caused by infection with this organism (type B). In both types, the risk of peptic ulceration, particularly duodenal, is low. The secretory function of the gastric mucosa becomes progressively impaired and if the antral mucosa is severely involved, there is a reduction/loss of the gastrin-secreting G-cells and the somatostatin-secreting D-cells.

Type A atrophic gastritis (autoimmune gastritis)

This affects mainly the body and fundus of the stomach and has an autoimmune aetiology with the presence of circulating autoantibodies. These are directed against at least three antigens: IF, parietal cell cytoplasmic (microsomal–canalicular) and plasma membrane antigens. Two types of IF antibodies are present (types I and II). The type I IF antibody is the more important as it blocks the IF–cobalamin binding site, thus preventing the uptake of vitamin B_{12}. As part of the cell-mediated immunity, T-cell lymphocytes infiltrate the gastric mucosal cells and contribute to epithelial cell destruction and gastric atrophy of the parietal and chief cells, which leads to achlorhydria and loss of secretion of IF with malabsorption of B_{12}, and, eventually, pernicious anaemia in some patients. As the antrum is relatively spared, the serum gastrin is elevated and this chronic hypergastrinaemia may lead to the development of endocrine tumours. There is an increased risk of gastric cancer, which is usually of the diffuse type.

Autoimmune gastritis is a relatively rare disease, most frequently encountered in individuals of northern European descent and blacks. The prevalence of pernicious anaemia is estimated at 127 cases per 100 000 members in the UK, Denmark and Sweden. In these countries pernicious anaemia is usually diagnosed in patients aged 60 years. Aside from the haematological manifestations (megaloblastic anaemia and rarely purpura), the patients exhibit symptoms of anaemia (weakness, light-headedness, vertigo and tinnitus, palpitations, angina) and may develop congestive heart failure. Some patients complain of a sore tongue. Anorexia with moderate weight loss with diarrhoea may also be present. Delayed diagnosis and treatment may result in neurological manifestations resulting from demyelination of peripheral nerves, posterior and lateral columns of the spinal cord and cerebrum (numbness and paraesthesias in the extremities, weakness, and ataxia). Sphincter disturbances may occur. Mental functional disturbances vary from mild irritability to severe dementia or psychosis. Patients with pernicious anaemia have an increased frequency of gastric polyps and gastric carcinoids (2.9-fold increase) together with an increased risk of invasive gastric cancer.

Type B atrophic gastritis

This is the commonest form of chronic gastritis and hence its clinical importance. It is the result of infection by *H. pylori* and eradication of the infection is followed by documented histological improvement although relapse may occur. *H. pylori* causes mucosal tissue damage with a mixed histological picture of both acute and chronic gastritis. There is T- and -cell lymphocyte infiltration as part of the host's chronic response to the infection. The acute response to the infection consists of polymorphonuclear infiltration of the lamina propria and gastric epithelium, often seen on histological sections to be phagocytosing the bacteria. The interaction of *H. pylori* with the gastric mucosa leads to the release of the proinflammatory cytokine interleukin (IL)-8, which is responsible for the recruitment of polymorphonuclear lymphocytes. Various other cytokines, including tumour necrosis factor (TNF)- and multiple interleukins (e.g. IL-6, IL-8, IL-10), are also released in the gastric mucosa of infected patients. Leukotriene levels are also secreted. In particular, leukotriene B4 (synthesized by host neutrophils) is paradoxically cytotoxic to gastric epithelium. In time, this mixed inflammatory response leads to structural and functional changes in the stomach, the outcome of which will depend on the areas involved: in gastric body and fundus, parietal and chief cells are destroyed (hypochlorhydria), whereas antral inflammation affects G- and D-cell function, gastrin secretion is abnormal in infected individuals and usually consists of an exaggerated meal-stimulated release of gastrin.

Individuals infected with *H. pylori* strains that secrete the vacuolating toxin A (vacA) are more likely to develop peptic ulcers. Other virulence factors are encoded by the *H. pylori* pathogenicity PAI, which contains the sequence for several genes and encodes the *CAGA* gene. Strains producing the CagA protein (CagA$^+$) are associated with a greater risk of development of both gastric carcinoma and *H. pylori*-associated chronic gastritis progresses along two patterns according to site of predominant involvement: *antral predominant gastritis* (APG) and *multifocal atrophic gastritis* (MFAG). APG is characterized by inflammation that is largely limited to the antrum. These individuals develop peptic ulcers, duodenal ulcer if the parietal cell mass is large usually demonstrate this pattern of gastritis. MFAG is characterized by involvement of the whole stomach with progressive development of gastric atrophy (loss of the gastric glands) and partial replacement by intestinal metaplasia. These patients are at risk of developing both gastric ulcers and gastric cancer. Some individuals also develop gastric MALT lymphomas. The normal healthy stomach lacks organized lymphoid tissue, but develops lymphoid tissue infiltrates in response to the infection with *H. pylori*. If the infection is not eradicated, the persistence of MALT aggregates may eventually progress to the development of both low- and high-grade MALT lymphomas (monoclonal proliferations of neoplastic -cells).

Gastric carcinomas develop in a small proportion of individuals with extensive atrophy and intestinal metaplasia. Persistence of the infection over a long period of time is thought to induce mutations in the genome of the gastric epithelial cells, leading to an increased risk of malignant transformation to invasive gastric adenocarcinoma. These mutations in the gastric epithelium are secondary to oxidative DNA damage associated with chronic inflammatory by-products caused by the chronic bacterial infection.

Special forms of gastritis

Reactive/erosive/chemical gastritis

This is sometimes referred to as *gastropathy* as the inflammatory component is not marked. It results from gastric mucosal damage by both exogenous and endogenous irritant chemicals. Histologically, there is foveolar hyperplasia, severe congestion, oedema and fibrosis of the lamina propria but a paucity of inflammatory cells. Reactive gastritis is commonly caused by drugs, e.g. NSAIDs (present in 25–45% of NSAID users) and alcohol. The usual locations of drug-induced chemical gastropathy are the antral and prepyloric regions. The lesions are produced by blockade of the cyclo-oxygenase pathway with reduction of the cytoprotective gastric prostaglandins. Thus NSAIDs that are prostaglandin sparing (non-acetylated salicylates such as carpofen, nabumetone, etc.) and low-dose steroids are less likely to produce erosive gastropathy. The alcohol-induced mucosal damage affects in addition the mucosal microvessels which undergo necrosis with resulting haemorrhage and thrombus formation. The role of leukotrienes in this pathological process is debatable.

Chemical gastropathy also develops as a result of enterogastric reflux usually in patients after partial gastrectomy. Several bile constituents are responsible for the damage: 5% lysolecithin and bile acids disrupt the gastric mucous barrier and thus cause back diffusion of positive hydrogen ions and cellular injury. Pancreatic juice also damages the gastric epithelium by virtue of its enzyme content. Other causes of haemorrhagic gastropathy with erosions include cor pulmonale, severe infections such as pneumonia, cirrhosis and blood disorders.

Lymphocytic gastritis

This rare form of gastritis accounts for 1–5% of cases of patients presenting with dyspepsia but is more commonly encountered among patients with coeliac disease in whom it is present in 15–45%. It is thought to be the result of an abnormal immunological reaction to unidentified luminal antigens. The condition may be intermittent. Histologically, it is characterized by infiltration of the surface gastric foveolar epithelium associated with chronic infiltrates in the lamina propria by T-lymphocytes similar to those encountered in coeliac disease (intraepithelial lymphocytes greater than 25/100 epithelial cells). Some cases are associated with infection by *H. pylori*. Antibody titres are certainly found in some patients with lymphocytic gastritis, and the gastritis resolves after *H. pylori* eradication. The majority of patients with lymphocytic gastritis are, however, serologically negative for *H. pylori*. Few cases of lymphocytic gastritis have been reported secondary to intolerance to drugs such as ticlopidine.

Although some patients do not exhibit any specific endoscopic features, in the majority a distinctive appearance consisting of nodularity, erosions and enlarged mucosal folds (referred to as varioliform gastritis) is observed. Lymphocytic gastritis is most commonly encountered in middle age. Lymphocytic gastritis may be associated with chronic *H. pylori* infection, gluten-sensitive enteropathy, Ménétrier disease and has been reported in both MALT lymphoma and gastric carcinoma.

Gastritis cystic polyposa

This is a rare late complication of gastric surgery (1–25 years), although instances without a history of previous gastric operations have been reported. The patients present with abdominal pain, nausea and vomiting or gastrointestinal bleeding. Endoscopically, a hypertrophic gastritis is present and this may be mistaken for carcinoma on the macroscopic appearance.

Gastritis in immunosuppressed patients

These patients are prone to infection by various viruses including cytomegalovirus, herpes simplex and bacteria (*Mycobacterium avium-intracellulare*) and parasites. In infections by cytomegalovirus, the histology shows the typical intranuclear eosinophilic inclusions with a patchy mild inflammatory infiltrate. Severe necrosis may result in ulceration. Infections with herpes simplex are diagnosed by basophilic intranuclear inclusions in epithelial cells. Infections by *M. avium-intracellulare* cause diffuse infiltration of the lamina propria by histiocytes.

In patients with AIDS vomiting due to gastric outlet obstruction from gross oedema of the pyloric ring is caused by infection with *Cryptosporidium*. In these patients, cryptosporidial oocysts can be recovered from the stools. An interesting confirmed observation is the low prevalence of *H. pylori* infection in HIV-positive patients with low CD4 counts (<200) compared to HIV-negative patients. This low prevalence is also accompanied by a reduced incidence of peptic ulcers. Gastric toxoplasmosis due to infection with *Toxoplasma gondii* is rare in AIDS patients, but when it occurs it causes abdominal pain. Diffuse thickening of the gastric folds is seen at endoscopy. Gastric mucosal biopsy confirms necrosis and intracellular trophozoites in gastric epithelial, smooth muscle and endothelial cells.

Eosinophilic gastritis

This occurs as part of eosinophilic gastroenteropathy in children and adults below 50 years and has an allergic basis (allergy to milk or soya protein especially in children). Some cases of eosinophilic gastritis are caused by parasitic infections, e.g. *Eustoma rotundatum* and anisakiasis. Eosinophilic gastroenteritis can also be found in patients with connective tissue disorders (polyarteritis nodosa, scleroderma, polymyositis and dermatomyositis).

The pyloric regions and the adjacent duodenum become diffusely thickened due to oedema of the submucosal and muscle layers, which are also infiltrated with eosinophils and occasional giant cells. The gastric antrum is the area of the stomach most severely affected. Histological examination of biopsies shows extensive eosinophilic infiltrates with oedema and lymphangiectasia. The elevation of the serum IgE correlates with the severity of the disease. In the majority of patients there is a peripheral eosinophilia. Cases arising as a complication of polyarteritis nodosa tend to be severe and life threatening. The clinical features of eosinophilic gastritis include symptoms of delayed gastric emptying, e.g. early satiety, nausea and vomiting and gastrointestinal bleeding. Patients with established food allergy often respond to removal of these items from the diet. Otherwise, the treatment is with sodium cromoglycate and/or prednisolone.

Granulomatous gastritis

Granulomatous gastritis may be infectious or non-infectious. Infectious granulomatous gastritis is rare and usually secondary to active pulmonary diseases, although caseating granulomas may be found in the absence of lung disease in malnourished and immunosuppressed patients. Tuberculosis infection causes multiple ragged ulcers and discrete tubercles may be visualised at endoscopy. Serosal inflammation is common and there is marked locoregional lymphadenopathy. Treatment is with antituberculous chemotherapy. Fungal infections can also cause caseating granulomas and necrosis, also in immunosuppressed patients.

Non-infectious granulomatous gastritis is usually caused by Crohn disease when it presents with gastric pain, nausea and vomiting. The reported estimates of Crohn's gastritis in patients with established intestinal Crohn disease varies from 6% to 24%. However, almost invariably, patients with gastric Crohn disease have associated small bowel disease which dominates the clinical presentation. Non-caseating granulomas are present in one-third of cases and involvement of the duodenum is common. In addition there is focal chronic active ulceration with erosion of the epithelium in the absence of *H. pylori* infection, which should suggest the diagnosis.

Sarcoidosis of the stomach is another cause of chronic non-infectious gastritis but is usually accompanied by granulomatous inflammation in other locations (lungs, hilar nodes or salivary glands). A few patients with gastric sarcoid involvement in the stomach have no gastric symptoms but others present with gastric ulcers, haemorrhage, and pyloric stenosis causing gastric outlet obstruction. Rarely, the granulomatous gastritis is idiopathic (diagnosis made after exclusion of all known causes). These patients are usually older than 40 years, and present with epigastric pain, weight loss and vomiting secondary to pyloric obstruction.

Radiation gastritis

Although small doses of radiation (up to 1500 R) cause reversible mucosal damage, higher radiation doses induce irreversible damage with atrophy and ischaemic-related ulceration from submucosal endarteritis. The severely damaged mucosa causes repeated episodes of bleeding and may require resection.

Suppurative (phlegmonous) gastritis

This is a rare and often fatal bacterial infection producing a cellulitis of the stomach wall. Haemolytic streptococci are the commonest infecting organisms. The condition usually complicates a pre-existing gastric lesion and is more commonly encountered in elderly and alcoholic patients. The presentation is usually one of severe progressive peritonitis. Treatment is with gastric resection and systemic antibiotics. At operation, the stomach exhibits a dusky discoloration and its serosal surface is covered with a fibrinous exudate. Necrotizing gastritis is an especially severe variant which results in overt infective gangrene. It is caused by a mixed infection with fusiform and spirochaete bacteria from the mouth.

Emphysematous gastropathy

Air-filled cysts in the gastric wall are rare and usually accompanied by *pneumatosis cystoides intestinalis*. Gas cysts in the wall of the stomach can also occur in association with pyloric obstruction and chronic obstructive airway disease with emphysema. Gas can also be introduced in the wall of the stomach following incomplete injuries during endoscopy.

Clinical management of gastritis

It is important to stress that, irrespective of symptoms and presentation, the specific diagnosis in the individual patient rests on endoscopy and biopsy, which is mandatory in all patients. The management then depends on the severity and effects of the gastritis (e.g. bleeding, acute or chronic symptoms), the removal of the underlying cause when applicable, or specific therapy (medical or surgical) when indicated. When the chronic gastritis is accompanied by dysplasia, surveillance by endoscopy is indicated and if the dysplasia becomes severe, then gastric resection is indicated.

Gastric tumours

Gastric adenocarcinoma

Incidence

Worldwide there is an estimated 930 000 new diagnoses and 700 000 deaths from gastric cancer. Overall incidence rates are 22 and 10.3 per 100 000 per annum in males and females respectively with the corresponding mortality rate being 14.3 per 100 000. Gastric cancer is the third most common cause of male cancer and the second most common cause of male cancer death. It is the fifth most common cause of female cancer and the fourth most common cause of female cancer death. Incidence rates in males are approximately double those in females and both sexes are strongly related to age. Most patients are between 60 and 80 years old at diagnosis.

There is a wide geographical variation in gastric cancer with the highest incidence in East Asia, South America and Eastern Europe and the lowest incidence seen in North America, Western Europe and Africa. Explanations of the geographical variation have been sought. High intake of traditional salt-preserved food and salt and low consumption of fresh fruit and vegetables are associated with a high risk of gastric cancer. In support of this observation, the gastric cancer incidence in migrants from low-incidence countries increased from a low rate in first-generation migrants to high incidence of their host country in the second generation. Also, *H. pylori* is a recognized risk in the development of gastric cancer. However, not all populations with high rates of *H. pylori* infection, such as Africa and South Asia, have a raised incidence of gastric cancer. Smoking is another environmental risk factor for gastric cancer.

The incidence of gastric cancer is declining. Even assuming the current decline, the incidence of gastric cancer will continue: the predicted growth in the world population combined with the increased longevity will most likely result in a net increase in the overall number of gastric cancers being diagnosed. Nevertheless, in the Western population there is an increase in adenocarcinoma of the gastric cardia, despite the decline in the incidence of gastric cancer.

Aetiology

Hereditary diffuse gastric cancer accounts for 1–3% of gastric cancer. In a third of familial gastric cancers, germline mutation in allele 1 of the E-cadherin gene (*CDH1*) is identified. Activation of the second allele occurs by either mutation or hypermethylation. Additional genotype changes lead to early onset of diffuse gastric cancer. The estimated life risk of gastric cancer in carriers of the *CDH1* mutation is 67% in men and 83% in women. Other hereditary syndromes that raise gastric cancer risk include Lynch syndrome (mutation in one of the mismatch repair gene) and Peutz–Jeghers syndrome (*SK11* mutation).

One of the most important aetiological factors associated with both intestinal and diffuse gastric cancer is *H. pylori*. Exposure to *H. pylori* results in inflammatory action and the production of reactive oxygen species and nitrous oxide which in turn deaminates DNA causing mutation. People who are positive to *H. pylori* have at least sixfold greater risk of developing gastric adenocarcinoma than those without infection. Long-term *H. pylori* infection may lead to atrophic gastritis and intestinal metaplasia with increased relative risk for developing gastric cancer ranging from 1.7 in moderate atrophy, 4.9 in severe atrophy to 6.4 in intestinal metaplasia. However, despite the high incidence of *H. pylori* infection in Africa and South Asia, the incidence of gastric cancer in those areas is much lower than in other countries. The incidence of gastric cancer tends to decrease from north to south in East Asia. Such geographical differences in the pathology can be explained at least in part by the presence of different types of *H. pylori* virulence factors, especially CagA, VacA and the right end of the Cag PAI.

Many studies showed that a diet high in fruit and vegetables reduces the risk of developing gastric cancer. While there are many potential mechanisms by which a diet rich in fruit and vegetables may be protective against gastric cancer, the active component is not clear. One possibility is related to the antioxidant capacity of fruit and vegetables. However, recent analysis did not find evidence that antioxidant supplements prevent gastrointestinal cancer in general or stomach cancer in particular.

A possible increase in risk of gastric cancer associated with alcohol intake has been suggested by meta-analysis of cohort and case–control studies of gastric cancer. However, on the basis of significant heterogenicity observed between studies, it is not possible to infer causality from these data.

Evidence that salt intake is inversely associated with stomach cancer has accumulated over many decades. There are many problems evaluating such studies because of the methods of measuring salt intake, the irritation effect of salt on the stomach lining and the development of atrophic gastritis is compounded by the effect of *H. pylori* infection, which is difficult to adjust for these studies. Also, the consumption of salty food commonly correlates with the intake of fresh vegetables and as a method of preservation and storage, which are difficult to control for those studies. Smoking is another aetiological factor. The results from both cohort and case–control studies are consistent with a causal role of tobacco smoking in the development of gastric cancer. There is a higher risk of gastric cancer among smokers than non-smokers in the order of 1.5–1.6.

With regard to PPIs, there is now sufficient experience to allow reasonable assessment of their safety in terms of cancer development. Long-term PPI use is associated with an increase in gastric inflammation and development of atrophy among those with active *H. pylori* infections. The actual risk is unknown but is certainly low. However, it can be markedly reduced or eliminated by *H. pylori* eradication leading to the recommendation that patients considered for long-term PPI therapy be tested for *H. pylori* infection and if present it should be eradicated. Oxyntic cell hyperplasia, glandular dilatations, and fundic gland polyps may develop in *H. pylori*-uninfected patients, but these changes are believed to be reversible and without significant cancer risk.

Histopathology

Gastric adenocarcinoma has two main types: the intestinal type and diffuse cancer. The *intestinal type* has well-defined ductal structures surrounded by desmoplastic stroma reaction containing different amounts of mixed inflammatory infiltrates. Tumour cells are large and nuclei are polymorphic and have a course chromaffin pattern. Mitotic figures are easily detected. Intestinal type carcinoma is usually well to moderately differentiated. The second type is *diffuse adenocarcinoma*, which has small groups of tumour cells without formation of glandular structure. Signet ring cell carcinoma has mucin-containing cells with nuclei at the periphery. It has extensive newly formed stroma making identification of cells difficult in standard haematoxylin and eosin sections.

It is important to realize that gastric carcinoma is a biologically heterogeneous disease involving numerous genetic and epigenetic alterations. A very small proportion of gastric cancers can be caused by a specific germline mutation of the *CDH1* gene. This cancer is developed through mismatched processes that begin with *H. pylori*-induced atrophic gastritis. Epstein–Barr virus is another infectious cause of gastric cancer. Mutations of tumour protein B53 -catenin genes occur early in the development of gastric cancer and contribute to gastric carcinogenesis. Also, a significant number of gastric cancers show loss of Runx3 due to homozygous deletion and hypermethylation of the promoter region. Cdx2 has been shown in precancerous lesions as well as gastric cancer. Gastric cancer with microsatellite instability is also a well-defined subset exhibiting distinct cardinal pathological features.

Diagnosis

Clinical assessment

There are no typical signs suggestive of gastric cancer. Patients can present with a variety of symptoms including epigastric pain, loss of appetite, weight loss, bleeding, obstruction or tiredness due to anaemia and perforation. It is important to realize that the majority of the symptoms are in advanced disease. Approximately 70% of patients with early gastric cancer have symptoms of uncomplicated dyspepsia with no associated anaemia, dysphagia or weight loss. The use of alarm symptoms to select patients for endoscopy may cause patients with localized disease to be overlooked. The recommendation in the UK is that patients with dyspepsia who are older than 55 years of age with persistent new symptoms or those with alarm features at any age should undergo endoscopy, as clinical diagnosis alone is inaccurate to distinguish between cancer and non-cancerous gastric disorders. All patients deemed to be at risk with dyspepsia should be considered for endoscopy, even though the overall detection rate is 1–3%.

The clinical examination of a patient with gastric cancer may reveal anaemia, positive Virchow lymph node or abdominal mass. Clinical examination is only positive in advanced disease. Routine blood and biochemistry are important to check for anaemia, dehydration or abnormal liver function.

Endoscopy

Upper gastrointestinal endoscopy with biopsies remains the gold standard for the diagnosis of gastric cancer. The reporting of endoscopic findings should be in a standard manner detailing the description of the lesion, satellite lesions, the distance from either the gastro-oesophageal junction or pyloris and the location in relation to the greater and lesser curvature. Thorough endoscopic examination is essential. Upper gastrointestinal tract endoscopy should not be regarded as an easy procedure performed by non-experienced endoscopists. Some studies found that about 10% of gastric cancers were missed at an earlier endoscopy in Western countries. It is important to realize that PPIs result in symptomatic improvement in patients with gastric cancer and also result in a degree of healing of ulcers due to gastric cancer.

Staging of gastric cancer

CT scan

The initial staging of gastric cancer should include CT scan with multiple planar reconstruction of the thorax, abdomen and pelvis to determine the presence of metastatic disease, the extent of lymph node involvement and local tumour invasion. The scan should be done with intravenous contrast using a protocol to distend the stomach. One litre of water can be used and gas-forming granules can be administered prior to scanning to achieve maximum distension in order to facilitate the delineation of gastric lesions. Studies have reported that CT scan has sensitivity between 92% and 95% and a specificity of 80–100% for T staging and a sensitivity of 62–90% and specificity of 50–87% for N status.

Endoscopic ultrasound

The main indications for EUS in gastric cancer are to (1) determine the extent of the proximal gastric lesion into the gastro-oesophageal junction; (2) confirm early lesions as these may need endoscopic submucosal resection or proceeding to surgery without neoadjuvant chemotherapy; and (3) examine invasion to the pancreas and other structures in selected cases. The reported sensitivity of EUS for T staging of gastric cancer is between 77% and 100% with a specificity of 67–95%. The reported sensitivity for N staging is between 30% and 96% with specificity of 48–98%. Nevertheless, EUS is not considered a routine investigation for all gastric cancer.

Staging laparoscopy

Laparoscopy with contact ultrasonography provides direct visualization of low-volume peritoneal and liver disease as well as assessing the extent of the tumour in the stomach. Peritoneal lavage and cytology is an integral component of laparoscopy to ensure the absence of small-volume peritoneal disease. The presence of positive peritoneal cytology will change the intent of management into palliative and is associated with poor long-term prognosis. Laparoscopy will upstage the disease in about 5–10% of patients because of peritoneal and liver lesions not seen on CT scan.

PET scan

PET scan if available may upstage patients with gastric cancer but it can be negative, especially in patients with mucinous and diffuse tumours. A PET scan may show distant metastatic disease, especially in patients with equivocal CT scan findings. A PET scan is not a routine investigation in staging gastric cancer.

Summary of preoperative investigations:

- routine bloods and biochemistry investigations such as full blood count, urea and electrolytes, and liver function test
- upper gastrointestinal tract endoscopy and biopsy to confirm the nature of gastric cancer
- staging of the disease with CT scan and staging laparoscopy
- EUS and PET scan may be done in selected cases.

Lymph node stations in gastric cancer

Description of lymph node (LN) stations (Japanese Gastric Cancer Association 2011) (Figure 23.25).

1	Right paracardial LNs, including those along the first branch of the ascending limb of the left gastric artery
2	Left paracardial LNs including those along the oesophagocardiac branch of the left subphrenic artery
3a	Lesser curvature LNs along the branches of the left gastric artery
3b	Lesser curvature LNs along the 2nd branch and distal part of the right gastric artery
4sa	Left greater curvature LNs along the short gastric arteries (perigastric area)
4sb	Left greater curvature LNs along the left gastroepiploic artery (perigastric area)
4d	Right greater curvature LNs along the 2nd branch and distal part of the right gastroepiploic artery
5	Suprapyloric LNs along the 1st branch and proximal part of the right gastric artery
6	Infrapyloric LNs along the first branch and proximal part of the right gastroepiploic artery down to the confluence of the right gastroepiploic vein and the anterior superior pancreatoduodenal vein
7	LNs along the trunk of the left gastric artery between its root and the origin of its ascending branch
8a	Anterosuperior LNs along the common hepatic artery
8p	Posterior LNs along the common hepatic artery
9	Coeliac artery LNs
10	Splenic hilar LNs including those adjacent to the splenic artery distal to the pancreatic tail, and those on the roots of the short gastric arteries and those along the left gastroepiploic artery proximal to its 1st gastric branch
11p	Proximal splenic artery LNs from its origin to halfway between its origin and the pancreatic tail end
11d	Distal splenic artery LNs from halfway between its origin and the pancreatic tail end to the end of the pancreatic tail
12a	Hepatoduodenal ligament LNs along the proper hepatic artery, in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas
12b	Hepatoduodenal ligament LNs along the bile duct, in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas
12p	Hepatoduodenal ligament LNs along the portal vein in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas
13	LNs on the posterior surface of the pancreatic head cranial to the duodenal papilla
14v	LNs along the superior mesenteric vein
15	LNs along the middle colic vessels
16a1	Para-aortic LNs in the diaphragmatic aortic hiatus
16a2	Para-aortic LNs between the upper margin of the origin of the coeliac artery and the lower border of the left renal vein
16b1	Para-aortic LNs between the lower border of the left renal vein and the upper border of the origin of the inferior mesenteric artery
16b2	Para-aortic LNs between the upper border of the origin of the inferior mesenteric artery and the aortic bifurcation
17	LNs on the anterior surface of the pancreatic head beneath the pancreatic sheath
18	LNs along the inferior border of the pancreatic body
19	Infradiaphragmatic LNs predominantly along the subphrenic artery

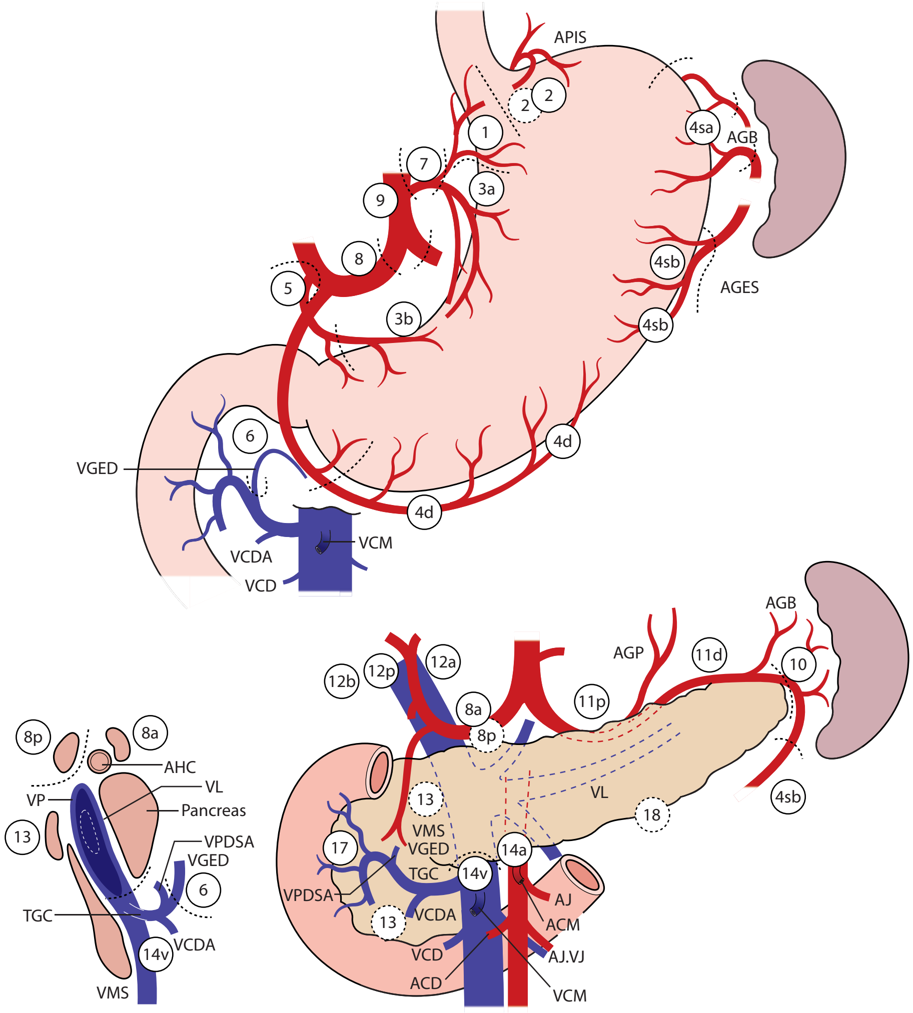

Figure 23.25 Description of lymph node stations (Japanese Gastric Cancer Association 2011). Please refer to text for key. AGB, ACM, AGP, AHC, AJ, TGC, VCD, VCDA, VCM, VGED, VMS, VPDSA.

20	Paraoesophageal LNs in the diaphragmatic oesophageal hiatus
110	Paraoesophageal LNs in the lower thorax
111	Supradiaphragmatic LNs separate from the oesophagus
112	Posterior mediastinal LNs separate from the oesophagus and the oesophageal hiatus

Management of gastric cancer (Figure 23.6)

Multidisciplinary team

Gastric cancer should be treated by a multidisciplinary team. The core members of the team include surgeons, gastroenterologists, oncologists, pathologists, interventional radiologists, palliative team and specialist nurses. All cases of gastric cancer should be discussed by the team to ensure adequate staging and an appropriate management plan. It has been shown that the workload of the surgeon is important for the outcome of gastric cancer in terms of postoperative morbidity and mortality because high-volume workload drives the processes of care and consequently improves early outcomes. The effect of surgeons' case loads on long-term outcome also depends on the quality of the surgery performed by surgeons. Long-term survival is a direct function of the stage of the disease and the extent of lymphadenectomy as a marker for surgical quality. Nevertheless, case workload and the extent of lymphadenectomy vary widely in clinical practice. Hospital case load is as important as surgeons' case load, although best results are seen in hospitals in which many patients are treated by surgeons with much experience.

Endoscopic treatment for early gastric cancer

Endoscopic resection has been accepted as a curative modality for early gastric cancer. Interventional mucosal resection was introduced in 1994 initially for early flat-type gastric cancer. The flat lesion is changed to a polypoid lesion by submucosal injection of a mixture of normal saline with diluted epinephrine (adrenaline) and dissected by grasper forceps and electrosurgical snare through a two-channel endoscope. This method has the advantage of easy technique, short procedure time and fewer complications, with a complete resection rate around 50–70%.

In 1988 the endoscopic mucosal resection (EMR) precutting method was developed in which, after hypertonic saline was diluted, epinephrine (adrenaline) is injected to the submucosal

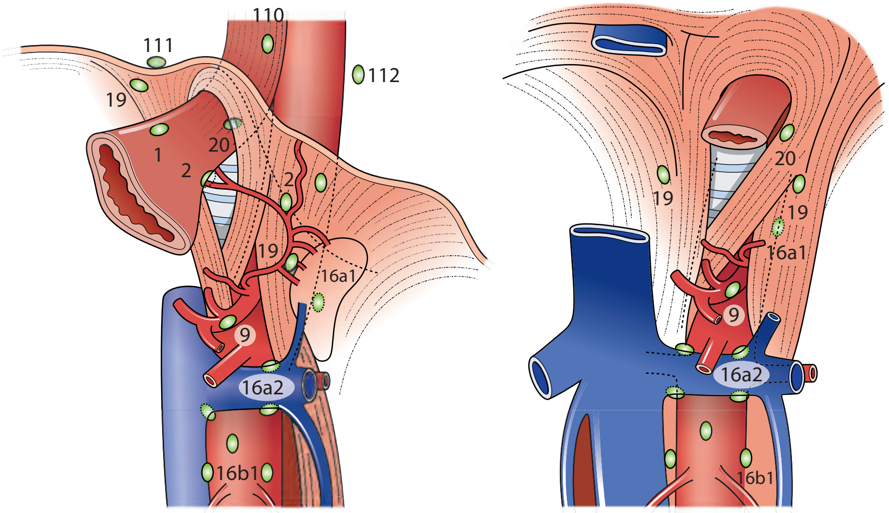

Figure 23.26 Diagrammatic representation of gastric station lymph nodes.

layer around the lesion; circumferential incision around the lesion with a needle knife and final resection of the lesion are performed with electrosurgical snares. This method has enabled complete envelope resection of the region rather than conventional EMR.

In 1992 EMR by a cap-fitted method was developed in which *en bloc* resection was performed with electrosurgical snare after suction of the lesion by a cap-fitted endoscope. Although this method was easier and safer than conventional EMR for *en bloc* resection of small early gastric cancer, *en bloc* complete resection with this technique was very difficult for larger sized lesions.

Endoscopic submucosal dissection (ESD) has been developed to overcome the limitations of EMR. In endoscopic submucosal resection circumferential incision and direct dissection of the submucosal layer of early gastric cancer has been possible with various knives. This enables complete resection, even in large or the depressed type of early gastric cancer. Various knives have been introduced for safe and complete ESD for early gastric cancer.

The rationale behind EMR is to maintain the quality of life without compromising long-term survival. This means that endoscopic resection of early gastric cancers should only take place in cases without lymph nodes or distant metastases to ensure that long-term survival rates are not inferior to surgical resection. Conventional indications for endoscopic resections are (1) differentiated adenocarcinoma confined to mucosa; (2) elevated lesion less than 2 cm; and (3) depressed type without an ulcer in less than 1 cm. With these indications the tumour rarely metastasizes to regional lymph nodes or distant organs. In the area of endoscopic submucosal resection, most limiting factors have been overcome in complete resection and the indications for ESD are decided by the risk of lymph node or distant metastases.

Early gastric cancer is defined as tumour of the stomach confined to the mucosa or submucosa. For this tumour, the risk of lymph node metastasis is very low. Systematic review of the effectiveness and safety of endoscopic resection was identified in a non-randomized trial comparing endoscopic resection treatment. The results of studies of endoscopically treated patients showed disease-specific survival at 5 years and 10 years of more than 95%. Incidence of local recurrence is only 6%, and the chance of complication compares favourably with surgery (0.6% perforation and 14% bleeding). Prophylactic eradication of *H. pylori* after EMR significantly reduces the development of metachronous tumours. Risk of lymph node metastasis rises with increased tumour stage. For early gastric cancer the risk of lymph node metastasis is between 2% and 5% in patients with mucosal cancer and 10–20% for those with submucosal cancer.

The following management of early gastric cancer by endoscopic resection is according to the Japanese Gastric Cancer Guidelines in 2010. In EMR, the lesion together with the surrounding mucosa is lifted by submucosal injection of saline and removed using high-frequency electrosurgery steel snare. In ESD, the mucosa surrounding the lesion is circumferentially incised using a high-frequency electric knife and the submucosal layer is dissected from the proper muscle layer. The lesion is histologically classified as either differentiated or undifferentiated type. The former includes capillary adenocarcinoma and tubular adenocarcinoma. The latter includes poorly differentiated adenocarcinoma, signet ring cell carcinoma and mucinous adenocarcinoma. The tumour consisting of both differentiated- and undifferentiated-type carcinoma is classified according to the quantitative predominance. Diagnosis of ulcerative findings is principally based on histological evidence of ulcerative findings.

The standard indication for EMR or ESD is differentiated-type adenocarcinoma without ulcerative findings of which the depth of invasion is clinically diagnosed as T1a and the diameter is less than 2 cm. Curative resection is judged when all the following conditions are fulfilled: *en bloc* resection, tumour size less than 2 cm, histologically or differentiated type, pT1a, negative horizontal margin, negative vertical margin and no lymph or vascular infiltration. There are expanded criteria for ESD which is regarded by the Japanese Cancer Association as investigational at this stage. After endoscopic curative resection, *H. pylori* should be tested and if positive eradicated. Follow-up by annual endoscopy is recommended.

Surgery

Surgery is the mainstay for curative treatment for gastric cancer.

Curative surgery

1. Standard gastrectomy is the principal surgical procedure performed with curative intent. It involves resection of at least two-thirds of the stomach with D2 lymph node dissection.
2. In a non-standard gastrectomy the extent of gastric resection and/or lymphadenectomy is altered according to the tumour characteristics.
   - In modified surgery the extent of gastric resection and/or lymphadenectomy is reduced compared to standard surgery.
   - In extended surgery, gastrectomy with combined resection of adjacent involved margin or gastrectomy extended lymphadenectomy beyond D2 resection.

Non-curative surgery

Palliative surgery is indicated for bleeding or obstruction in patients with advanced gastric cancer with unresectable metastases. Palliative surgery usually aims to relieve the symptoms. Palliative gastrectomy or gastrojejunostomy is selected depending on tumour characteristics and surgical risk. However, palliative surgery is an extremely uncommon procedure in Western centres because of the advances of pyloric stents and oncological management.

Extent of gastric resection

A sufficient gastric resection margin should be ensured when determining the resection line in operations with curative intent. A proximal margin of at least 3 cm is recommended for T2 or deeper tumours with expansive growth pattern types I and II, and 5 cm is recommended for those with expansive growth pattern types III and IV. When tumours invade the gastro-oesophageal junction a 5 cm margin may not be achieved, and therefore frozen section is recommended to ensure R0 resection. The standard surgical procedure for clinically node positive or T2 to T4a tumours is either total or distal gastrectomy. Distal gastrectomy is selected when a satisfactory proximal margin can be obtained. Pancreatic invasion by tumour requiring pancreaticosplenectomy necessitates total gastrectomy regarding the tumour location. Total gastrectomy with splenectomy should be considered for tumours that are located along the greater curvature and harbour metastasis to 4sb lymph nodes even if the primary tumour could be removed by distal gastrectomy.

For T1N0 tumours, gastric resection can be modified as pyloric preserving gastrectomy for tumours in the middle portion of the stomach with distal tumour at least 4 cm proximal to the pylorus and proximal gastrectomy for proximal tumours more than half of the distal stomach being preserved.

For a proximal gastric tumour invading the gastro-oesophageal junction, gastrectomy with lower oesophagectomy is recommended. If the tumour invading the oesophagus is less than 2 cm, a total abdominal approach with transhiatal resection of the lower oesophagus and lower mediastinal lymph nodes can be achieved. If the tumour extends more than 2 cm into the oesophagus, patients usually require left thoracolaparotomy. Extensive gastric tumour involving the junction more than 2 cm usually requires total gastrectomy with lower oesophagectomy with Roux-en-Y oesophagojejunal reconstruction.

Omentectomy

Removal of gastric omentum is usually integrated in standard gastrectomy for T3 or debulked tumours. Bursectomy has a survival benefit in T3 and T4a tumours. For tumour penetrating the serosa or the posterior gastric wall, complete bursectomy including the pancreatic capsule is performed with the aim of removing microscopic tumour deposits in the lesser sac. Bursectomy should be avoided in T1–T2 tumours to minimize chances of injury to the pancreas.

Combined resection

It is essential to obtain R0 resection and therefore, for tumour invading adjacent organs, combined resection may be necessary.

Laparoscopic surgery

The benefits of laparoscopic surgery in benign disease and colorectal cancer surgery have encouraged surgeons to adopt this in gastric cancer. There is a wide variation in the indications of laparoscopy between the Western countries and Japan. In Japan, although the laparoscopic approach is widely performed for early distal gastric cancer, it is still considered an investigational procedure. The long-term oncological value of laparoscopic distal gastrectomy is not proven in the randomized control trial and we are still awaiting the outcomes in those trials in Japan and Korea. Small randomized control trials showed the potential benefit in terms of general postoperative outcomes, although trials have shown no difference in major postoperative complications. Some trials documented shorter hospital stay with the laparoscopic approach. It is important to recognize that the aim of surgery for gastric cancer is long-term cure. If the surgeon feels that the laparoscopic approach may compromise the oncological quality of the resection, surgeons should revert to the traditional open approach.

Lymph node dissection

The extent of systemic lymphadenectomy is defined according to the type of gastrectomy indicated.

Total gastrectomy

- D1: lymph node stations 1–7
- D1+: D1 + lymph node stations 8a, 9, 11p
- D0: lymphadenectomy less than D1
- D2: D1+ 8a, 9, 10, 11p, 11d, 12a

For tumours invading the oesophagus, D1+ includes lymph node station 110 (lower thoracic, paraoesophageal nodes), and D2 includes lymph node stations 19, 20, 110 and 111.

Distal gastrectomy

- D1: lymph node stations 1, 3, 4sb, 4d, 5, 6, 7
- D1+: D1 + lymph node stations 8a and 9
- D0: lymphadenectomy less than D1
- D2: D1 + lymph node stations 8a, 9, 11p, 12a

Pyloric preserving gastrectomy

- D1: lymph node stations 1, 3, 4sb, 4d, 6, 7
- D1+: D1 plus lymph node stations 8a and 9
- D0: lymphadenectomy less than D1

Proximal gastrectomy

- D1: lymph node stations 1, 2, 3a, 4sa, 4sb and 7
- D1+: D1 + lymph node station 8a, 9, 11p
- D0: lymphadenectomy less than D1

In principle D1 or D1+ lymphadenectomy is indicated for T1N0 tumours and D2 is indicated for N+ or T2–T4 tumours. Because the pre- and intraoperative diagnosis of lymph node metastasis may need revision, D2 lymphadenectomy should be performed whenever nodal involvement is suspected. D1 lymphadenectomy is indicated for a T1a tumour that does not meet the criteria for EMR and for T1bN0 tumours that are not histologically of the differentiated type and 1.5 cm or smaller in diameter. A D1+ lymphadenectomy is indicated for T1N0 tumours other than the above. D2 lymphadenectomy is indicated for potentially curable T2–T4 tumours as well as T1N+ tumours.

D2+ lymphadenectomy: gastrectomy with extended lymphadenectomy beyond D2 is classified as a non-standard gastrectomy. The benefit of prophylactic para-aortic lymphadenectomy was not proven in the Japanese randomized control trial.

Rationale for lymph node dissection

Evidence for D1 dissection

Two randomized trials in the Western countries (MRC trial and the Dutch trial) showed no significant survival benefit of D2 lymphadenectomy. The 5 year survival in the MRC trial was 35% for D1 vs 33% for D2 while in the Dutch trial it was 45% for D1 vs 47% for D2. This equality of long-term survival was associated with higher morbidity and mortality for D2 lymph node dissection. The postoperative mortality was 6.5% vs 13% and 4% vs 10% for D1 vs D2 in the MRC and Dutch trials respectively. The morbidity was 28% vs 46% and 25% vs 43% for the D1 vs D2 gastrectomy in the MRC and Dutch trials respectively. The conclusion from both trials favoured D1 gastrectomy because of similar long-term survival while D1 has a better early postoperative outcome. Therefore the value of D2 dissection was not proven by these trials. The trials also showed that D2 was technically a more demanding operation. Nevertheless, the results of those trials were inferior compared with specialized Western centres.

There are several factors responsible for the outcomes of these trials. The annual average number of cases per hospital was 1 and 1.5 resections for the Dutch and MRC trials respectively. The surgical inexperience and the learning curve occurring throughout the trials may have impacted on the results of both arms of the trial. In the Dutch trial, the contamination rate of 52% in D1 resection (performance of more extensive dissection than specified) and a non-compliance rate of 84% in D2 gastrectomy (performance of less dissection than specified) led to partial homogenization of the groups undermining the likelihood of detecting any potential advantage to D2 dissection. Similarly in the MRC trial only 75% of D2 group had an adequate lymphadenectomy. Also, the high 30 day mortality offsets the effects of D2 dissection in the long term. This inadequate surgical performance was coupled with inexperience in managing postoperative complications. For instance, the mortality rate was 41.3% and 20% for patients who developed anastomotic leakage and pancreatic fistula, respectively, in the Dutch trial.

The evidence drawn from the randomized control trials conducted more than 20 years ago may not be applicable to modern surgical treatment for gastric cancer, as practice has changed significantly. Nowadays, surgery for invasive gastric cancer is carried out in regional high-volume centres by multidisciplinary teams with careful case selection and appropriate high-quality postoperative support. The reported outcomes of D2 cohort studies from several European high-volume centres have shown a lower postoperative mortality and a better 5 year survival than those reported in the MRC and Dutch trials. The principal investigator in the MRC D1 vs D2 gastrectomy randomized control trial believes that the results of this trial are no longer a sustainable argument against D2 gastrectomy in modern surgery for invasive gastric cancer. The fact is that every randomized control trial has a limited lifespan during which its data should influence surgical practice and, although we should adhere firmly to the practice of evidence-based medicine, we should also recognize that like everything else in life including results of randomized control trials have a sell-by date and that pertaining to the MRC D2 gastrectomy has now expired.

Evidence for D2 lymphadenectomy

- Biological behaviour of cancer spread
- Pattern of recurrence
- Value of local control
- Survival after D2 gastrectomy dissection
- Morbidity and mortality after D2 dissection

The incidence of lymph node metastasis with gastric cancer highlights the biological behaviour of gastric cancer. The data from the National Cancer Centre, Tokyo, showed that the incidence of positive lymph nodes with pT2 is 46–64%, for pT3 is 78.9% and for pT4 is 89.8%. This means that limited lymphadenectomy is likely to leave tumour in the non-resected stations.

With regard to recurrence after limited resection, local recurrence and/or lymph node metastasis are the only failures in 53.7% of the failure group when localized peritoneal failure is included, and as a component of failure in 87.8% of patients. By contrast, lymph node recurrence after D2 lymphadenectomy in the National Cancer Centre, Tokyo, is 7%. This contrast highlights the value of lymphadenectomy in minimizing local disease recurrence. It is known that local recurrence is very difficult to palliate and compromises the quality of life of patients. Good local control is essential in the management of cancers and R0 is the most important prognostic factor after gastrectomy, as shown in many clinical studies. The postoperative chemotherapy randomized control gastric trial (IT-116/SWOG) showed that chemoradiotherapy improves survival after limited gastrectomy. It also showed that surgical undertreatment was an independent prognostic factor in retrospective analysis of the trial. Subgroup analysis showed that chemoradiotherapy does not improve survival following D2 gastrectomy. These data showed that D0/D1 are inadequate for local control requiring chemoradiotherapy to improve the outcome.

The value of D2 gastrectomy has been proven in several D2 cohort studies from European centres which showed postoperative mortality less than 5% and 5 year survival of 50–60%, approaching the Japanese standard. This encouraged surgeons to adapt extended lymphadenectomy with improved results. Also the 15 year follow up of the Dutch trial showed a significant survival benefit of extended lymphadenectomy. The benefit of D2 gastrectomy was proved in the Taiwan randomized control trial, which showed overall long-term survival benefit with extended lymphadenectomy compared with D1 dissection. No postoperative death occurred in either group. However, D2 gastrectomy caused increased morbidity. It is important to note that distal pancreatectomy and splenectomy should not be routinely done in D2 gastrectomy because they increase the morbidity and mortality of the operation.

Perioperative chemotherapy

The MAGIC trial demonstrated that a treatment plan of three cycles of preoperative and postoperative epirubicin (E) 50 mg/m^2, cisplatin (C) 60 mg/m^2 and continuous intravenous infusion of 5-fluorouracil (F) 200 mg/m^2 per day (ECF) significantly improved 5 year survival from 23% with surgery alone to 36.3%. The main non-haematological toxicity was alopecia, nausea and vomiting. The results were supported by the FFCD trial. This perioperative approach has been adopted as the standard of care in most of the UK and parts of Europe. Because of the non-inferiority of capecitabine (X) compared with 5FU in advanced gastric cancer and because it obviates the need for an indwelling central venous access device, many centres use ECX in the perioperative setting.

Postoperative chemoradiotherapy

A North American intergroup randomized trial demonstrated that five cycles of postoperative chemotherapy with 5FU/leucovorin before, during and after radiotherapy (45 Gy in 25 fractions over 5 weeks) resulted in about a 15% improvement in overall survival. Although this treatment is considered to be the standard in the USA, it has not gained acceptance in Europe because of the late toxicity with abdominal chemoradiotherapy and because of the quality of surgery used in this trial. Only 10% of trial participants underwent D2 dissection, whereas the beneficial effect of postoperative chemoradiotherapy appeared greatest in patients who received D1 dissection (36%) or less than D1 (54%) resections. Although this study suggested that postoperative chemoradiation compensates for suboptimum surgery, a large non-randomized observational study suggested a potential benefit for postoperative chemoradiation after D2 dissection. The results of the randomized study from Korea in which patients were given either capecitabine and cisplatin chemotherapy or capecitabine and cisplatin chemoradiotherapy after D2 resection are awaited with great interest. In a meta-analysis, postoperative chemoradiotherapy was reported to improve survival significantly. Modern high-precision radiation techniques and more intensified chemoradiation regimes are more likely to further improve the results of postoperative chemoradiation.

Adjuvant chemotherapy

Several meta-analyses have suggested a small survival benefit for adjuvant chemotherapy. However, there is considerable variation between the treatment regimes and outcomes between Western and Asian populations. The Japanese adjuvant chemotherapy trial of Ts1 for gastric cancer demonstrated a significant benefit in overall survival for patients receiving 12 months of S1 (an oral fluoroamidine) monotherapy compared with observation after curative D2 gastrectomy for node-positive disease. No similar trial has been carried out in Western populations. Adjuvant chemotherapy alone is not a standard practice in the UK, although it may be used in patients with high risk of recurrence who did not have neoadjuvant chemotherapy.

Neoadjuvant chemoradiotherapy

Neoadjuvant chemoradiation with cisplatin and etoposide after induction chemotherapy with cisplatin, 5FU and leucovorin is feasible for locally advanced carcinoma at the gastro-oesophageal junction. However, the study was underpowered due to poor recruitment. There are small randomized controlled trials which showed that neoadjuvant chemoradiotherapy results in improved overall 3 year and 5 year survival. A meta-analysis comparing surgery with surgery preceded by radiotherapy showed significant improvement in 3 and 5 year survival without a rise in postoperative mortality. Although these studies showed advantages of preoperative radiotherapy and surgery, further studies are unlikely because current research is directed towards either perioperative chemotherapy or postoperative chemoradiotherapy. Theoretically neoadjuvant chemoradiation could be a good strategy because chemotherapy would not be delayed by postoperative recovery; the treatment target area is easy to identify because the tumour and stomach are still in the normal position, with good vascularization and oxygenation of tumour tissue without major anatomical deviation; and tumour downsizing could facilitate surgery. A disadvantage is that the pathological staging is unavailable.

Staging of gastric cancer

Rules for classification

The classification applies to carcinomas. There should be histological confirmation of the disease. A tumour the epicentre of which is within 5 cm of the oesophagogastric junction and also extends into the oesophagus is classified and staged according to the oesophageal scheme. All other tumours with an epicentre in the stomach greater than 5 cm from the oesophagogastric junction, or those within 5 cm of the junction without extension into the oesophagus, are staged using the gastric carcinoma scheme.

The following are the procedures for assessing T, N and M categories:

- T categories: physical examination, imaging, endoscopy and/or surgical exploration
- N categories: physical examination, imaging and/or surgical exploration
- M categories: physical examination, imaging and/or surgical exploration.

Regional lymph nodes

The regional lymph nodes of the stomach are the perigastric nodes along the lesser and greater curvatures, the nodes along the left gastric, common hepatic, splenic and coeliac arteries and the hepatoduodenal nodes. Involvement of other intra-abdominal lymph nodes such as retropancreatic, mesenteric and para-aortic is classified as distant metastasis.

TNM clinical classification (version 7)

TNM classification (version 7) showed a better prognostic predictive ability than TNM (version 6) in both T and N status.

T – Primary tumour

- Tx: Primary tumour cannot be assessed
- T0: No evidence of primary tumour
- Tis: Carcinoma *in situ*: intraepithelial tumour without invasion of the lamina propria, high-grade dysplasia
- T1: Tumour invades lamina propria, muscularis mucosae or submucosa
  - T1a: Tumour invades lamina propria or muscularis mucosae
  - T1b: Tumour invades submucosa
- T2: Tumour invades muscularis propria
- T3: Tumour invades subserosa
- T4: Tumour perforates serosa or invades adjacent structures
  - T4a: Tumour perforates serosa
  - T4b: Tumour invades adjacent structures
- The adjacent structures of the stomach are the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine and retroperitoneum.
- Intramural extension to the duodenum or oesophagus is classified by the depth of greatest invasion in any of these sites, including the stomach.
- Tumour that extends into gastrocolic or gastrohepatic ligaments or into greater or lesser omentum, without perforation of visceral peritoneum, is T3.

N – Regional lymph nodes

- Nx: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Metastasis in 1 or 2 regional lymph nodes
- N2: Metastasis in 3–6 regional lymph nodes
- N3: Metastasis in 7 or more regional lymph nodes
  - N3a: Metastasis in 7–15 regional lymph nodes
  - N3b: Metastasis in 16 or more regional lymph nodes

M – Distant metastasis

- M0: No distant metastasis
- M1: Distant metastasis
  - Distant metastasis includes peritoneal seeding, positive peritoneal cytology and omental tumour not part of continuous extension.

In *pTNM Pathological Classification,* the pT and pN categories correspond to the T and N categories.

- pN0: Histological examination of a regional lymphadenectomy specimen will originally include 16 or more lymph nodes. If the lymph nodes are negative, but the number ordinarily examined is not met, classify as pN0.
- pM1: Distant metastasis microscopically confirmed.

G histopathological grading

- Gx: Grade of differentiation cannot be assessed
- G1: Well differentiated
- G2: Moderately differentiated
- G3: Poorly differentiated
- G4: Undifferentiated

Stage grouping

- Stage 0: TisN0M0
- Stage 1A: T1N0M0
- Stage 1B: T2N0M0
  - T1N1M0
- Stage IIA: T3N0M0
  - T2N1M0
  - T1N2M0
- Stage IIB: T4aN0M0
  - T3N1M0
  - T2N2M0
  - T1N3M0
- Stage IIIA: T4aN1M0
  - T3N2M0
  - T2N3M0
- Stage IIIB: T4BN0, N1M0
  - T4aN2M0
  - T3N3M0
- Stage IIIC: T4aN3M0
  - T4bN2, N3M0
- Stage IV: Any T, Any NM1

Summary

- T1: Lamina propria (T1a), submucosa (T1b)
- T2: Muscularis propria
- T3: Subserosa
- T4a: Perforates serosa
- T4b: Adjacent structures
- N1: 1 or 2 nodes
- N2: 3–6 nodes
- N3a: 7–15 nodes
- N3b: 16 or more

Quality of pathological examination

As discussed earlier the value of extended lymphadenectomy by the surgeon is recognized. The TNM staging necessitates a minimum of 16 lymph nodes for staging. The authors of this chapter believe that it is important to retrieve the maximum number of lymph nodes from any given specimen.

This is essential for accurate staging as the N staging of the TNM classification depends on the number of lymph nodes involved with metastasis. Ignoring small lymph nodes can be a major cause of staging error. For instance, if nodes 5 mm or less are ignored, 38% of all metastatic nodes will be missed. Downstaging will occur in 15% and 4% of the cases if nodes of less than 6 and 4 mm respectively are ignored. Accurate staging determines disease prognosis and the need for adjuvant oncological treatment in advanced cases. In addition, the lymph node number is a measure for the extent of lymphadenectomy and operative performance. This is particularly important in oncological trials when added value of oncological therapy is evaluated in a combined arm against surgery alone.

Primary gastric lymphoma

A primary gastric lymphoma is generally non-Hodgkin's lymphoma. They represent 5% of gastric malignancies and show an apparently increasing incidence worldwide. Primary and secondary involvement of the stomach is extremely rare in Hodgkin's disease.

Histological characteristics

Primary extranodal non-Hodgkin's lymphoma was taken into consideration for the first time in 1994 with the REAL classification (Revised European American Lymphoma classification). The WHO classification originates directly from the REAL classification and distinguishes over 30 different forms. As a result non-Hodgkin's gastric lymphoma forms a very heterogeneous group of lymphoproliferative tumours with a wide variety of biological and clinical responses to treatment. There are two main histological types: diffuse large B-cell lymphoma and marginal zone B-cell lymphoma of MALT type. Follicular, mantle cell and peripheral T-cell lymphomas represent about 2% of gastric lymphomas.

Pathogenesis of B-cell MALT gastric lymphoma

This is associated with chronic *H. pylori* infection. MALT lymphoma represent 8% of all B-cell lymphomas and approximately 50% of gastric lymphomas. They originate in the stomach from lymphatic tissue that is in association with the mucous membrane, which usually develops following chronic *H. pylori* infection. *H. pylori* is detected in 60% of gastric lymphomas. The presence of *H. pylori* is significantly more frequent in patients with lymphoma restricted to the mucosa and submucosa (76%) than in those with lymphoma invading beyond the submucosa (48%). It is also more common in patients with maltomas than in those with high-grade tumours. The frequency of *H. pylori* positivity is significantly lower in gastric lymphoma cases than in chronic active gastritis (100%) or peptic ulcer disease (91%). In a large case–control study, there was a statistically significant association between previous *H. pylori* infection and the development of primary gastric lymphomas with either low-grade (MALT type) or high-grade diffuse large cells (histology). The correlation between *H. pylori* and lymphomas has been confirmed on biological and molecular levels both through gastric biopsies showing the presence of B lymphocytic clones that will later give origin to the tumour and through the ability to induce growth of the lymphomatous tissue *in vitro* when stimulated by *H. pylori* in culture. Importantly, it is known that *H. pylori* eradication with antibiotics is able to induce remission of gastric MALT lymphomas in the majority of cases.

In MALT lymphomas at least three recurrent chromosomal translations have been identified and together are present in approximately 65% of cases: the t(11:18)(q21) translocation, which causes the formation of the chimaeric fusion chain AP12-MALT1; the t(1:14)(p22:q32) translocation, which causes deregulation of PCL10; and the t(14:18)(q32:q21) translocation, causing the deregulation of MALT1.

Pathogenesis of diffuse large B-cell gastric lymphomas

In a high percentage of extranodal high-grade lymphomas, the oncogene BCL6 (located in chromosome 3q27) is altered due to translocations, somatic hypermutation or deregulation mutations involving the promoter region. These three arrangements induce an overexpression of the gene which seems to predict a better prognosis.

Grade of lymphomas

The grading of gastric lymphoma is important in both prognosis and treatment. Most gastric lymphomas are of B-cell origin and divided into low-grade and high-grade tumours. Low-grade MALT lymphomas are fairly indolent tumours that often remain localized for extended periods of time. High-grade MALT lymphomas perforate and disseminate more rapidly. The frequency of lymph node involvement also correlates with the grade of lymphoma.

Clinical picture

The initial clinical picture is often non-specific and indicative of a gastric or ulcerative process rather than a neoplasm. The most common symptoms are epigastric pain and dyspepsia with nausea and vomiting, anorexia and weight loss. Gastrointestinal haemorrhage occurs in the outset in 20% of patients, whereas gastric occlusion and perforation are quite uncommon. On examination, it is important to palpate all lymph node regions as well as the abdomen for hepatosplenomegaly or organomegaly.

Investigations

Routine laboratory investigations include full blood count, biochemistry, liver function tests and serum protein electrophoresis. Diagnosis is usually established with upper gastrointestinal tract endoscopy. The three main patterns are ulcerative, diffuse infiltration or polypoid mass. Therefore the endoscopic findings can range from gastritis-like and superficial ulcers to diffuse thickening and granularity of mucosal folds and submucosal mass-like effect. CT scan of the chest, abdomen and pelvis is required. Abdominal CT scan abnormalities are found in 70% of patients and include gastric wall thickening and lymphadenopathy. These abnormalities are more common with high-grade lymphoma than low-grade lymphoma

(100% vs 51%). PET is important in staging lymphomas (Box 23.6) as it will demonstrate extragastric metabolically active lymphadenopathy.

Management

Treatment of early-stage H. pylori-positive MALT-type gastric lymphoma

The most widely accepted initial treatment for localized disease is aimed at eradication of *H. pylori* infection using a combination of antibiotics and PPIs. Numerous reports confirmed the effectiveness of antibiotics in sustaining long-term remission in 60–100% of patients with localized *H. pylori*-positive maltoma. There is no evidence to suggest additional treatment with chemotherapy in patients who respond to eradication therapy.

Treatment of patients with advanced or H. pylori-negative MALT-type gastric lymphomas

In general *H. pylori*-negative gastric MALT lymphomas do not regress when treated with antibiotics, but some response has been reported in early-stage cases and therefore due to the indolent nature of the disease and taking into account more aggressive approaches used in antibiotic-refractory patients, an initial therapeutic attempt might be considered for *H. pylori*-negative patients with MALT lymphomas confined to the stomach. Excellent results in local disease control have been reported using radiotherapy on the stomach and perigastric lymph nodes.

Up to 90% of patients receiving radiotherapy alone achieved a complete response with 5 year disease-free survival and an overall survival rate of 98% and 77% respectively. There are now sufficient data to demonstrate that conservative therapy permits a better quality of life with no negative impact on survival rates. Therefore, surgery no longer has a central role in the therapeutic strategy and is reserved only for carefully selected cases in which alternative treatments are not possible. Surgery is also used for the treatment of complications.

In all patients with disease that has spread, systemic therapy similar to that of advanced lymphomas must be taken into consideration. Treatment options include chemotherapy and the use of monoclonal antibodies.

BOX 23.6 International Workshop Staging System for gastrointestinal non-Hodgkin's lymphoma

Stage I Tumour confined to the gastrointestinal tract
- Single primary site or multiple non-continuous lesions

Stage II Tumour extending to the abdomen for the primary gastrointestinal site
- Nodal involvement:
- II1 local (paragastric or paraintestinal)
- II2 distant (mesenteric para-aortic, paracaval, pelvic, inguinal)

Stage III Penetration of the serosa to involve adjacent organs or tissue

Stage IV Disseminated extranodal involvement or gastrointestinal tract lesion with supradiaphragmatic nodal involvement

Treatment of high-grade gastric lymphoma

Diffuse large -cell non-Hodgkin's lymphoma represents the most common histological type of lymphoma. The treatment is based on aggressive polychemotherapy that is usually combined with rituximab. The need for surgery for these cases has completely disappeared because of the advances in chemotherapy and staging modality. There is no need for surgery as a staging procedure. The same guidelines followed for aggressive lymphomas can be applied to gastric lymphoma with aggressive histology.

Follow-up

Regular follow-up is mandatory as negative biopsy cannot exclude the presence of aggressive diffuse large -cell lymphoma and should require proactive therapy with curative intent. EUS with multiple biopsies should be done 3–6 months following *H. pylori* eradication to evaluate lymphoma regression, repeated every 6 months for 2 years. For aggressive histology, CT scan every 3 months for 2 years is recommended. When performed and it shows a positive diagnosis, the PET scan should be repeated.

In summary, most strategies for the treatment of gastric lymphoma no longer include surgical resection in primary treatment and surgery is reserved for the management of complications or unique cases or locally persistent disease.

Gastric gastrointestinal stromal tumour

Epidemiology

GIST is a rare sarcomatous tumour of the gastrointestinal tract with an incidence of 10–20/million per annum. It occurs most frequently in the submucosal connective tissue of the stomach (50–70%). Additionally, the small intestine (20–30%) and, more rarely, oesophagus, colon, rectum, omentum and mesentery are also sites of GIST formation. There is a higher propensity in men with a median age of diagnosis between the fifth and seventh decades.

GISTs are the result of mutations of either the *c-kit* proto-oncogene (encoding the cytokine receptor protein CD117/KIT protein) or *PDGFRA* gene (which encodes the cell surface tyrosine kinase receptor, -type platelet-derived growth factor receptor). Eighty per cent of mutations occur in the *c-kit* gene whereas 5–10% occur in the *PDGFRA* gene. Ten to 15% of cases of GISTs have no detectable gene mutation; however, the diagnosis is not excluded by their absence.

Pathology

Histologically, GISTs are predominantly composed of spindle-shaped tumour cells (70%) but some can show evidence of epithelioid tumour cells (20%) or even a combination of the two cell types, the so-called 'mixed type' (10%). As a result, standard haematoxylin and eosin staining can make it difficult to differentiate GISTs from other spindle cell tumours such as leiomyoma or leiomyosarcoma as well as carcinomatous and carcinoid lesions especially in the presence of epithelioid-type GISTs.

As a result, although a large part of tissue diagnosis is based on standard histological findings, immunostaining is a necessary investigative component for histological confirmation of a GIST. The KIT/CD117 protein is the most important of these markers. GISTs share a common precursor with the interstitial cells of Cajal, which regulate autonomic gut peristalsis and are found between the longitudinal and circular layer of the muscularis propria. The KIT protein is expressed on these cells and is known to be positive in upwards of 95% of GISTs, but is rarely expressed in other abdominal tumours (but may be positive in non-abdominal tumours such as melanoma, seminoma and breast cancer). Additionally, CD34 (positive in 70%), smooth muscle actin (positive in 40%), PS-100 (positive in 5%) and desmin (positive in 2%) are further considered to be useful immunohistochemical markers when diagnosing GIST.

In cases of KIT-negative GISTs (5%), molecular analysis of *c-kit* and *PDGFRA* is considered a useful adjunct for confirming the diagnosis, with their detection having the potential to predict patient response to the tyrosine kinase inhibitors (TKIs). However this technique is not yet widely available and remains predominantly a research tool.

Clinical picture

Presenting features of gastric GIST are often non-specific and, in the case of small tumours, will most often be found on a routine gastroscopy or imaging (CT, MRI, etc.) of the abdominal cavity in asymptomatic patients for an unrelated pathology. Symptomatic patients will typically have larger tumours. GISTs are known to be soft and friable, and gastric GISTs in particular may present with abdominal pain or acute haemorrhage. As tumours tend to grow outwards into the abdominal cavity without impinging on organs, obstruction is rare. Metastatic spread is via the haematogenous route, most frequently to the liver or peritoneal cavity and patients may occasionally present with signs and symptoms of advanced disease.

Diagnosis

Gastric GIST is most commonly diagnosed via direct endoscopy as a submucosal tumour when undertaking a routine gastroscopy. However, given the small circumferential nature of the lesion and non-specific appearance, it must be distinguished from a wide range of differentials including lipoma, leiomyoma, metastatic tumour, carcinoma and gastric cancer.

EUS and fine-needle aspiration biopsy (FNAB) are relatively novel techniques which are increasingly employed to obtain samples from small tumours (especially those up to 3 cm in size) that may not be amenable to standard endoscopic biopsy. This is a specialized technique which allows visualization of tumour up to its origin in the submucosa and together with echogenicity will provide an accurate assessment of its nature.

CT scanning of the abdominal cavity with intravenous contrast allows tumours to be differentiated from the surrounding structures. CT gives the additional benefit of being widely available and permitting tumour grading and staging (as well as being a modality for follow-up imaging), but the resolution of current scanners for small tumours (<2 cm) is limited.

Classification of gastrointestinal stromal tumour

TNM clinical classification

T – Primary tumour

- Tx: Primary tumour cannot be assessed
- T0: No evidence for primary tumour
- T1: Tumour 2 cm or less
- T2: Tumour more than 2 cm but not more than 5 cm in greatest dimension
- T3: Tumour more than 5 cm but not more than 10 cm in greatest dimension
- T4: Tumour more than 10 cm in greatest dimension

N – Regional lymph nodes

- Nx: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Regional lymph node metastasis

Regional lymph node involvement is rare for GISTs, so that cases in which the nodal status is not assessed clinically or pathologically could be considered N0 instead of Nx or pNx.

M – Distant metastasis

- M0: No distant metastasis
- M1: Distant metastasis

G histopathological grading

Grading for GIST is dependent on the mitotic rate. The mitotic rate of GIST is best expressed as the number of mitoses per 50 high-power fields (HPF) using the 40× objective (total area 5 mm^2 in 50 fields):

- low mitotic rate: 5 or fewer per 50 HPF
- high mitotic rate: over 5 per 50 HPF.

Stage grouping

- Stage 1A: T1, T2N0M0, Low
- Stage 1B: T3N0M0, Low
- Stage II: T1, T2N0M0, High
  - T4N0M0, Low
- Stage IIIA: T3N0M0, High
- Stage IIIB: T4N0M0, High
- Stage IV: Any TN0M0, Any rate
  - Any T: N1M1, Any rate

Summary

- T1: <2 cm
- T2: >2–5 cm
- T3: >5–10 cm
- T4: >10 cm

Surgical management

Surgical resection is the mainstay for the treatment of gastric GIST. Given the relative rarity of GIST, most patients are best managed by multidisciplinary teams in specialist centres, where diagnostic and specialist techniques can be concentrated together with a greater expertise of managing sarcomas.

There are several important features of GISTs which have to be taken into consideration when performing a surgical resection, particularly in the stomach. These are also reflected in the consensus guidance for the surgical management of GIST.

- Primary resection should be complete with margins being macroscopically clear to prevent local or peritoneal recurrence.
- GISTs are soft and friable tumours which can rupture and disseminate. The tumour pseudocapsule should be preserved to prevent spillage. If the procedure is being performed laparoscopically, the tumour should be removed within a bag to prevent intra-abdominal rupture and port site seeding.
- Tumour dissemination is predominantly via the haematogenous route and in particular to the liver and peritoneum. Metastatic spread to local and regional lymph nodes is consequently rare, obviating the need for extensive anatomic and nodal resection as performed in cases of gastric adenocarcinoma. Partial resection to preserve organ function and continuity is the standard treatment.
- GISTs tend to grow into the abdominal cavity, without invading into surrounding tissues and therefore allowing a limited wedge resection to be performed, provided there is no evidence of disseminated disease.
- Although laparotomy has been the traditional approach to resection of gastric GIST, as with all areas of abdominal surgery, the laparoscopic approach is also gaining popularity and becoming the gold standard for tumours up to 4–5 cm diameter. The recognized benefits of laparoscopy are particularly suited to gastric GIST resection, as tumours tend to be excised through a wedge resection, resulting in shorter operative time, reduced blood loss and shorter length of postoperative stay. However, for very large GISTs, surgeons should be very cautious to try the laparoscopic approach as splitting the tumour will result in tumour recurrence.

Gastric GISTs are understood not to metastasize to regional lymph nodes and as a result a limited wedge resection through either an open or laparoscopic approach is preferred, depending on the site of the exact location of the tumour, with the aim of achieving an adequate resection margin and maintaining luminal continuity.

- Around 30% of gastric GISTs are reported to occur on the greater curvature and fundus. This location is amenable to laparoscopic wedge resection. Short-term follow-up data have shown a disease-free survival of more than 90% at 36 months' follow-up in patients who have undergone curative laparoscopic resection, suggesting that the technique is safe.
- GISTs at the gastro-oesophageal junction in particular can be difficult to resect and are associated with a recurrence rate of up to 42%. Owing to the high risk of losing gastro-oesophageal junction patency with a wedge resection, most experts advocate a proximal gastrectomy or even oesophagogastrectomy where there is locally advanced disease via the traditional open approach.
- Small antral tumours may be amenable to wedge resection but larger tumours are typically treated with a distal gastrectomy to maintain gastric continuity.

Medical management

Medical therapy was historically based on chemotherapy which showed little or no response from patients and was associated with an overall 5 year survival rate of only 25%. In the past decade, TKIs have become the mainstay, with ongoing clinical trials showing that tumour growth is controlled in up to 85% of advanced GISTs.

Patients who have non-resectable, metastatic or recurrent disease not amenable to further surgery typically undergo medical management with the TKI imatinib, which blocks the activated proteins produced by the mutated *c-kit* and *PDGFRA* genes. Following the initial dosing of imatinib for 1 month, patients undergo CT or PET scanning to assess response. The medication is continued for as long as possible, as interruption has been associated with a high rate of relapse even in individuals showing complete remission, and is reduced or stopped only if associated with significant side effects (in around 20% of patients) or if responsiveness diminishes over time (this occurs in up to 50% of patients). Intolerant and resistant individuals can be commenced on sunitinib, a second-generation TKI. Patients will generally be scanned every 3 months, to assess response. If a tumour becomes resectable following treatment, then it should be considered for resection. However, at present routine adjuvant and neoadjuvant therapy with TKI is not advocated by any of the GIST consensus groups.

Prognosis

Patients who have had a curative resection are stratified as high, intermediate, low or very low risk as per the guidance of the National Institutes of Health consensus conference (Table 23.5) which links together tumour size and mitotic count under a HPF to give an indication of tissue proliferation potential and therefore the risk of recurrence. Tumour location appears to be important, with gastric GISTs having a more favourable overall outcome than tumours at other sites.

At present there appears to be no consensus as to the frequency of follow-up and reimaging for recurrence, but is generally based on patient risk stratification with CT being the preferred imaging modality as it is quick to perform in regional centres and allows examination of the entire abdominal cavity in a single sitting. The North American National Comprehensive Cancer Network GIST practical guidance recommends CT scanning every 3–6 months for 3 years and yearly thereafter for a further 5 years in high- and intermediate-risk patients. The European Society for Medical Oncology

Table 23.5 Classification according to the National Institutes of Health consensus conference

	Tumour size (cm)	**Mitotic count (per 50 HPF)**
Very low risk	<2	<5/50
Low risk	2–5	<5/50
Intermediate risk	<5	6–10/50
	5–10	<5/50
High risk	>5	5–10/50
	>10	Any mitotic count
	Any size	>10/50

HPF, high-power fields

consensus group advises scanning the same patient group every 3–4 months for the first 3 years and then every 6 months for 5 years. Low-risk individuals are advised to be scanned every 6 months for 5 years. A joint Japanese guideline adopts a middle approach, recommending that patients of high or intermediate risk are followed up with CT scans every 4–6 months, whereas those with a low or very low risk are scanned every 6–12 months.

Overall 5-year survival is highly variable. Patients with primary gastric GISTs who have had a complete resection have a documented survival rate between 20–63% and recurrence rate of 17–76%.

Summary

- GIST is a rare connective tissue tumour occurring predominantly in the stomach (60–70%) and small intestine (10–20%) but may affect any part of the gastrointestinal tract, mesentery and omentum.
- GIST is usually associated with a mutation to the *c-kit* or *PDGFRA* genes encoding receptor tyrosine kinases.
- Presenting symptoms are non-specific but gastric GIST may present with acute haemorrhage given its soft and friable nature.
- Diagnosis is through a multimodality approach using immunostaining and imaging techniques of which EUS with FNAB is particularly useful for small tumours.
- Surgery is the mainstay of treatment although tyrosine kinase inhibitors such as imatinib and sunitinib have an important role in prolonging life in cases of unresectable or metastatic disease.
- Tumour size and mitotic rate are used as a guide to predict the malignant potential of GISTs and divide patients into high-, intermediate-, low- and very low-risk groups.
- Follow-up and regular imaging is recommended approximately every 3–6 months in high- and intermediate-risk cases but varies from region to region.

CHAPTER 24

Disorders of the liver

FRANCESCO M. POLIGNANO, JOHN F. DILLON, IAN A. ZEALLEY, AARON J. QUYN, AILEEN SMITH AND SIR ALFRED CUSCHIERI

Anatomy of the liver

The liver is the largest organ in the body, with a weight varying from 1200 to 1600 g. It arises from the foregut endoderm as a diverticulum which extends into the septum transversum and connects with the vitelline veins of the yolk sac. The caudal section of the hepatic anlage ultimately forms the biliary tract and gallbladder while the cephalic section forms the hepatic parenchyma. The vitelline veins form the portal and hepatic veins. The left umbilical vein persists as the ductus venosum and diverts oxygenated blood from the placenta around the liver directly into the inferior vena cava. After birth the vestigial ligamentum venosum runs in the free edge of the falciform ligament (round ligament, ligamentum teres). It may recanalize in patients with portal venous hypertension or can be used after dilatation for exchange blood transfusion or to permit radiological investigation of the portal venous system.

Morphology and topographical anatomy of the liver surfaces

The liver can be regarded as a wedge with rounded edges tapering to the left. It has three surfaces: anterosuperior, inferior and posterior. The anterosuperior surface is marked by the umbilical fissure in the depths of which (recessus of Rex) is inserted the round ligament (obliterated umbilical vein) attached to the cornu of the left portal vein. The umbilical fissure and the falciform ligament are the most conspicuous anatomical landmarks and divide the liver into right and left lobes. The posterior surface of the liver is largely formed of the bare area of the right lobe of the liver attached loosely to the diaphragm and retroperitoneum, and the caval canal that accommodates the retrohepatic vena cava and hepatic veins. The inferior surface of the liver is more complicated. The gallbladder is attached anteriorly some distance to the right of the umbilical fissure. The area between the gallbladder and the umbilical fissure is known as the quadrate lobe. Behind this and the neck of the gallbladder is the transverse hilar fissure that contains the main divisions of the portal vein, hepatic artery and common hepatic duct, and forms the posterior limit of the right lobe. The hepatic parenchyma separating the hilar fissure and the inferior surface of the left lobe from the vena cava forms the caudate lobe.

Relations

In terms of anatomical relations, the anterosuperior surface of the liver is in contact with the diaphragm and its upper margin reaches the level of the fourth interspace on the right and crosses the junction of the xiphisternum and sternum. Inferiorly the tip of the right liver reaches the costal margin, though Riedel's extension commonly extends below the costal margin and can reach the iliac crest. The gallbladder lies in the gallbladder fossa on the undersurface of the liver. There is a layer of fascia between the liver and the gallbladder (which must not be transgressed during cholecystectomy). Inferior relations of the right lobe include the upper pole of the right kidney and the right adrenal gland and more anteriorly the first part of the duodenum as it is overlapped by the gallbladder. The much thinner left lobe overlies the gastro-oesophageal junction. The lesser sac lies below the liver and behind the lesser omentum. It usually communicates with the rest of the peritoneal cavity through the foramen of Winslow lying behind the portal vein, hepatic artery and common bile duct. Occlusion of these structures (by finger, sling or vascular clamp) stops the arterial and portal venous inflow and this manoeuvre first described by Pringle is used to control bleeding during liver surgery and liver trauma.

Ligaments

The coronary and triangular ligaments suspend the liver from the diaphragm. The left triangular ligament is a thin peritoneal fold that is relatively avascular. Its two layers separate medially as the caval canal is reached: one sweeps back to the lesser sac and the other forms the left leaf of the falciform ligament. The coronary ligament is composed of two separate peritoneal folds (superior and inferior) between which lies the 'bare area' of the liver that is connected to the diaphragm by loose relatively avascular areolar tissue. The two leaves of the coronary ligaments join laterally, thus forming a V-shaped attachment to the diaphragm and retroperitoneum. The superior layer is an extension of the right leaf of the falciform ligament and attaches the superior surface to the diaphragm. The inferior leaf of the coronary ligament is a reflection of the peritoneum covering the right perinephric and adrenal region on to the inferior surface of the liver to the right of the infrahepatic vena cava.

Caval canal

This important region is often ignored in accounts of surgical anatomy. It is essentially a gutter in which lies the retrohepatic vena cava and the hepatic veins, all of which are enveloped in a loose fibrous meshwork rather than membranes. The caudate lobe separates the caval canal from the hilar fissure anteriorly and from the left lobe. The caval canal is best exposed during hepatectomy by a combined superior and inferior approach. Superiorly, the caval canal is covered by the diverging layers of the falciform ligament. When these are divided, a loose fibrous packing tissue envelops the vena cava and the right and left hepatic veins. Below, the caval canal is opened by division of the inferior leaf of the coronary ligament. The fibrous tissue covering the vena cava is loose in this region. A variable number of unnamed hepatic veins are encountered and these include veins to the caudate lobe. The retrohepatic vena cava also receives the phrenic veins and below these it is loosely attached to the retroperitoneum and, thus, provided the correct plane is identified, a sling can be passed around it and including the right and left hepatic veins in the immediate suprahepatic region.

Functional or segmental anatomy of the liver

The segmental anatomy of the liver on which modern hepatic surgery is based comes from the anatomical dissections performed by Rex (1888) and Cantlie (1898) more than 100 years ago and subsequently elaborated by Goldsmith and Woodburne (1957), Couinaud (1957), Healy and Schroy (1953) and Elias and Petty (1952).

In essence, the liver should be regarded as a paired organ (right and left livers) fused along a line extending from the middle of the gallbladder fossa anteriorly to the left edge of the suprahepatic inferior vena cava posteriorly. Within the liver this corresponds to a vertical plane (the main portal scissura or Cantlie's line) in which lies the middle hepatic vein. The right liver receives the right portal vein, right hepatic artery and right hepatic duct and the left liver the corresponding left portal vein, left hepatic artery and left hepatic duct.

Considerable confusion is often caused by the discrepancy between surface and functional anatomy of the liver, with a portion of the right anatomical lobe (segment IV) effectively belonging to the left functional hemiliver. For this reason, it is advocated that the anatomical division in right and left lobe be left to the anatomists, whereas the terms right and left hemilivers are to be used in all clinical and surgical settings. A further element of confusion is generated by the subdivision of the two hemilivers in sectors and segments, which are effectively fully independent subunits, and by the different terminology used by the influential French school with its followers and the wider international community. A consensus document has recently been produced by the International Hepato-Pancreato-Biliary Association entitled 'IHPBA Brisbane 2000 Terminology of Liver Anatomy & Resections', which is reported in its entirety and whose use is now widely advocated (Figure 24.1).

Because of this segmental liver anatomy, it is possible to resect a single or several segments even in the liver that has been distorted by chronic hepatic disease. A careful identification of the vessels and ducts supplying each segment can be achieved by dissection above the portal hilum or within the liver parenchyma and each segmental or sectorial pedicle may be ligated separately prior to resection of the corresponding portion of liver realizing an 'anatomical resection'.

The right hemiliver

The right hemiliver, situated to the right of Cantlie's line, is further subdivided into two sectors by the vertical right portal scissura in which lies the right hepatic vein. This scissura, which has no surface markings, is a plane that subtends an angle of 40° with a coronal plane conducted through the inferior vena cava (horizontal plane) and on the liver surface corresponds to a line extending from the anterior edge of the liver (midway between its rightmost tip and the right border of the gallbladder fundus) to the confluence of the right hepatic vein with the vena cava. The right posterior sector is situated to the right of the right portal scissura (and of the right hepatic vein) while the right anterior sector (also known as the right paramedian sector) is to the left of it, between the right and middle hepatic veins. The two

1 *First-order division*

Anatomical term	Couinaud segments referred to	Term for surgical resection	Diagram (pertinent area is shaded)
Right hemiliver **OR** *Right liver*	*Sg 5–8(+/–Sg1)*	*Right hepatectomy* **OR** *Right hemihepatectomy* *(stipulate +/–segment 1)*	Left hemiliver **OR** *Left liver*	*Sg 2–4 (+/–Sg1)*	*Left hepatectomy* **OR** *Left hemihepatectomy* *(stipulate +/–segment 1)*	
Border or watershed: The border or watershed of the first-order division which separates the two hemilivers is a plane which intersects the gallbladder fossa and the fossa for the IVC and is called the midplane of the liver.

Figure 24.1 International Hepato-Pancreato-Biliary Association Brisbane 2000 Terminology of Liver Anatomy and Resections. IVC, inferior vena cava.

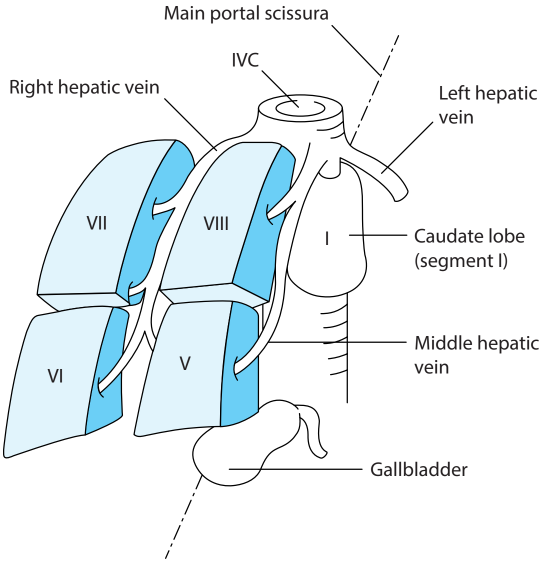

Figure 24.2 Schematic representation of the right liver. The main portal scissura (plane) containing the middle hepatic vein marks the territory between the two livers. It is also known as Cantlie's line and roughly makes an angle of 75° with the horizontal to the left, and extends from the middle of the gallbladder fossa to the left side of the vena cava. The right liver is divided into two sectors by the vertical right portal scissura containing the main trunk of the right hepatic vein. These two sectors are split by a horizontal plane through the right portal vein into two anteroinferior (V and VI) and two posterosuperior (VII and VIII) segments. Thus the right liver is smaller than the right lobe. Unfortunately, the vertical scissurae (planes) are undulating and not straight as shown in the drawing. This precludes a good correlation between radiological and anatomical segmentation (see text). IVC, inferior vena cava.

sectors are further divided in segments by a horizontal plane passing through the hilum of the liver (hilar plane); the anterior sector is therefore composed of segments V (anteroinferior) and VIII (anterosuperior) and the right posterior sector of segments VI (posteroinferior) and VII (posterosuperior). Each segment receives a portal pedicle (a segmental branch of the portal vein and a segmental branch of the hepatic artery) and is drained by a separate bile duct. Thus in the supine patient, segments V and VIII partially overlap segments VI and VII, respectively (Figure 24.2).

The left hemiliver

The left hemiliver is divided by the umbilical fissure in the left lateral sector (situated to the left of it) and left medial sector (segment IV also known as the left paramedian sector). The umbilical fissure is easily recognized on the liver surface by the presence of the round ligament (ligamentum teres) and of the falciform ligament. The left portal scissura, in which lies the left hepatic vein, has no surface marking and is said to run from the left margin of the suprahepatic inferior vena cava to the mid-point of the anteroinferior margin of the left lobe of liver. It divides the left lateral sector into an anterior segment (segment III) and a posterior segment (segment II) (Figure 24.3).

Caudate (dorsal, Spigel) lobe

Although this is customarily labelled as segment I, it is really a separate 'liver' because it has its own hepatic veins (Spigelian veins) and bile ducts, although it receives portal and arterial branches from both right and left sides. The caudate lobe is situated behind the hilar fissure and embraces the vena cava from the left forming an L-shaped structure with the horizontal limb separating the hilar fissure from the vena cava and the vertical limb the left liver from the vena cava. Its uppermost part lies posteriorly to the confluence of the hepatic veins and anteriorly to the inferior vena cava.

Main hepatic veins

Each numbered segment contributes hepatic veins that coalesce to form the main venous drainage of the livers and lie between the segments. There are three main veins of surgical importance:

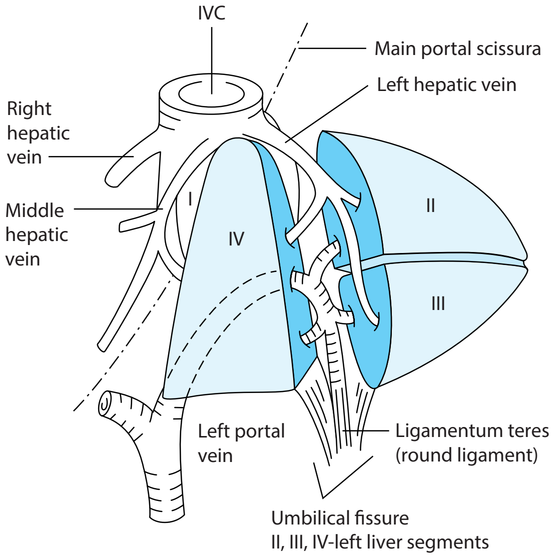

Figure 24.3 Schematic representation of the left hemiliver that is split by the umbilical fissure and by the left portal scissura into segment IV medially and segments II and III laterally. Thus the left liver is larger than the left lobe. IVC, inferior vena cava.

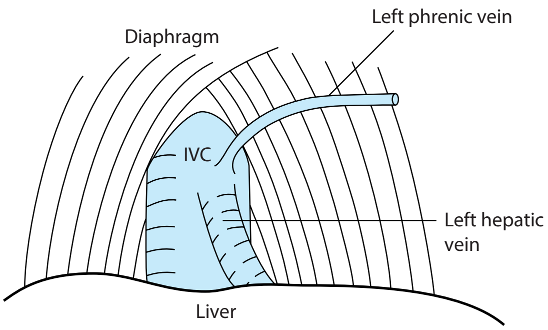

Figure 24.4 Schematic representation of the left hepatic vein. IVC, inferior vena cava.

the right hepatic vein drains segments V–VIII by a short vessel directly into the suprahepatic vena cava; the middle hepatic vein drains from both livers (segments IV and V–VIII) and empties either directly into the vena cava in isolation or with a common trunk with the left hepatic vein. The latter vein drains segments II and III. Segment I, the caudate lobe, drains by one or more small hepatic veins directly into the retrohepatic vena cava.

In the majority of patients both the right hepatic and the left hepatic veins can be identified and secured extrahepatically within the caval canal, but this manoeuvre is often hazardous for the middle hepatic vein. The left hepatic vein is exposed by complete division of the left triangular ligament. It slopes down from the vena cava to the liver so that its posterior wall is in contact with the vena cava and separated from it by loose fibrous tissue (Figure 24.4). The right hepatic vein is exposed only after the right lobe is completely mobilized and dislocated to the left. It runs directly posteriorly from the liver in intimate contact with the vena cava before entering it more posteriorly (Figure 24.5). Again only a loose layer of fibrous tissue separates the medial wall of the right hepatic vein from the vena cava but the fibrous tissue on its outer surface is usually firm and thickened.

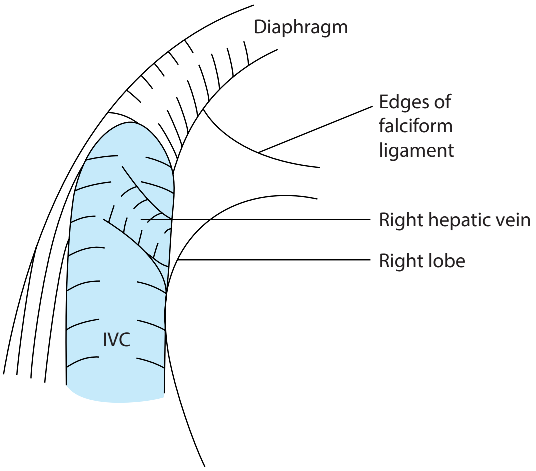

Figure 24.5 Schematic representation of the right hepatic vein after dislocation of the right lobe of the liver. IVC, inferior vena cava.

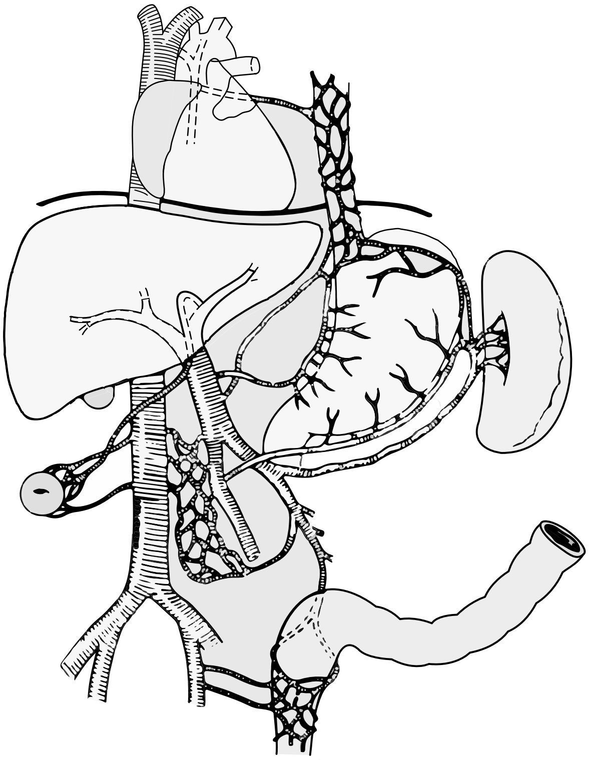

Figure 24.6 This shows the portal venous drainage from the gastrointestinal tract and demonstrates the major anastomotic sites between the portal and systemic systems: the cardio-oesophageal junction leading up to the azygos system, the retroperitoneum, the umbilicus and the inferior rectal plexus.

Portal hilum

In the portal hilum, the portal vein that has formed behind the head of the pancreas with the confluence of the splenic and superior mesenteric veins passes along the edge of the lesser omentum for 7.5 cm. It receives branches from the pylorus and the important left coronary vein from the cardio-oesophageal region (Figure 24.6). The portal vein provides the final conduit for the venous return from the gastrointestinal tract and its usual distribution to the various functional segments is shown in Figure 24.7. In the axial plane, the two main branches of the

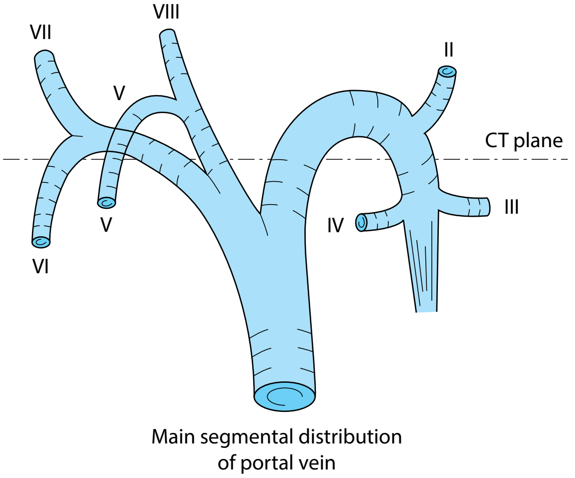

Figure 24.7 Schematic representation of the usual intrahepatic distribution of the portal vein. Above the transverse line (representing the transverse scissura marking the plane of the right and left portal veins) the upper branches supply segments VII, VIII, I, II and the lower branches VI, V, IV, III.

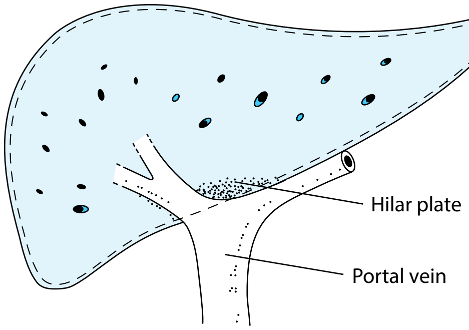

Figure 24.8 To the undersurface of the liver, the bifurcation of the major hilar structures is secured by a dense fibrous sheath termed the hilar plate. After incising this structure the vessels to the left liver segments run for 1.5 cm before dividing into segmental branches.

portal vein lie in the same plane (sometimes referred to as the transverse scissura). From right to left, segments VI, V, IV and III are below this plane, whereas segments VII, VIII, I (caudate) and II are above it.

There are major anastomotic sites between the portal and systemic systems that open up in the presence of occlusion/obstruction to portal blood flow to the liver:

- the cardio-oesophageal junction – left gastric (coronary) vein to the azygos system
- communications with the retroperitoneal veins of Sappey
- umbilicus – recanalized left umbilical vein to abdominal parietal veins – caput medusae
- communications with the inferior rectal plexus (Figure 24.6).

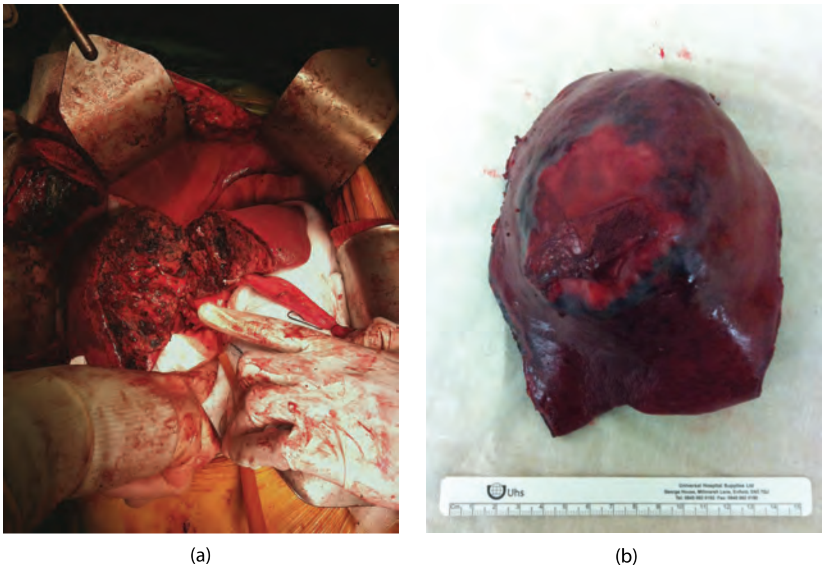
The common hepatic duct draining both livers passes in front of and to the right of the portal vein and receives the cystic duct at a variable point of its course to form the common bile duct. The common hepatic artery runs to the left of the common bile duct giving off the main cystic artery and branches to the common bile duct prior to division into right and left branches.

An understanding of the point of the division of the structures in the portal hilum is essential for the surgeon. The vasculobiliary sheath, described originally by Walaeus in 1640 and commonly referred to as the Glissonian sheath, surrounds the main vessels and ducts following them well into the depth of the parenchyma and it is still recognizable around the tertiary ramifications (segmental pedicles). While the portal vein is loosely enclosed, the bile duct and hepatic artery are firmly adherent to the Glissonian sheath. The upper surface of the sheath which is in contact with the liver parenchyma thickens to become the hilar plate. This structure can be released from the liver surface because there are no branches along it and permits the surgeon to isolate the bifurcation of the hepatic pedicle to the right and left hemilivers extrahepatically but *en bloc* (the three elements together, portal vein, hepatic artery and bile duct) and to proceed to liver resection more safely with an extraglissonian approach (Figure 24.8).

Techniques of anatomical liver resection and intraoperative ultrasound

Different approaches to liver resection surgery have been developed during the years, with the most influential contributions coming from the French (Couinaud, Lotart-Jacob and Bismuth) and Vietnamese (Ton That Tung) schools. More recently the wide adoption of intraoperative ultrasound during liver surgery has facilitated the recognition of intrahepatic structures, like the hepatic veins and the second- and third-order portal pedicles, and has contributed enormously to the spreading of more complex resections like the mesohepatectomy (right anterior and left median sectoriectomy, equivalent to a resection of segments V, VIII and IV) or to anatomical resections of the caudate lobe, of segment VIII or of segment VII in isolation (Figure 24.9).

The French school has popularized a technique whereby major hepatectomies are performed ‘with preliminary vascular division’, where the elements of the vascular pedicle to the liver being resected are dissected out and divided extrahepatically. The relevant hepatic vein is also isolated and divided prior to commencing the transection of the liver parenchyma. In a right hepatectomy, for example, this would typically involve a meticulous dissection within the hepatoduodenal ligament to identify and divide individually the elements of the right glissonian pedicle (right hepatic artery, the right branch of the portal vein). The right hepatic vein would then be dissected out and divided prior to commencing the hepatotomy. The right hepatic duct is usually left intact and divided at the very end of the operation once the frequent anatomical variants of the biliary tree have been ruled out. With this technique, a clear ischaemic demarcation of the liver being resected is determined, which facilitates the subsequent hepatotomy and allows a reduction in intraoperative blood loss resulting from the preventive devascularization of the prospective specimen. However, the risks posed by the difficult dissection of the hepatic veins and of the three glissonian elements individually are well recognized and complications like major haemorrhages from the inferior vena cava or hepatic veins and unintentional devascularization or interruption of bile ducts to the prospective liver remnant have been widely reported, the latter particularly in the presence of anatomical variants. Furthermore, with this



(a) (b)

Figure 24.9 (a) Surgical view after a mesohepatectomy (resection of segments IV, V, VIII) for large colorectal cancer metastasis centred in segment IV–VIII and corresponding surgical specimen. (b) A small section of diaphragm is visible attached to the tumour surface.

technique, the anatomical resection of sectors or liver segments in isolation is more challenging, as the secondary and tertiary glissonian pedicles are located very deep in the liver and are very difficult if not impossible to access without a certain degree of dissection within the liver parenchyma.

A recent modification of this technique is the approach to liver resection 'with selective clamping', where structures at the hepatic hilum are still dissected intraglissonially according to Lotart Jacob but are simply clamped and not irreversibly divided, thus allowing the surgeon more time to interpret the anatomy variants while preserving the benefits of preventive devascularization of the prospective specimen and of its ischaemic demarcation.

In contrast to this technique, the Vietnamese surgeon Ton That Tung proposed in the late 1960s an approach to liver surgery 'with primary parenchymal transection', based on in-depth knowledge of the intrahepatic anatomy and corresponding surface landmarks and on the observation that, even though variations of the extrahepatic arterial, portal and biliary anatomy are common, the intrahepatic distribution of these structures and their relation with specific surface landmarks is surprisingly consistent. With this technique the hepatotomy is started at the outset along the line of a scissura and the glissonian pedicle to the prospective specimen is dissected out and divided within the depth of the liver parenchyma, usually preserving the integrity of its glissonian sheet. The relevant hepatic vein is also reached and divided inside the liver parenchyma and no attempt is made at extrahepatic dissection of it. The main advantage of this approach lies in its safety, because by approaching the glissonian pedicle inside the liver substance, well above the hilum, and by preserving the integrity of its sheet, all possible anatomical variants are easily circumvented and the difficult and hazardous intraglissonian dissection at the hilum can be avoided. Fear of a more significant blood loss or a more prolonged clamping time of the hepatoduodenal ligament (Pringle manoeuvre) and the need of a rapid execution were often listed as downsides of the Ton That Tung technique and have ultimately hampered its spreading in Europe and in the Western world for a long time. Poor understanding of intrahepatic anatomy in the Western world has also been a contributing factor. Nowadays, however, the availability of faster and more haemostatic devices for the transection of the liver (CUSA and radiofrequency devices like the Tissuelink), and of intraoperative ultrasound to guide the parenchymal transection, has determined a resurgence of interest around this technique and its principles, in its original description or in modified forms.

The extrahepatic extraglissonian approach has also been described in combination with the conventional extrahepatic approach to the relevant hepatic vein during a right hepatectomy or posterior sectoriectomy and during mesohepatectomy. It has also been proposed for resections '*à la demande*' where strict respect of the segmental borders is not possible.

Whichever the technique employed, intraoperative ultrasound has most certainly become mandatory during liver surgery and has greatly increased its safety. It has allowed liver surgeons to circumvent the lack of surface landmarks by direct visualization of hepatic veins or pedicles within the parenchyma. It also permits direct visualization of the deep tumour margins, which is essential to achieve a radical resection. In expert hands, the identification of anatomical variants can also be achieved by intraoperative ultrasound and the identification of unrecognized pathologies or additional liver lesions, which can ultimately lead to a change of surgical strategy.

Hepatic architecture

Conventional morphology considers that the liver is composed of pyramidal lobules based on a central vein and surrounded on the periphery by portal trunks with terminal radicles of bile duct, portal vein and hepatic artery (Figure 24.10). The two vascular systems of the central vein and portal tract lie on planes at right angles to one another and never interdigitate. Thus the sinusoids

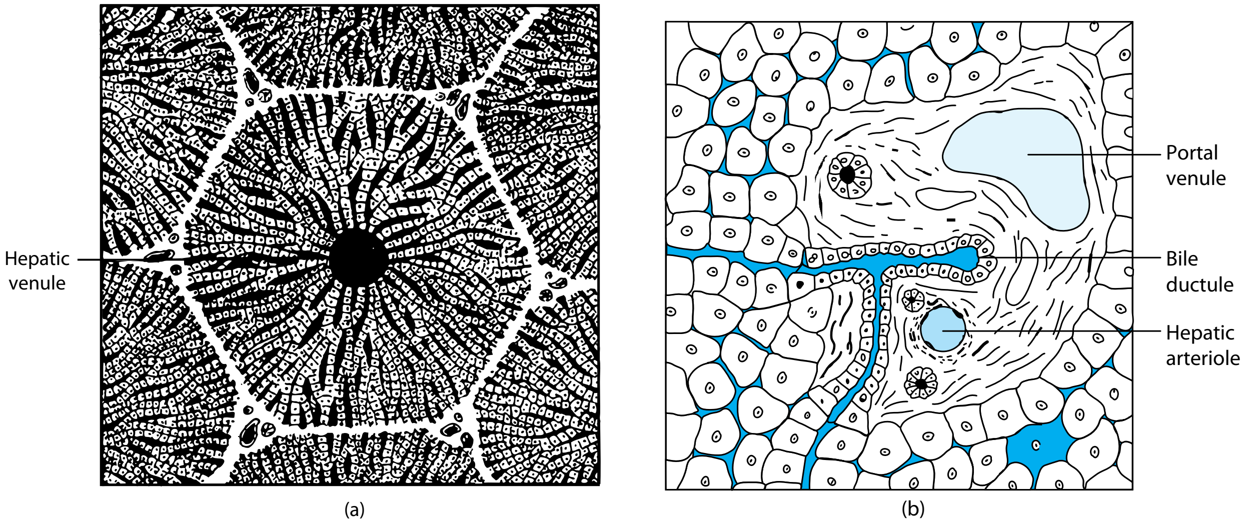


Figure. 24.10 (a) This demonstrates the normal liver architecture in which a hepatic plate apparently surrounds a hepatic vein through which blood from the hepatic sinusoids drains. (b) In fact it is more appropriate to centre the hepatic plate on the portal tract which contains the elements of the bile ducts into which bile can directly drain from the hepatocytes and branches of the portal vein and hepatic artery together with connective tissue stroma. Zones closest to this portal tract (zone 1) are protected in most circumstances from liver damage. Liver cells surrounding the hepatic vein (zone 3) are more susceptible to all forms of hepatic damage. Regenerative nodules are normally centred on a portal tract.

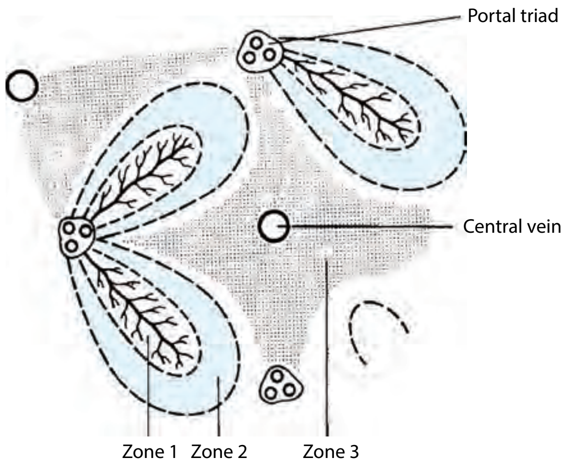

Figure 24.11 According to Rappaport, there are three zones of liver parenchyma. Zone 1 adjacent to the portal triad is the best vascularized and least susceptible to injury. Zone 3 is adjacent to the central vein and most susceptible to injury.

are arranged perpendicular to the planes of the central veins and portal blood passes to the central vein along a pressure gradient. The walls of the sinusoids are composed of endothelial and phagocytic cells, termed Kupffer cells. Between the hepatocytes and Kupffer cells is the space of Disse. Bile canaliculi are shown to be channels or grooves in the hepatocyte surface, lined by microvilli. The network of canaliculi drains the liver lobules into the terminal bile ducts.

It may help in the understanding of liver injury and its consequences to view the liver morphology somewhat differently. The concept of Rappaport is to regard the liver as a series of acini supplied by a portal triad of structures (Figure 24.11). Three zones of sinusoids are envisaged in which the peripheral zone of the acini (zone 3) is damaged more severely in any form of injury. Adjacent forms of injury may coalesce to form areas of bridging necrosis and, later, fibrosis, producing the common pattern of postsinusoidal block; zones 1 and 2 may form the nidus of surviving cells which then regenerate in nodular form.

Liver function tests and testing liver function

The analytes commonly called liver function tests (LFTs), alanine amino transaminase (ALT), aspartate transaminase (AST), alkaline phosphate and -glutamyltransferase, do not give any information about liver function and are biomarkers of liver damage. The other biochemical analyses commonly performed as part of the LFTs group are albumin and bilirubin: these do give some indication of liver function but with important caveats. Other biochemical abnormalities include elevations of acute phase reactant proteins ($_2$-macroglobulin, C-reactive protein, etc.). Other changes include lowering of serum proteins, release of integral proteins, raised immunoglobulins and the appearance of abnormal protein antigens.

Liver function tests

In hepatocellular injury, integral cellular enzymes are released into the circulation. These include AST and ALT. The levels of both transaminases in the serum reflect the severity of the ongoing liver cell damage and necrosis. Minor elevations are encountered in cholestasis and chronic liver disease, whereas substantial serum levels (>400 units) are encountered in acute hepatitis with liver cell necrosis from any cause; acute cholangitis can also be associated with a very elevated ALT, sometimes causing diagnostic confusion. The ALT is more specific for liver tissue, and is often the only transaminase routinely measured; however, the ratio of ALT–AST can give additional information about hepatic fibrosis or non-alcoholic fatty liver disease (NAFLD).

The group of isoenzymes responsible for the hydrolysis of phosphate esters in an alkaline medium are termed alkaline phosphatases. These enzymes are found in the liver, biliary tract, bone, intestine, kidney and placenta. The various isoenzymes can now be differentiated by special immunoassays establishing the exact tissue origin of the circulating enzyme. In cholestasis and obstructive jaundice, the conjugated hyperbilirubinaemia is usually accompanied by a significant elevation of the serum alkaline phosphatase activity due to impaired excretion of the enzyme in the bile and hepatic induction (overproduction). Other (alkaline phosphatase type) enzymes associated with the biliary tract such as 5-nucleotidase and -glutamyl transpeptidase (-GT) exhibit a parallel elevation. The -GT is highly inducible in hepatocytes, by drugs and alcohol so may be disproportionately elevated in some patients. It should not be regarded as diagnostic in isolation; it should be interpreted in the context of the rest of the LFTs and the clinical situation. The biochemical picture in patients with diffuse infiltrative lesions of the liver or secondary deposits is often of a marked elevation of the bile ductular enzymes (alkaline phosphatase, -GT) out of proportion to the small rise in the serum bilirubin; this observation is a pointer to performing further imaging; the absence of these changes does not indicate the liver is uninvolved in infiltrative disease.

Albumin

The serum albumin is often low in patients with chronic liver disease and the hypoalbuminaemia is associated with a complementary rise in the other serum proteins, particularly globulins (altered albumin–globulin ratio). The fall in the serum albumin is often used in the grading of the severity of hepatic decompensation, e.g. Child–Pugh's classification. When severe, the hypoalbuminaemia is usually accompanied by fluid and salt retention, but reduced plasma oncotic pressure is only one of several interrelated factors responsible for ascites in patients with chronic liver disease. The exact mechanism (defects in transcription, mRNA processing or translation, defective export) for the depressed albumin synthesis in patients with hepatic fibrosis or cirrhosis is not known. Paradoxically, in some patients with cirrhosis, albumin synthesis by the liver is actually increased, but often not enough to compensate for the expansion in extracellular fluid.

Immunoglobulins

Marked elevation of the serum immunoglobulin (Ig)G is encountered in patients with cirrhosis and autoimmune hepatitis, but is non-specific and more a marker of activity than a diagnostic aid. Serum IgA, which is normally secreted in the bile, is also elevated in these conditions but to a lesser extent and may also be elevated in alcohol-related liver disease, but with diagnostically poor sensitivity and specificity. Primary biliary cirrhosis is associated with elevation of the serum IgM and the presence of antimitochondrial antibodies.

Biomarker proteins

The only commonly available biomarker is α-fetoprotein (AFP), which is detected in the serum of about 60% cases of hepatocellular carcinoma (HCC). AFP is commonly used in the surveillance of patients at increased risk of HCC, but its use is now controversial, with guidelines advocating its use only in combination with hepatic ultrasound examination and some evidence suggesting AFP has no added benefit to ultrasound. An AFP level of over 100 kU/L is highly suspicious of HCC, and a level between 7 and 100 kU/L may be indicative of a small HCC (<5.0 cm) but is also encountered in benign liver disease associated with necrosis and regeneration, e.g. hepatitis C. A rising level of AFP even if below the diagnostic range is indicative of HCC and should provoke a search using hepatic CT or MRI. AFP is most useful in monitoring patients with HCC, which is known to produce AFP. Persistent elevation after resection of HCC indicates residual disease and re-elevation after initial normalization is suggestive of recurrence. A correlation between serum level of AFP, tumour size and survival has been established by a number of studies. Thus patients with marked preoperative elevation have a poor survival after surgery. The well-differentiated variant of HCC, fibrolamellar carcinoma, does not cause an elevation of AFP and this oncofetal antigen is not expressed by cholangiocarcinoma.

Measuring liver volume

Advances in imaging and software have allowed the development of *in vivo* imaging of the liver. Three-dimensional models of the liver can be constructed from CT or MRI scans. The volume of liver can then be calculated based on known separation of image slices combined with planar mapping of cross-sectional areas. In addition, these three-dimensional models can be simulated to map the effects of surgery by performing virtual hepatic resections. Studies have shown this to be of value as a predictor of hepatic dysfunction after major liver resection.

Testing liver function 'hepatic functional reserve'

In assessing a patient with a liver condition requiring surgical intervention and/or a patient with underlying parenchymal liver who requires major surgery, the usual decision-making process about the correct intervention has to take into account the influence of the liver on the prognosis of the condition. In clinical practice assessment of the hepatic reserve is based predominantly on standard 'liver function tests' together with a clinical assessment of nutritional state, muscle wasting and degree of sodium retention (based on peripheral oedema and ascites). Prothrombin time is a sensitive test of hepatic synthesis of vitamin K-dependent factors that is impaired in jaundice and hepatocellular disease. In addition to the level of prothrombin activity, the response to a parenteral dose of vitamin K analogue is a most useful test of hepatocyte function. Thus restoration to normal within 24–48 hours is expected in patients with obstructive jaundice without significant impairment of hepatocyte function. Failing to do this shows significant impairment of synthetic liver function. These are often combined into scoring schemes, the most commonly used are the Child–Pugh score/grading (modified from the initial Child–Turcotte). The Child's score is based on bilirubin, albumin, prothrombin time, presence of ascites and presence of encephalopathy (Tables 24.1 and 24.2). The Child's score has

Table 24.1 Child–Pugh classification of disease severity in cirrhotic patients

Parameter	A	B	C
Albumin (g/dL)	>3.5	3.0–3.5	<3.0
Bilirubin (mol/L)	<25	25–40	>40
Prothrombin (s) >normal	<4	4–6	>6*
Prothrombin (%)	>64	40–65	<40
Ascites	None	Controlled	Refractory
Encephalopathy	None	Minimal	Advanced

* In the original Child–Turcotte classification nutrition was used but this has been substituted with prothrombin activity. The bilirubin has to be adjusted for patients with primary biliary cirrhosis (A, 5–7; B, 8–10; C, 11 or more).

Table 24.2 Paul Brousse hospital classification system

Parameter	Number of criteria
Albuminaemia <3.0 g/100 mL	1
Hyperbilirubinaemia >30 mol/L	1
Encephalopathy	1
Clinical ascites	1
Coagulation factors II and V 40–60%	1
Coagulation factors II and V <40%	2

A, none of the criteria.
B, 1 or 2 criteria.
C, 3 or more criteria.

some utility at identifying those patients with good prognosis and those with very bad prognosis but many patients that it is applied to have an intermediate B class, which has a much wider range of prognosis in studies so is of limited usefulness to the individual patient. The predictive tools developed for allocation of transplant organs, i.e. MELD or UKELD, are increasingly being used as predictors of poor outcome for non-transplant surgical intervention; they are promising in this role but require further validation.

There are in addition tests that give an assessment of the functional capacity (reserve) of the liver. These are not often used clinically except in specialist hepatobiliary centres and in clinical research studies. Some are tests of microsomal function (e.g. antipyrine clearance, caffeine clearance), others of cytosolic function (e.g. galactose elimination capacity) or hepatic perfusion and excretion [e.g. indocyanine green (ICG) clearance] or synthesis (albumin, urea and prothrombin). In practice, the most commonly used are ICG clearance and the prothrombin activity after administration of vitamin K.

Indocyanine green clearance

This is presently considered to be the best test of hepatic functional reserve. Previously it had been most commonly used to select patients for hepatic resection. More recently, ICG clearance has been reported to be beneficial in liver transplantation – selection of patients and prediction of graft viability. Hepatic clearance of ICG is dependent on many factors, the most important of which are hepatic blood flow, binding to plasma proteins, transport across the sinusoidal–hepatocyte membrane, intracellular transport, export across the canalicular membrane and bile flow. In clinical practice, hepatic clearance is derived from the plasma ICG clearance curve. The test is carried out after an overnight fast when ICG (0.5 g/kg body weight) is injected intravenously, usually in the antecubital vein. Blood samples are taken from the contralateral antecubital vein before administration (plasma blank) and at 5, 10, 15 and 20 minutes after injection of ICG. Most consider that a retention of greater than 14% at 15 minutes precludes major resection as it indicates a significant reduction in the hepatic reserve.

However, good survival has been reported in patients having an ICG retention greater than 14% provided the resection is carried out expertly and is not accompanied by significant blood loss. The limitation of this technique is its dependence on hepatic blood. In many patients in whom resection is being considered and there is concern about residual liver function, there will be underlying cirrhosis, which makes the ICG clearance unreliable, depending on the degree of portosystemic shunting.

Imaging of the liver

General considerations

A wide range of diagnostic imaging investigations are useful for diagnosis and assessment of diffuse liver disease, and for the identification and characterization of focal liver lesions. However it is important to remember that imaging is an adjunct to, and not a replacement for, clinical evaluation. The choice of imaging investigation and its interpretation must be guided by factors unique to each patient. Every patient presents a different combination of age, sex, risk factors, comorbidities and expectations, and imaging tests should be chosen and interpreted in the light of these. Although numerous 'protocols' for imaging exist, these are no substitute for comprehensive evaluation of individual patients and consideration of the diagnostic requirements in each unique case.

When considering a patient who is clinically suspected of having a diffuse liver disease such as cirrhosis there are a variety of imaging findings which may assist the diagnosis and go some way to determining the severity of the disease. However, when considering the various clinical, laboratory and imaging findings the clinician must consider whether for *this individual patient* they are sufficiently confident in the diagnosis to manage the patient effectively. They must always consider whether a biopsy of the liver tissue will or will not substantially improve the confidence and appropriateness of patient management.

Similar considerations apply when considering a patient in whom focal liver lesions have been identified or are suspected. There are a variety of imaging findings which may assist the identification and characterization of focal liver lesions, but there are very few such lesions which present an absolutely diagnostic appearance on which a clinician can rely with complete confidence. Lesions which may be diagnosed with absolute confidence using non-invasive imaging techniques are simple liver cysts and cavernous haemangiomas. All other focal liver lesions may present a range of findings on imaging tests and the best that may be achieved is to suspect, but never attain, complete confidence in diagnosis. An important example is the overlap which exists between the imaging findings that may be presented by tumours of hepatocyte origin at the benign and malignant ends of the spectrum. For instance a HCC lesion may present imaging features which are identical to those typically considered characteristic for a benign lesion such as hepatic adenoma or focal nodular hyperplasia (FNH) (Figure 24.12). As with diffuse liver disease, the clinician must consider how the various clinical, laboratory and imaging findings combine to influence the management of the *individual patient*, who has their own unique combination of age, risk factors and comorbidities. In essence, the question which the clinician must ask themselves is whether, for this *individual patient*, there is an important possibility that they may be undertreating on the basis of non-invasive tests alone, or is further investigation with biopsy or laparoscopy warranted.

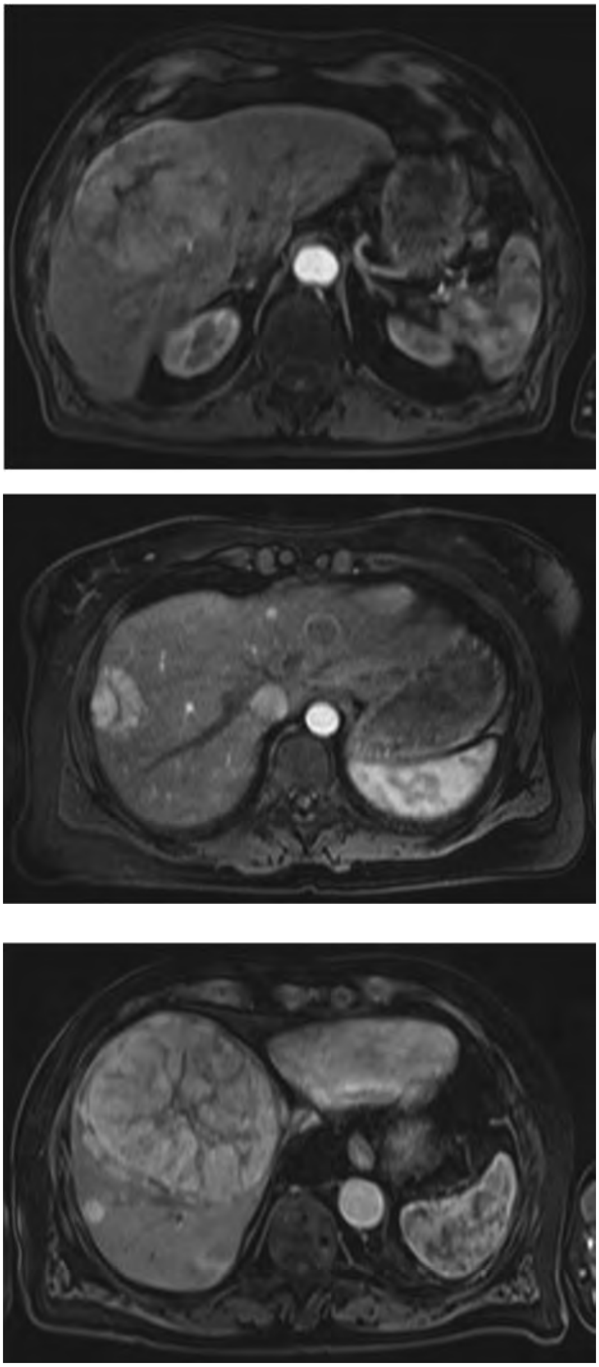

Figure 24.12 Axial MR images of three different focal liver lesions each exhibiting similar characteristics including enhancement during the arterial phase following intravenous gadolinium contrast administration and central 'scars'. These features are typical for focal nodular hyperplasia (FNH) but (a) is a hepatocellular carcinoma, (b) is a FNH lesion, and (c) is a fibrolamellar hepatocellular carcinoma.

Different imaging tests have different strengths and weaknesses. For any specific clinical scenario there is usually an optimal test. In addition there are often a variety of different ways in which an imaging test may be performed. Effective communication between clinician and radiologist is essential in order to maximize the diagnostic utility of imaging tests for the patient. Performing the right test in the right way minimizes the potential for 'false reassurance', when an inappropriate test fails to identify pathology which is in fact present, and also minimizes the potential for identification of 'pseudolesions' and irrelevant incidentalomas which may cause unnecessary and unwarranted distress to the patient.

Plain radiography

Plain abdominal radiographs may give some indication of the size of the liver but they rarely assist in the confident diagnosis or exclusion of liver disease. Mature hydatid cysts may be identified by virtue of calcification within the cysts wall, and liver abscesses may contain sufficient gas to be identified on a plain radiograph.

Ultrasonography

Because it does not involve ionizing radiation and is relatively inexpensive, ultrasonography is the primary investigation in patients with suspected biliary tract pain, cholestasis and non-dyspeptic upper abdominal pain. The normal liver is seen as a large homogeneous mid-grey structure in which the portal vein, hepatic veins and inferior vena cava are well shown. In patients with cholestasis the observation of dilated intrahepatic bile ducts throughout the liver indicates the presence of a large duct obstruction and occasionally the cause for this obstruction may be seen downstream in the biliary tree. Gallbladder disease is particularly well demonstrated, and gallstones and cholecystitis may be diagnosed reliably in most cases.

Ultrasound may also be employed to demonstrate the portal venous system. The patency of the portal vein and other major vascular channels, including surgical shunts, is usually well demonstrated with combined greyscale and Doppler ultrasound scanning ('duplex' scanning). The colour Doppler facility demonstrates the direction of flow.

A specialized modification of liver ultrasound involves the intravenous administration of contrast agents which enhance the image contrast between normal and abnormal liver tissue. These agents are stabilized forms of microscopic bubbles and may be employed either to increase the sensitivity of ultrasound for the detection of focal liver lesions or to aid characterization of focal liver lesions once found.

When screening the liver for focal lesions, ultrasound may identify lesions as small as 1 cm. Echo-poor liver cysts and profoundly echogenic cavernous haemangiomas are particularly well demonstrated. Liver neoplasms including primary liver tumours (benign and malignant) and metastases may also be seen. Used as a screening test in patients at high risk for development of HCC, for instance those with chronic hepatitis B or C infection, ultrasound has been demonstrated to identify patients with small, curable tumours in whom prolonged survival has been reported.

Once focal liver lesions have been identified (by whatever means), ultrasound may be used to follow up known lesions in order to assess for stability, growth or regression which may help to clarify diagnosis and influence management.

Diffuse liver disease may be inferred from ultrasound findings. In cirrhosis the characteristic features are generalized hyperechogenicity which is typically irregular and 'grainy'. The degree of fibrosis may be estimated non-invasively by means of ultrasound elastography but this application is still at an experimental stage. In diffuse hepatic steatosis a more diffuse generalized hyperechogenicity is typically observed.

Intraoperative ultrasound screening of the liver is an excellent adjunct to operative evaluation of the liver and may be performed during laparoscopic or open surgery. The ultrasound probes employed are of the curvilinear or linear array configuration with high frequencies in the 7.5–10 MHz range providing very high definition, particularly in the near field (2.0–3.0 cm depth). These provide the best achievable demonstration of the anatomy of vascular structures and the boundaries of liver tumours. They may also identify previously undetected lesions which may influence the planning or progress of hepatic resection. One of the most useful applications of intraoperative ultrasound is to take advantage of its unparalleled resolution to identify previously undetected foci of malignancy in the residual liver remnant following curative hepatic resection. Identification and characterization of such lesions (sometimes assisted by intraoperative ultrasound-guided biopsy) may allow the surgeon to avoid potentially high-morbidity surgery in patients who will not benefit. Intraoperative ultrasound may also be used to clarify the relationship between tumour and vascular structures in order to confirm the feasibility of planned operative procedures before embarking on dissection.

CT scanning

CT scanning is an extremely useful modality for diagnosis, follow-up and treatment planning in liver disease. Ultrafast multislice helical CT scanning has replaced older techniques and allows the whole liver to be assessed in a few seconds. During these scans the patient is moved through the scanner gantry while both the X-ray source and X-ray detectors rotate around the patient. The X-ray detectors stream data to a computer, which uses complex mathematical algorithms to generate volumetric datasets based on the attenuation values of the different tissues. This dataset can be manipulated in a variety of ways in order to present the anatomy in the manner which best suits the clinical scenario.

CT scanning is particularly valuable in the diagnosis of focal liver lesions such as tumours, cysts or abscesses (Figure 24.13). It is also useful in the assessment of traumatic liver injury as haematoma, laceration and active bleeding may all be identified.

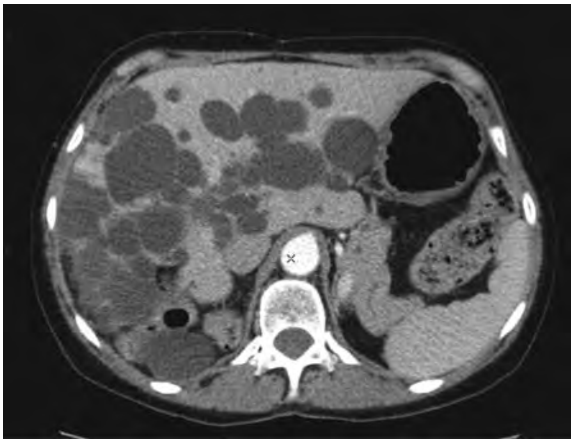

Figure 24.13 Axial CT scan image demonstrating multiple well-defined, round, uniformly fluid attenuation cysts in the liver of a patient with adult polycystic liver and kidney disease.

In modern practice, CT scanning is almost invariably assisted by the administration of intravenous iodinated contrast agents to 'enhance' both the parenchyma and blood vessels. Increased accuracy for detection of focal liver lesions is the principal benefit. In addition, focal liver lesions may also be characterized by observing the change in enhancement behaviour over time, relative to the surrounding liver parenchyma.

Specific timings of CT scan acquisition after administration of intravenous contrast may be employed to demonstrate suspected pathologies to best advantage. For example, lesions which characteristically receive a relatively abundant arterial blood supply relative to normal liver tissue [e.g. HCC, adenoma and neuroendocrine tumours (NETs)] may become conspicuously hyperenhanced during an 'arterial' phase approximately 25–35 seconds after administration of intravenous contrast. Such lesions may become inconspicuous during other phases of enhancement. On the other hand there are many liver lesions which are best demonstrated by virtue of their relatively poor blood supply compared with normal liver tissue. For instance, adenocarcinoma metastases from stomach, small bowel and colorectal primary tumours are most conspicuous during the 'portal venous' phase of enhancement approximately 65–75 seconds after administration of intravenous contrast.

These examples serve to illustrate the importance of tailoring the specific parameters of the CT scan to the specific circumstances of each patient. Effective communication between clinician and radiologist is essential in order to maximize the diagnostic utility for the patient.

MRI of the liver

MRI is an extremely useful tool in the assessment of both parenchymal liver disease and biliary disease, where it has superseded and replaced non-therapeutic endoscopic retrograde cholangiography.

The free protons in patients placed inside the bore of an MRI scanner align themselves with the static magnetic field of the scanner. These spinning protons are deliberately disrupted by pulses of radiofrequency energy which knock them out of alignment and out of synchronization. As the protons revert back to their original synchronization and alignment they themselves emit radiofrequency energy which is detected by receiver coils placed around the patient: these are analogous to aerials picking up conventional radio broadcast transmissions. The received radio signals are converted by computer algorithms into diagnostic images.

Different methods of applying radiofrequency pulses accompanied by different timings of 'listening' to the emitted radiofrequency energy are referred to as 'acquisition sequences'. Most liver imaging using MRI is produced using acquisition sequences which can be completed during a single breath-hold. One exception is free-breathing T_2 weighted cholangiography acquisition sequences which monitor the position of the diaphragm during the acquisition phase: the image reconstruction algorithm discards the data acquired while the diaphragm is moving and produces images only from data acquired while the bile ducts are stationary at end expiration.

Two common examples of image types produced by different acquisition sequences are known as T_1 and T_2 'weighted' images. T_1 weighted images reflect the fat content of tissues, among other features, and may be used to assess hepatic steatosis and examine focal liver lesions for the presence of fat which is characteristic for tumours of hepatocyte origin. T_1 weighted images may also be 'enhanced' by the administration of a variety of rare earth element-containing intravenous contrast agents which appear white on these images. T_2 weighted imaging produces images which reflect the amount of free water in the tissues, thus bile and other fluids appear white while denser tissues such as normal liver parenchyma appear darker grey. Magnetic resonance cholangiopancreatography (MRCP) images are produced using heavily T_2 weighted acquisition sequences. T_2 weighted images may also be 'enhanced' by the administration of a variety of iron-containing intravenous contrast agents, which appear dark on these images.

A variety of different intravenous contrast agents may be employed to enhance liver MR images. One class of contrast agents is based on the paramagnetic properties of rare earth elements such as gadolinium and manganese which affect the way protons realign themselves with the static magnetic field in the MRI scanner during some types of acquisition sequence. This type of MRI contrast agent modifies image appearances on T_1 weighted images. The rare earth contrast agents are further subclassified into conventional gadolinium chelate agents which enter the blood pool and subsequently become dispersed non-selectively throughout the extracellular space: these agents behave in a fashion similar to that of the iodinated intravenous contrast agents employed in CT scanning. During multiple phases of image acquisition these agents produce patterns of liver lesion enhancement and washout which are essentially the same as those observed during CT scanning (Figure 24.14). Another subclass of rare earth contrast agents are those which are selectively taken up by hepatocytes and subsequently excreted into bile. Immediately following intravenous administration these hepatocyte-specific contrast agents are located in the blood pool and influence tissue appearances in the same way as the conventional gadolinium chelate agents. However, their subsequent uptake by hepatocytes allows for more accurate characterization of focal liver lesions than can be achieved with conventional gadolinium chelate contrast agents. During a further late phase, when the hepatocyte-specific contrast agent is excreted into the bile, the bile becomes white on T_1 weighted images, thereby facilitating the identification of bile leaks (Figure 24.15) and assisting evaluation of the patency of biliary

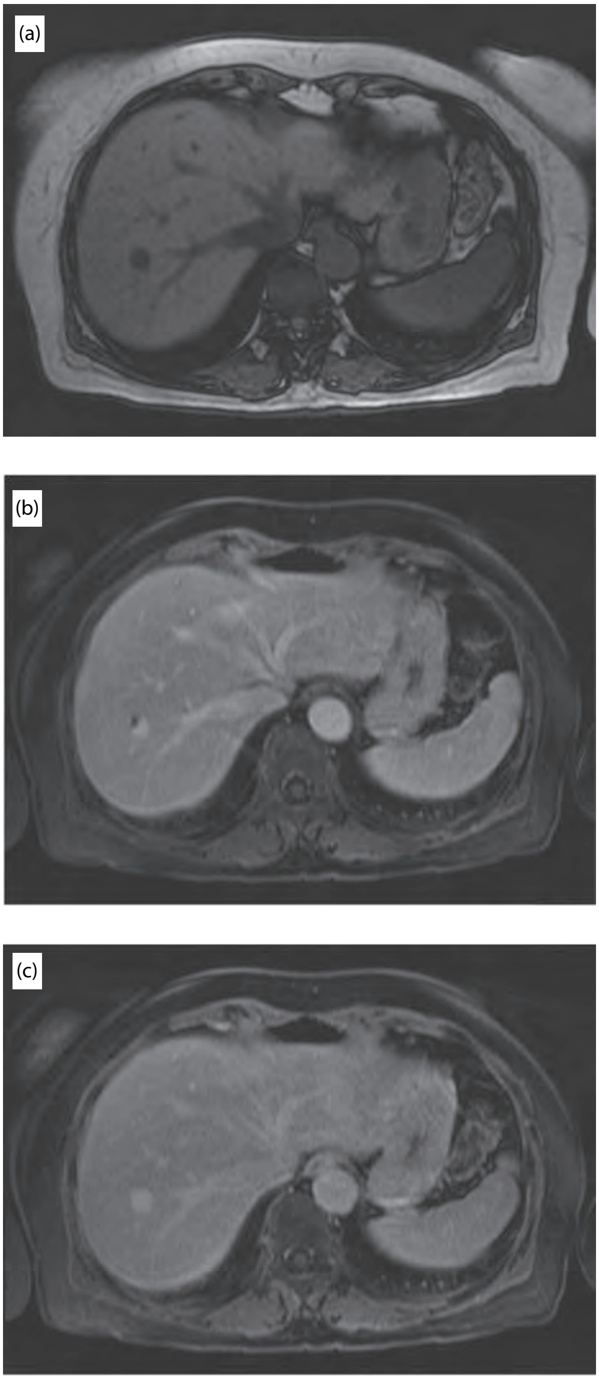

Figure 24.14 Axial MR images illustrate the behaviour of a conventional gadolinium-chelate intravenous contrast agent during dynamic imaging of a typical small cavernous haemangioma. The lesion appears as (a) uniformly low signal on the precontrast T_1 weighted image, then (b) fills in a globular fashion from the periphery before (c) becoming uniformly high signal several minutes after contrast administration.

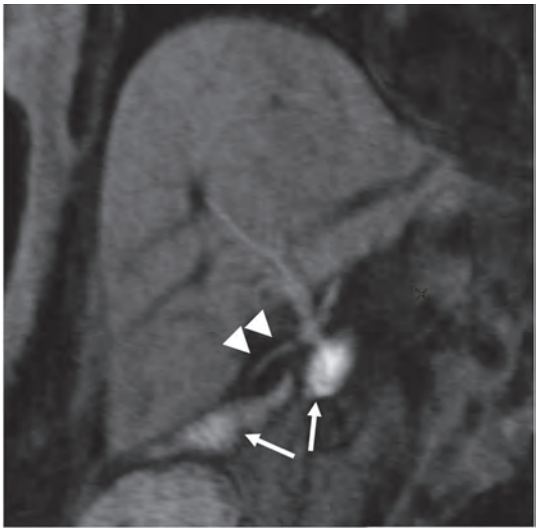

Figure 24.15 Coronal MR image illustrates the use of a biliary excreted hepatocyte-specific contrast agent to identify a bile leak at a biliary-enteric anastomosis. Contrast-enhanced bile traverses the anastomosis to enter the jejunal loop (long arrows) and also leaks laterally from the anastomosis and enters the lumen of an adjacent surgical drain (arrowheads).

enteric anastomoses. These two features are of great value to the liver surgeon.

The other class of contrast agent is based on the superparamagnetic properties of iron oxide which affect the way the spinning protons lose their synchronization during some types of acquisition sequence. This type of MRI contrast agent modifies images on so-called $T_2^\star$ weighted images. These contrast agents rely on uptake by cells of the reticuloendothelial system. In the liver normal liver parenchyma and some focal liver lesions contain Kupffer cells. On $T_2^\star$ weighted images the signal intensity from these tissues drops dramatically after administration of these reticuloendothelial contrast agents, rendering lesions which do not contain Kupffer cells conspicuous against a dark background. This behaviour facilitates both the detection of focal liver lesions which do not contain Kupffer cells (e.g. metastases) and also the characterization of focal liver lesions which otherwise display similar imaging characteristics on ultrasound, CT and MRI (e.g. hepatic adenoma, which does not contain Kupffer cells, and FNH lesions, which do contain Kupffer cells).

Recent advances in MRI of the liver include the application of diffusion-weighted imaging and MR spectroscopy. Diffusion-weighted imaging highlights the restricted potential for diffusion of water in some pathological tissue states and may aid identification and characterization of focal liver lesions. MR spectroscopy reveals varying levels of metabolites between normal and abnormal liver tissue and by means of this may assist characterization of focal liver lesions.

The following is a summary of contrast agents used in MRI of the liver (Figure 24.16):

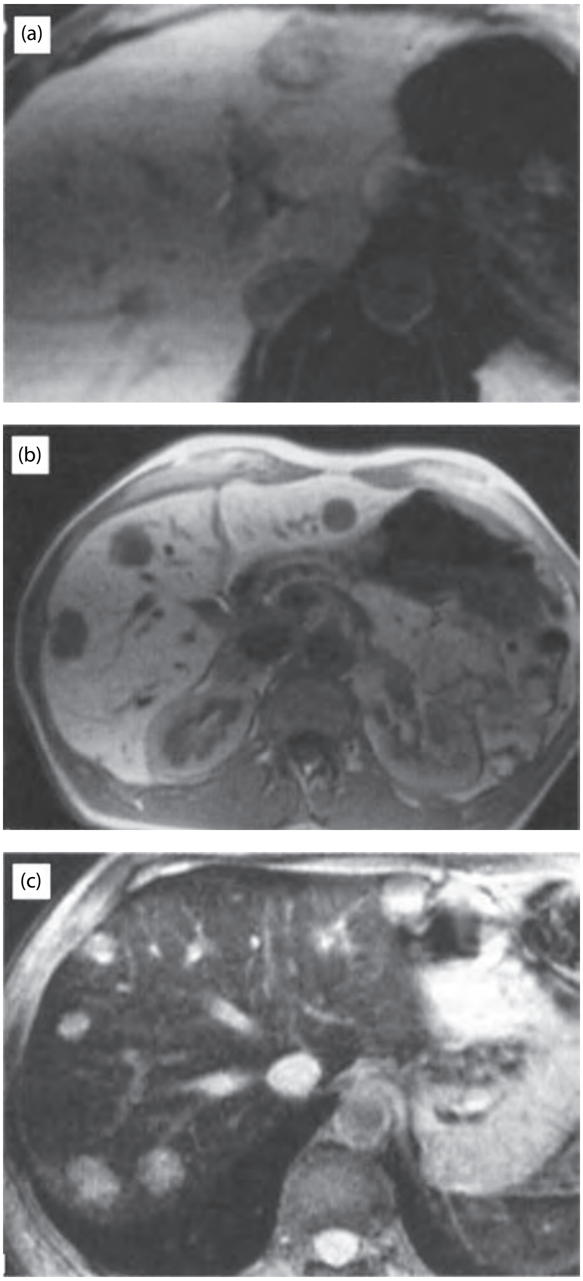

Figure 24.16 MRI scanning for liver metastases: (a) delayed T_1 weighted image following Gd-BOTA, (b) delayed T_1 weighted image following Mn-DPDF, (c) T_2 weighted image following superparamagnetic iron oxide – as the tumour deposits do not contain Kupffer cells, they appear as bright white lesions against the black (negatively enhanced) normal hepatic parenchyma.

- *Gadolinium (Gd) chelates with extracellular distribution (e.g. Gd-DTPA)*–following intravenous injection, these leave the intravascular compartment rapidly to equilibrate in the interstitial space. This limits their usefulness in the detection of focal hepatic lesions, but the technique is valuable in characterizing the nature of identified lesions by the different patterns of enhancement and washout, e.g. persistence of enhancement on delayed images in haemangiomas, strong initial transitory enhancement followed by delayed enhancement in FNH.
- *Hepatobiliary contrast agents (e.g. Gd-EOB-DTPA)* – these are hepatocyte specific and thus provide prolonged enhancement of normal liver parenchyma and lesions that contain hepatocytes. Thus HCC, FNH and the regenerative nodules of cirrhosis enhance with these agents, whereas secondary deposits, lymphomas and cholangiocarcinomas do not.
- Macrophage–monocyte–phagocyte system (MMPS) target agents – these consist of superparamagnetic iron oxide (SPIO) particles

coated with dextran that are cleared from the blood by the macrophage-monocyte system following intravenous injection. In the liver, they are taken up by the Kupffer cells abolishing the signal on heavily weighted T_2 imaging. As focal lesions (tumours in particular) do not contain Kupffer cells, they appear as bright white lesions against the black (negatively enhanced) normal hepatic parenchyma. This contrast imaging provides one of the best techniques currently available for the detection and precise location of hepatic secondary deposits particularly with three-dimensional reconstruction from the volumetric dataset.

- *Intravascular (blood pool) contrast agents* – ultra - small superparamagnetic dextran - coated particles (USPIO) are used as intravascular contrast agents in view of their long half-life in the blood (200 minutes). They are useful in the detection of hypervascular lesions (HCC, deposits from carcinoid tumours, haemangiomas, etc.) using dynamic MRI in much the same fashion as dual helical CT.

Ultrasound vs CT vs MRI scanning for liver imaging

Focal liver lesions

CT and MRI guarantee a comprehensive evaluation of the whole liver which may not be possible with ultrasound scanning depending on the body habitus of the patient. Ultrasound is also notoriously dependent on the skill of the operator, so reproducibility may be an issue in follow-up of challenging focal liver lesions. Nevertheless, in many situations, particularly for screening of high-risk patients and for follow-up of readily visualized focal liver lesions, the convenience and low cost of ultrasound may justify its use in preference to more costly MRI and CT which use ionizing radiation. CT and MRI may both be employed to detect and characterize focal liver lesions. Where focal liver lesion characterization proves challenging MRI has advantages over CT in that it allows for a greater range of tissue characteristics to be demonstrated, and hepatocyte-specific contrast agents may provide additional information which cannot be yielded by other means. Ultrasound using intravenous contrast agents may also assist the characterization of focal liver lesions. CT scanning retains a particularly valuable role in the evaluation of the profoundly unwell patient for whom the long duration and long breath-hold requirements of MRI scanning preclude practical application.

Diffuse liver disease

Diagnosis and evaluation of diffuse liver disease with non-invasive imaging techniques is a contentious area. There is no universally accepted technique, although some specialized methods involving ultrasound elastography are under evaluation. There are also MRI-based imaging techniques which may prove useful in this challenging diagnostic area.

Gallbladder and bile duct disease

Ultrasound remains the workhorse of suspected inflammatory gallbladder disease, and may be supplemented by CT evaluation if there is a clinical suspicion that sepsis has extended beyond the gallbladder. Ultrasound has limited utility in evaluation of the rest of the biliary tree in large part because it is only very rarely that the lower half of the common bile duct may be adequately visualized. For complex bile duct disease MRI using T_2 weighted acquisition sequences (MRCP) has become the technique of choice for high-quality non-invasive evaluation of suspected pathology of both the intra- and extrahepatic bile ducts. Coupled with anatomical information from T_1 weighted imaging the current ability of MRI to depict the extent of hilar cholangiocarcinoma allows the surgeon to determine the feasibility of resection in cases without resorting to trial of dissection. MRI in the delayed phase after administration of biliary excreted hepatocyte-specific contrast agents is the best non-invasive technique for detection and localization of bile leaks.

Conventional radionuclide scanning (scintigraphy)

Conventional radionuclide imaging produces images by detecting the radioactive decay of exogenously administered 'tracer' radioisotopes. These are usually tagged onto carrier compounds, thereby forming radiopharmaceutical agents, which direct the radioactive molecule to the target organs.

Advances in ultrasound, CT scanning and MRI, which produce images in far higher resolution than can be achieved with radionuclide imaging, have led to a reduction in the use of these techniques in the liver.

One specific radionuclide technique that retains a role is radiolabelled sulphur colloid scanning. Particles of sulphur colloid which have been labelled with the tracer technetium-99m are taken up by functioning cells of the reticuloendothelial system. In the liver these are the Kupffer cells, which are present in FNH lesions but not in hepatic adenomas. Radiolabelled sulphur colloid scanning may be useful to discriminate between these two focal liver lesions when the results of other imaging tests have been equivocal. Generalized impairment of hepatic tissue may be reflected in generally poor uptake of radiolabelled sulphur colloid when compared with other tissues containing large numbers of reticuloendothelial cells (spleen and bone marrow). In Budd–Chiari syndrome this generally poor uptake may spare the caudate lobe.

Another conventional radionuclide test, which retains a place in the diagnostic imaging toolbox, is functional biliary imaging with HIDA scanning. This test produces images based on the biliary excretion of intravenously administered ^{99m}Tc-labelled hepatobiliary iminodiacetic acid. In normal subjects the gallbladder is seen to accumulate the agent. If the gallbladder is not visualized within 4 hours of administration, then we can conclude that the cystic duct is obstructed. This finding may be useful in the assessment of patients whose symptoms point to a diagnosis of cholecystitis but in whom other imaging test findings are equivocal.

Positron emission tomography

Until fairly recently positron emission tomography (PET) has been used to investigate single organs, particularly the heart (myocardial perfusion, oxygen extraction, etc.) and the brain (metabolism, neurotransmitter function, etc.). With the advent of whole-body PET scanning, the technique is being introduced in oncology where it has potential and advantages over other imaging modalities:

- In principle, whole - body PET can identity a tumour and indicate the presence of spread anywhere in the body at an early stage (micrometastases).
- It can differentiate between benign and malignant tumours (metabolic activity of the lesion).
- It differentiates viable from non-viable tumour, which may be increasingly important for *in situ* ablation of tumours, e.g. liver, prostate.

PET scanning produces images by detecting the -radiation resulting from decay of positron-emitting radioisotopes. Positrons are short-lived positively charged electrons which generate a matter–antimatter annihilation interaction when they encounter electrons in the body. PET images are formed by detecting the -radiation emitted by these interactions. A unique feature is that each annihilation event generates two identical -rays which travel in diametrically opposed directions. PET scanners detect these pairs of -rays and use complex computer algorithms to produce a map of radioisotope distribution in the tissues.

The commonest positron-emitting isotope in current use is fluorine-18, which is usually administered in radiopharmaceutical form as ^{18}F-fludeoxyglucose. This is a glucose analogue which is taken up by actively metabolizing cells. The amount of uptake of this radiopharmaceutical in any tissue is proportional to the overall metabolic activity within the tissue. Thus lesions which are more or less metabolically active than surrounding normal tissues may be identified and differentiated. PET scanners are usually coupled with CT scanners to produce 'fused' images which allow the map of metabolic activity to be overlaid onto anatomical images produced by CT scanning.

The principal application of this technique in the liver itself is to aid discrimination between benign and malignant lesions. This discrimination is based on the assumption that malignant lesions are more metabolically active than benign lesions, although this may not always be the case. A further application is to detect residual viable tumour tissue at sites of resection or *in situ* ablation. However the commonest application of ^{18}F-fludeoxyglucose PET scanning in liver surgery practice is to detect previously unsuspected extrahepatic disease in patients with malignant liver lesions who are being considered for potentially curative hepatic resection or ablation therapies.

Although PET scanning of the liver is certainly a promising technique, further evidence and data are needed to fully establish its usefulness in clinical practice, its accuracy and specificity in different clinical scenarios.

Invasive imaging of the liver

In the past a variety of invasive interventional radiology techniques were employed in order to produce images of vascular structures in and around the liver and assess portal venous pressure. These have been almost entirely superseded by advances in the imaging techniques previously discussed. Modern interventional radiology applications in the liver are invariably performed with therapeutic intent (as is endoscopic retrograde cholangiography) and are guided by prior high-quality non-invasive imaging examinations. The commonest example is percutaneous transhepatic cholangiography performed to relieve obstructive biliary lesions by insertion of stents across obstructions and drainage catheters to facilitate resolution of biliary sepsis. Diagnostic brushings from obstructing biliary lesions may be taken at the same time and these may confirm the presence of malignancy on cytological examination. Hepatic arterial angiography may be performed to target arterial administration of therapeutic pharmaceutical agents in patients with HCC; a procedure usually referred to as transarterial chemoembolization (TACE).

Needle biopsy of the liver and of focal liver lesions

Despite advances in non-invasive imaging techniques imaging-guided biopsy still retains a valuable role in the evaluation of both diffuse liver disease and focal liver lesions. Please see the section General considerations (above) for further discussion of the place of liver and liver lesion biopsy in modern clinical practice.

The indications for biopsy in suspected or confirmed diffuse liver disease are where there is doubt as to the diagnosis, or where it is clinically important to determine the degree of advancement of the disease process. The indications for biopsy of focal liver lesions are where there is clinical concern that a potentially life-threatening pathology may be passing undiagnosed at a stage where there is still potential for cure, or where potential for cure has passed but tissue confirmation is required before embarking on palliative therapy. Occasionally biopsy is indicated when patients demand confirmation of diagnosis for peace of mind.

There is some debate about the appropriateness of biopsy in cases where a focal liver lesion may be a potentially life-threatening tumour but has not been characterized with absolute confidence using non-invasive imaging techniques. The concern arises because of the risk of causing tumour cell dissemination into the peritoneal cavity and chest or abdominal wall during the biopsy procedure itself. The perceived risk of such dissemination may be higher than the actual incidence of this phenomenon, but it is generally accepted practice that, for instance, a potentially resectable lesion which is likely to be a HCC should not be biopsied prior to attempting surgical resection.

Imaging-guided liver biopsy may be performed as a day case and carries a very low mortality rate (less than 0.1%). Evaluation of diffuse liver disease can only be performed on core biopsies obtained using Tru-Cut-type needles. Similarly for evaluation of focal liver lesions core biopsies are far preferable to fine-needle aspiration cytology samples.

Biopsy for diffuse liver disease may be performed without imaging guidance. However, ultrasound is so ubiquitous and so easy to use that it seems sensible to select a target site for biopsy using this imaging modality to ensure that, for instance, no lung tissue is traversed and that there are no unsuspected loops of bowel between the chest or abdominal wall and the liver.

Biopsy of focal liver lesions is most readily performed using ultrasound to guide the biopsy needle to the target tissue.

Histopathologists particularly appreciate biopsy cores which include the transition from normal to abnormal tissue and obtaining these requires practised technique. Highly skilled operators may even successfully biopsy lesions which are undetectable on ultrasound by targeting tissue using the relationship of the lesion to vascular structures as demonstrated on CT scanning or MRI.

All liver biopsies should be performed under conditions which minimize the likelihood of haemorrhagic complications: this includes the correction of any coagulopathy. If this cannot be achieved a transjugular biopsy may be performed to sample liver parenchyma in cases of diffuse liver disease: in this technique bleeding from the biopsy site is immaterial as the blood simply enters the systemic venous circulation. As well as haemorrhage other rare potential complications of liver biopsy include haemobilia, biliary peritonitis and hepatic arteriovenous fistula.

The most common complications of liver needle biopsy are:

- pleural effusion
- haemorrhage from the liver and thoracic wall
- intrahepatic haematoma
- hepatic arteriovenous fistulas
- haemobilia
- accidental puncture of the gallbladder and large bile ducts leading to bile peritonitis
- tumour cell implantation.

Laparoscopy with contact ultrasonography of the liver

Laparoscopy with contact ultrasound is an invaluable investigation that provides direct information on the state of the liver and the peritoneal cavity. It is particularly useful in the investigation of patients with jaundice, chronic liver disease, ascites of unknown origin and in the diagnosis and staging of both primary and secondary hepatic tumours. The advent of laparoscopic contact ultrasonography using high-resolution linear array probes has added considerably to the diagnostic yield of laparoscopy for the detection and staging of hepatic tumours. In addition to detecting secondary hepatic deposits in the liver and peritoneal cavity that are too small to be detected by CT scanning and MRI, laparoscopic contact ultrasonography permits the visualization of the hepatic vasculature (portal vein, hepatic artery, hepatic veins and retrohepatic vena cava) and examination of the entire biliary tract. This accurate assessment of the extent of involvement of the liver by tumour and relation to hepatic veins enables surgical planning of the resection necessary in the individual case.

Laparoscopy with contact ultrasonography and colour Doppler readily identifies haemangiomas. Visually guided biopsies or fine-needle aspiration cytology of both the hepatic parenchyma (in cirrhosis) and focal lesions (tumours) for histological confirmation carries a higher diagnostic yield than percutaneous liver biopsy, and should bleeding occur from the biopsy site, this can be controlled by compression or electrocoagulation.

In many centres it is routinely used to guide and monitor *in situ* ablation treatments like radiofrequency or microwave ablation (see below) and it is routinely employed during laparoscopic liver resection surgery (see below).

Clinical features of liver disease

Acute liver disease

Signs and symptoms

Patients may be asymptomatic or complain of non-specific symptoms, e.g. fatigue, malaise, anorexia, nausea, headache, myalgia, arthralgia and fever which commonly occur in hepatitis. Jaundice may develop in the later stages of illness.

There may be few signs apart from jaundice, best seen in the sclera, and hepatomegaly. Dark urine and pale stool are present in cholestatic disorders. Acute liver failure patients may develop features of hepatic encephalopathy with disease progression.

Chronic liver disease

Symptoms

This may be asymptomatic or patients may report non-specific symptoms, most commonly fatigue. Anorexia and nausea are common in all forms of hepatic and biliary disease and may be accompanied by weight loss and malnutrition. Jaundice is the most obvious symptom and in many instances will be accompanied by dark urine, pale stools and pruritus. Confusion, forgetfulness, poor concentration and personality change are central nervous symptoms of advanced hepatic cirrhosis [portosystemic encephalopathy (PSE)]. Fluid retention, ascites and dependent oedema, or haematemesis and melaena from gastrointestinal bleeding are manifestations of portal hypertension. Patients may complain of right hypochondrial pain due to hepatic distension or generalized abdominal discomfort due to ascites. Endocrine dysfunction may cause amenorrhoea, loss of libido or gynaecomastia.

Signs

General examination may reveal jaundice in the sclerae and skin. Pruritus may lead to scratch marks and may be present earlier than other manifestations of liver disease, especially in primary biliary cirrhosis. Xanthelasma and hyperpigmentation are also features very common in Primary biliary cirrhosis.

Chronic liver disease may show stigmata in the form of palmar erythema, finger clubbing, leuconychia, spider naevi, particularly over the upper half of the body, muscle wasting, loss of axillary/pubic hair and gynaecomastia. Central nervous system effects may be apparent with a liver flap, peripheral neuropathy and loss of consciousness ranging from confusion to full hepatic coma. In advanced disease with significant shunting, a sweet musky odour may be apparent on the breath: foetor hepaticus due to unmetabolized mercaptopurines; this is commonly associated with encephalopathy but is not pathognomonic and may occur in patients in clear consciousness.

On abdominal examination, there may be evidence of collateral veins in the abdominal wall, distension of the abdomen and eversion of the umbilicus from ascites, dependent oedema and testicular atrophy. On palpation, hepatomegaly should be searched for and a decision made whether this is real or apparent, whether it is diffuse, focal or multifocal. Liver tenderness may be elicited either abdominally or by palpation or through the rib cage by percussion. Auscultation may rarely elicit a friction rub over an expanding tumour or abscess. A systolic hepatic bruit is sometimes heard over a HCC or in patients suffering from alcoholic hepatitis. Splenomegaly may accompany hepatomegaly in patients with portal hypertension, it is rarely massive and frequently absent in patients with significant portal hypertension.

Parenchymal disorders of the liver

A full description of all liver disease is beyond the scope of this chapter. The management of parenchymal liver disease is predominantly medical, although some complications require surgical intervention. Both acute and chronic parenchymal liver disease can present with features suggestive of surgical pathology; failure to recognize this can have serious consequences and so these conditions should be considered in any differential diagnosis. Equally anyone suffering from a chronic liver disease can develop another condition requiring surgical intervention, which requires appropriate precautions. Many disorders require joint management between hepatologist, hepatic surgeon and an interventional radiologist.

Acute and chronic liver disease

Acute liver disease is a disease process affecting the liver for less than 6 months, e.g. hepatitis A, and implies that the insult will resolve. Clearly chronic liver disease must start and therefore have a period of time when its duration is of less than 6 months; for most chronic liver disease the start is subclinical for alcohol-related liver disease, and presentation is that of the chronic condition. Some conditions can present acutely and become chronic, e.g. hepatitis B. Most patients with chronic liver disease have no overt signs or symptoms of liver impairment and are considered to have 'compensated' disease; those with liver impairment evidenced by jaundice, ascites, encephalopathy are classed as 'decompensated'. The term 'acute-on-chronic' liver disease has recently been postulated to describe patients with a cirrhotic process, with evidence of liver failure associated with a 'systemic inflammatory response syndrome'. The usefulness of this concept is still debated but it does identify a group of patients with a very poor prognosis. This syndrome can be provoked after surgery in patients with chronic liver disease. Specific treatments that are of benefit to these patients over and above standard of care for liver failure have yet to be defined and trialled, but early aggressive support of the circulation and treatment of infection appear to be important.

Acute liver disease

Viral hepatitis

Acute viral hepatitis presents with nausea, right upper quadrant pain and usually jaundice, so should be included in many differential diagnoses. However, many cases of acute hepatitis are subclinical and will be discovered incidentally on testing of LFTs. It can be caused by hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis E virus (HEV) and by hepatitis C virus (HCV). A milder hepatitis can also be caused by cytomegalovirus, the Epstein–Barr virus and the protozoan Toxoplasma. In some cases of hepatitis, serological testing will be negative, no other aetiology will be evident, and it is assumed that this condition has a viral aetiology, as yet unidentified. It is further assumed that there is more than one agent and the illness is termed seronegative hepatitis. A small subset of these patients develops fulminant hepatic failure (FHF). The management of all these conditions is supportive, with observation for the tiny minority who will develop fulminant liver failure and will need invasive support and consideration of liver transplantation. In surgical practice, universal precautions should always be employed, particular care should be taken in operating on patients who are known to be infected with bloodborne hepatitides, but this should in no way prejudice the care of the patient. HAV and HEV are spread by the faecal–oral route. HAV is becoming much less common but continues to give rise to epidemics. Although the disease is usually benign, complications including prolonged cholestasis and macropapular skin reactions are common. A vaccine developed from killed virus A propagated in fibroblast culture is available. It appears to be particularly effective when combined with recombinant hepatitis B vaccine. HEV is predominant in Asia but is now endemic in the UK, but still more common in patients with a clear travel history to Asia. It has a generally benign course, except in pregnancy where there is a significant mortality. Neither HAV nor HEV infection leads to chronic infection or chronic liver damage.

HBV, which was first isolated in 1966, has infected in excess of 350 million individuals worldwide. It is a leading cause of chronic hepatitis, cirrhosis and HCC. The hepatitis B vaccination programme is altering the epidemiology of hepatitis B. Thus infection in healthcare workers and homosexuals (who have accepted the vaccination programme) has fallen. In those countries that have adopted universal vaccination programmes, huge reductions in HBV prevalence have been achieved and a decline in the complications of chronic infection has already been observed. It should be stressed that the infectivity of HBV is much greater (eight times) than that of HIV.

Chronic HBV infection is defined as the presence of HBsAg persistent more than 6 months after infection; spontaneous clearance is still possible at this stage but runs at between 2% and 4% per annum. The risk of chronic infection depends on the age of acquisition: with adult infection less than 10% become chronically infected, whereas infection in the under fives has a greater than 40% risk of chronic infection. The assessment of chronic HBV infection involves HBV serology, but also HBV DNA and an assessment of liver damage by either biopsy or non-invasive markers such as sonoelastography. The recognition of mutant HBV now means that viral load is more important than 'e-antigen' status in predicting prognosis and therefore the need for treatment. The specific therapy of chronic hepatitis B disease is now possible, but is complicated and rapidly evolving and should be undertaken in consultation with expert centres. Therapy has one of two different aims, either viral eradication with defined therapy or viral suppressive therapy long term to prevent complications of cirrhosis or HCC. Currently eradication therapy is based on -interferon, which inhibits the replication of HBV, and treatment can lead to remission of the disease with clearance of the hepatitis B e-antigen in up to 30% and hepatitis B surface antigen often follows. -Interferon is administered subcutaneously in a pegylated formulation weekly for 12 months. Factors associated with better response to -interferon include:

- HBeAg+
- a raised aminotransferase concentration >100 IU/mL
- low values for HBV DNA
- liver biopsy showing moderate to severe inflammatory activity
- age <65 years.

Viral suppressive therapy should only be contemplated in those patients who have significant risk of developing damage from their HBV infection, as it is likely to be lifelong and expensive. The aim of therapy is to depress viral load below the limit of detection, which not only reduces the risk of disease progression but also substantially reduces the risk of viral resistance. Therapy is dependent on nucleoside or nucleotide analogues; there is no synergy between these drug classes but there is a different resistance profile. Older antiviral drugs included the nucleoside analogue lamivudine (3-thiacytidine); although some patients remain on this drug, up to 40% will develop resistant virus within 2 years, with viral escape. Newer drugs with higher genetic barriers to resistance are preferred as front-line therapy. HBV antivirals have revolutionized liver transplantation for HBV with much improved survival rates.

Hepatitis C infection becomes chronic in 80% of cases; of these, 20% will progress to cirrhosis within 20 years. Worldwide 200 million people are chronically infected, and in many parts of the world it is now the leading cause of HCC and the commonest indication for liver transplantation. The commonest routes of transmission are intravenous drug misuse, unscreened blood products (pre-1991 in the UK) and unsterile medical practices. There are six genotypes of the virus with geographical variation: genotypes 1 and 3 are predominant in the UK, Europe and the USA. HCV infection is curable with combination therapy of pegylated -interferon and ribavirin in the majority of cases. Genotype 2 and 3 patients are easiest to treat, needing 6 months' therapy to achieve cure in 70% and 90% respectively. Genotype 1 patients, with a year of combination therapy, have cure rates of 40%; however, very shortly genotype-specific protease inhibitors will increase this to 70%. Following transplantation in those not cured pretransplant, nearly all patients become reinfected and 20% develop cirrhosis in the transplanted liver within 5 years.

Drug-induced liver injury

Since one of the main functions of the liver is to detoxify or to metabolize many pharmaceutical agents, it is perhaps not surprising that an overdose or abnormal response to the agent may lead to problems. It is not usually the drug but a metabolite that causes the liver cell damage, with overt jaundice and in some cases acute hepatic insufficiency (fulminant liver failure). There are many drugs that cause liver damage to varying extents. These may be classified as:

- directly hepatotoxic agents, e.g. carbon tetrachloride, tetracyclines, paracetamol, DDT and benzene derivatives
- drugs that interfe with bilirubin metabolism/transport:
  - haemolysis, e.g. para-aminosalicylic acid and phenacetin
  - impaired bilirubin excretion, e.g. methyl testosterone and norethandrone
  - interference with uptake and transport of bilirubin, e.g. rifampicin
  - interference with bilirubin conjugation, e.g. novobiocin
  - interference with bilirubin binding, e.g. salicylates and sulphonamides
- intrahepatic cholestasis, e.g. phenothiazine derivatives, chlorpromazine
- hepatitis-like disease, e.g. iproniazid, halothane, trichloroethylene
- hepatic fibrosis, e.g. methotrexate.

Damage is maximal in zone 3, where metabolizing enzymes are in the highest concentration and oxygen tension is the lowest. The histological picture may resemble acute hepatitis and, if so, has a poor prognosis. In other cases, light microscopy shows only scattered fatty change and no inflammation. A careful history of both prescribed drugs and self-medication is required for all jaundiced patients or those who have abnormal LFTs. From a clinical standpoint, drug-induced liver injury (DILI) has to be included in the differential diagnosis of most presentations of liver disease:

- cholestatic jaundice
- acute hepatitis
- chronic active hepatitis
- pseudoalcoholic liver disease
- hepatic sclerosis (due to vascular damage)
- hepatic neoplasia
- fulminant liver failure
- hepatic veno-occlusive disease
- vanishing bile duct syndrome.

DILI accounts for 40% of hospitalized cases of 'acute hepatitis'. Over 50% of cases of FHF are caused by drugs such as acetaminophen (paracetamol), halothane, phenytoin and methyl dopa. In surgical practice, hepatic injury induced by antimicrobial drugs is not uncommon, in particular co-amoxiclav (amoxicillin conjugated to clavulanate) can cause a hepatocellular or, more commonly, a cholestatic injury. The mechanism appears to be drug hypersensitivity to the clavulanic acid or a metabolite derived from it. Similar damage can be seen with flucloxacillin.

Halogenated anaesthetic agent-induced hepatitis

Although rare, halothane hepatitis is most likely to occur postoperatively and deserves mention. Although usually recoverable, severe hepatocellular damage progressing to fulminant liver failure is well documented. The injury appears to be due to hypersensitivity, and the impaired liver function is associated with pyrexia, skin rashes and eosinophilia. Importantly, the condition develops in patients after previous exposure to halothane. An antibody to a hapten metabolite of the anaesthetic agent (trifluoroacetate) is found in 30% of suspected cases of halothane hepatitis. Biochemically, there is elevation of the serum glutathione 5-transferase activity, and this appears to be a more specific and sensitive measure of anaesthetic-induced hepatic injury than the serum aminotransferases. Although there has been only one single case report implicating isoflurane and the hepatotoxic potential of this agent remains debatable, covalently bound antigens which are recognized by antibodies from patients with previous halothane hepatitis have been reported, indicating the distinct possibility of cross-sensitization with halothane or a common immune-mediated mechanism. Thus the practice of changing halogenated anaesthetics in patients requiring multiple anaesthetics does not guarantee a reduced risk.

Hepatotoxic herbal remedies

The range of DILI is not limited to prescription medication and can occur with over-the-counter medication and alternative remedies. Some herbal remedies are hepatotoxic and the spectrum of the disorders ranges from mild hepatitis to extensive necrosis, prolonged cholestasis, occlusion of the small hepatic veins (veno-occlusive disease), chronic hepatitis and cirrhosis. Chinese herbal teas (popular in the treatment of dermatitis) derived from the plants *Dictamnus dasycarpus* and *Paeonia* sp. have been confirmed to have hepatotoxic substances, and cases of severe jaundice and hepatitis have been reported after drinking these teas. Black cohosh used for menopausal symptoms and glucosamine used for joint pain have been associated with liver failure.

Ischaemic hepatitis

This condition, also known as 'shock liver', is the commonest cause of very elevated transaminases in hospital practice. It usually arises in older patients who have had an episode of hypotension. It is characterized by a rapid rise in transaminases into the 1000s within 24–36 hours of the insult and a rapid fall over the following days; often there is a secondary cholestatic phase lasting several weeks. In most patients these abnormalities are asymptomatic compared with the underlying illness, and the abnormalities resolve spontaneously. A small proportion of patients will become jaundiced; of these, some will develop a prolonged prothrombin time and even spontaneous hypoglycaemia. Management is supportive but the prognosis is poor and liver transplantation is usually contraindicated because of comorbidity that leads to shock liver.

Postoperative cholestasis

This is an old term coined more than 100 years ago with the advent of anaesthesia. It still has usefulness describing a syndrome of cholestasis seen in patients after major surgery and major sepsis and multiorgan failure in intensive treatment unit patients, but it is important to exclude drug reactions and ischaemic hepatitis. The aetiology is unclear but can be viewed as a toxic insult to the biliary canalicular system and epithelium from a combination of: bacterial products (from the gut or systemic sepsis), reduced perfusion and toxic bile. The reduced perfusion has been associated with the use of positive end-expiratory pressure in cardiothoracic procedures. The toxic bile may result from the downregulation of some canalicular transport systems in response to toxins. The clinical syndrome can vary from an asymptomatic biochemical cholestasis to prolonged jaundice or the development of a secondary sclerosing cholangitis.

Chronic liver disease

As described above, chronic liver disease has a duration of greater than 6 months. To some extent, depending on aetiology, it does not cause many symptoms or clinical complications until sufficient loss of liver parenchyma and increase in fibrosis has led to the development of cirrhosis. This and its aetiologies are described below; of course, viral hepatitis, both HBV and especially HCV, can cause chronic disease as described above.

Cirrhosis of the liver

Liver cirrhosis is the end result of hepatocyte death and regeneration with fibrosis. It must be distinguished from hepatic fibrosis, which can occur in the portal regions from chronic bile duct obstruction or congenitally, or around the central veins in chronic cardiac failure. Confluent necrosis of zones 1 and 3 leads to fibrotic bridges, and the regeneration of surviving hepatocytes results in a further distortion of hepatic architecture. There are multiple causes of cirrhosis. In the Western world, alcohol, hepatitis C and non-alcoholic steatohepatitis (NASH) would be the commonest causes. Irrespective of the underlying aetiology of the cirrhosis, the clinical syndrome and complications are very similar or identical, i.e. liver failure and portal hypertension.

Not uncommonly, the condition will be unsuspected and comes to light because of a routine estimation of LFTs or found incidentally at laparotomy. Clinical suspicion is aroused by finding stigmata of chronic liver disease such as palmar erythema, spider naevi, or otherwise unexplained peripheral oedema. Alternatively, the patient may present in a later stage of disease with muscle wasting and ascites, with gastrointestinal haemorrhage from varices, jaundice or hepatic encephalopathy.

In most patients, liver cirrhosis has a poor prognosis. However, if the underlying cause can be removed, return to normal function is possible with a huge improvement in prognosis, abstinence from alcohol being a typical example. Other diagnoses are less likely to regress, but in some the prognosis may be improved with appropriate management. Thus in the patient with chronic liver disease who presents with a condition requiring surgical intervention, not only is it important to be sure that the patient requires the intervention, but also is this the optimum time? Can the patient's condition be improved. If it can then the correct decision will often be to delay surgery.

Non-alcoholic fatty liver disease

NAFLD is the most common form of liver disease in the Western world. It is considered part of the metabolic syndrome, and as such is closely associated with type 2 diabetes mellitus, obesity, insulin resistance, hypertension and dyslipidaemia. The definition of non-alcoholic varies and in clinical practice a common-sense approach should be taken as to the main driver of liver damage: in general those drinking around 21–28 units of alcohol per week should be regarded as being within NAFLD.

NAFLD is an umbrella term encompassing a histological spectrum of disease ranging from simple steatosis to NASH. NASH can progress to the development and propagation of fibrosis leading ultimately to cirrhosis and HCC.

The pathology of NAFLD is characterized by excess fat within the liver. The excess fat is predominantly macrovesicular fat and usually seen in a perivenular (zone 3) pattern. Beyond simple fatty change, liver injury in NAFLD includes evidence of hepatocellular injury, most commonly seen as hepatocyte ballooning. Inflammatory changes and the development of fibrosis are also key histological changes seen in progressing NAFLD (or steatohepatitis).

To aid histological assessment, numerous scoring systems have been proposed. The most commonly used and widely accepted is the NAFLD activity score (NAS). The NAS is a semiquantitative assessment of the three cardinal histological features of NAFLD – steatosis, lobular inflammation and hepatocyte ballooning. Both steatosis and lobular inflammation are graded 0–3, with ballooning graded 0–2. The unweighted sum of these features constitutes the NAS, with score 5 diagnostic of NASH, score 3 considered borderline NASH and scores 2 labelled ‘not NASH’. Although the NAS system is not widely used in routine clinical practice, it is an essential component of many research studies in the NAFLD arena.

Clinical signs and symptoms are uncommon in NAFLD. When seen, the most common complaints are of vague right upper quadrant discomfort and fatigue. Most commonly, mildly abnormal elevations of aminotransferases are found incidentally in patients with some or all of the components of the metabolic syndrome. In patients undergoing obesity surgery, the prevalence of simple steatosis was 91% and 37% for NASH. NALFD is also more commonly found in patients with impaired glucose tolerance and overt type 2 diabetes mellitus, with up to 62% of newly diagnosed type 2 diabetes mellitus patients having coexisting NAFLD. As well as associations with the more commonly recognized features of the metabolic syndrome, NAFLD is also associated with other disease states including polycystic ovarian syndrome, hypothyroidism and colorectal adenomatous polyps.

There is currently no specific drug treatment; weight loss with an increase in physical activity is effective if it can be achieved. The prognosis is generally good for patients with steatosis, although they appear to have excess cardiovascular mortality. For those with NASH the prognosis is poorer with many progressing to cirrhosis within 10 years of diagnosis and those that do having an increased risk of developing HCC.

Alcohol-related liver disease

Alcoholic liver disease (ALD) is a major problem, especially in the affluent Western countries. The spectrum of liver damage varies from fatty infiltration to alcoholic hepatitis, hepatic fibrosis and cirrhosis. The last one is the commonest cirrhotic liver disease in some Western countries. The increasing per capita alcohol consumption is not just due to those who drink to excess drinking more but also to an increase in the median level of consumption; as a consequence, there has been a dramatic increase in the amount of alcohol-related liver disease. With the increase in the average amount drunk, many people now drink hazardously without signs of alcohol dependency but can still develop significant liver disease. However, it is important to note that only about 20% of those drinking at hazardous levels develop overt liver disease.

Despite intensive research, the exact mechanism responsible for the hepatic damage remains unknown; genetic factors must be important but so far polymorphisms of key genes have not been shown to confer susceptibility to ALD. Dietary deficiencies are not considered a major causal influence, but are highly prevalent as a secondary phenomenon and should be sought and treated. However, oxidative stress is a central mechanism of damage and a failure to adapt to this stress will predispose to alcohol-related liver disease. While the mechanism of activation of the stellate cells in ALD is the subject of much research, once activated they are the central players in the ongoing fibrosis of the liver in a similar manner to other liver diseases. Serum endotoxin levels are known to be increased in patients with ALD and stimulation of the phagocytes by endotoxin with excess production of tumour necrosis factor- has been suggested as a possible mechanism for hepatocyte damage. Acetaldehyde derived by oxidation from ethanol in the liver is involved in the increased synthesis of type I collagen in the liver, hence the fibrosis. Another factor which has been implicated in the fibrosis is the cytokine transforming growth factor (TGF)- , which is produced in excessive amounts by the Kupffer cells in response to alcohol. The excess TGF- stimulates the transformation of stellate into active fibroblasts. It is unclear yet which subtype of TGF- is implicated and although TGF- 1 has been widely reported, it is currently thought that more than one subtype is involved.

The presentations of alcohol-related liver disease can be divided into three: fatty liver disease, alcoholic hepatitis and cirrhosis, either compensated or decompensated. Alcohol-related fatty liver disease is now more commonly know as alcoholic steatohepatitis; it usually presents with incidental discovery of abnormal LFTs. Occasionally, there may be right upper quadrant discomfort and sometimes hepatomegaly, which may be tender due to fatty infiltration of the parenchyma. At this stage liver biopsy is not usually needed unless after screening for other liver diseases an alcohol history raises diagnostic uncertainty. If performed, it shows the hepatocytes to be distended with fat and sometimes there is an inflammatory infiltrate, early fibrosis or hyaline deposits (Mallory’s hyaline).

Alcoholic hepatitis is an acute severe condition that develops on the background of chronic alcohol use, either in a liver with normal architecture or more usually cirrhosis. The clinical features are of jaundice, often with ascites or encephalopathy, pyrexia and a bounding vasodilated circulation. Laboratory investigations reveal leucocytosis, raised inflammatory markers but only a mild elevation of the transaminases. The syndrome is defined by its poor short-term prognosis with untreated mortality of over 50%. The diagnosis can reliably be made on clinical grounds; some authorities advocate liver biopsy to confirm the diagnosis. The liver biopsy in alcoholic hepatitis shows a cellular infiltrate, liver cell necrosis, cholestasis, variable degree of fatty change and sometimes Mallory’s hyaline. These classical features can be seen in patients who are entirely well, adding to the controversy of biopsy. Treatment of alcoholic hepatitis includes cessation of alcohol and most advocate the use of corticosteroids guided by the Maddrey's discriminant function or the Glasgow alcoholic hepatitis score, which both identify high-mortality groups. Ongoing trials are comparing the use of pentoxifylline in combination with steroids or as monotherapy. The differential diagnosis is of end-stage liver disease with no inflammatory components.

The final stage is the development of cirrhosis, which is usually of the micronodular variety, but this is no longer a useful concept. The development of cirrhosis occurs some time in advance of clinical consequences, so may not be obvious until a hepatic insult such as surgery causes it to decompensate and manifest as liver failure with jaundice, ascites or encephalopathy. The most important factor in the treatment of ALD is abstinence from alcohol, and considerable improvement is seen both in LFTs and on repeat biopsy. Enteral nutrition imparts significant benefit in patients with alcoholic hepatitis and may improve survival, although this is debatable. The evidence for specific nutritional aids or supplements is poor and the control arm of the studies, if any, often represents inadequate standard hospital nutrition, so ensuring adequate dietary intake is clearly better than starvation for these patients. Transplantation is now performed for advanced alcohol-related chronic liver disease. Minimum periods of 6 months' abstinence before transplantation have previously been applied; however, these are currently being challenged as many patients with most to gain from transplantation do not survive that long. Also, due to the ill health of the patients, the abstinence is less meaningful as the patients are hospitalized for much of the duration. The results to date have been better than predicted and only about 15% of patients have resumed drinking after transplantation.

There are no specific laboratory markers of ALD, although the following are suggestive: raised levels of γ-GT, presence of carbohydrate-depleted (sialic acid depleted) transferrin and a specific isoenzyme of alanine aminotransferase (F-AAT). However, none is specific enough to rely on in an individual case, but they can raise the index of suspicion of an alcohol-related aetiology.

Cholestatic liver diseases

Cholestasis, impaired bile secretion/excretion, with the development of conjugated hyperbilirubinaemia and raised bile ductular enzymes can be caused by obstructive lesions of the biliary tract such as stones and tumours. In addition, the same pattern can be seen without dilated bile ducts and is described as intrahepatic cholestatsis. The causes of this include drugs, alcohol, viral hepatitis, primary biliary cirrhosis and primary or secondary sclerosing cholangitis. The term 'vanishing bile duct syndromes' is sometimes applied collectively to these disorders; it is a histopathological observation of ductopenia, or a paucity of bile ducts, and is not a specific disease. It can be observed in the conditions listed above and also hepatic sarcoidosis, graft-vs-host disease and hepatic transplant rejection, but is only present in a minority of cases.

Primary biliary cirrhosis

This is a disease of unknown aetiology in which the intrahepatic bile ducts are progressively destroyed by an immunological process. It runs a variable course but ultimately ends in primary biliary cirrhosis (as distinct from secondary biliary cirrhosis due to chronic obstruction of the extrahepatic biliary tract, e.g. strictures). Circulating antibodies against mitochondrial constituents (antimitochondrial antibodies) are found in all patients. These antibodies are non-organ and non-species specific and their relationship to the aetiology of the disease remains speculative but they are useful in the diagnosis of the condition. The most widely held immunological hypothesis for the development of the disease is aberrant expression of class II histocompatibility antigens on the epithelium of the bile ducts which induces a T-cell-related progressive immune destruction. There is some evidence that the mitochondrial antigens responsible for the production of antimitochondrial antibodies (e.g. E_2 antigen, which is also present in Gram-negative bacteria) may cross-react with the bile duct antigens.

The disease is often asymptomatic for long periods. Some cases are discovered accidentally because of abnormal LFTs obtained before blood donation. There is a female preponderance and the mean age at symptomatic presentation is 40 years. The symptoms include itching, weight loss, malaise and icterus. The liver becomes enlarged and, with progression of the disease, portal hypertension with splenomegaly develops. There is deposition of cholesterol in the tissues especially around the orbits and on the extensor surface of the large joints. In advanced disease, intrapulmonary shunting is associated with finger clubbing. The malabsorption secondary to the diminished bile salt pool leads to deficiency of fat-soluble vitamins (A, D, E, K) with the development of osteoporosis. In addition to biochemical features of cholestasis and presence of antimitochondrial antibodies, the serum IgM is elevated. Smooth muscle antibodies are also present in many patients.

There is no effective medical therapy but symptomatic relief is obtained by a variety of drugs. Cholestyramine is used for itching and ursodeoxycholate improves symptoms and the LFTs by replacing the toxic hydrophobic bile acids. Prednisolone seems to reduce fatigue and itching and may improve liver function. Monthly injections of fat-soluble vitamins are administered to counteract the deficiencies caused by the malabsorption. However, the disease process is not influenced by medical treatment and the only effective therapy that imparts a long-term cure is hepatic transplantation. Primary biliary cirrhosis is the second most frequent indication for liver transplantation. Nowadays, this operation is undertaken before the development of end-stage disease and the onset of hyponatraemia or significant bone disease. It is considered in patients whose quality of life has deteriorated or in whom the bilirubin exceeds 100 mol/L, and in those who develop portal hypertension.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic inflammatory large duct cholangiopathy, leading to fibrotic strictures of the intra- and extrahepatic bile ducts, of unknown aetiology. It is rare in the UK, but the leading indication for transplantation in Scandinavia. The clinical course of PSC varies considerably between patients, from decades of asymptomatic abnormalities in LFTs to frequent recurrent bouts of cholangitis progressing to liver failure requiring transplantation within a decade. Median survival from diagnosis to death or transplantation is 12 years, but the variability of the natural history makes prognostication difficult for the individual patient. The disease also carries an increased risk of cholangiocarcinoma occurring in 10–15% of cases. The diagnosis of this malignant stricture among the strictures in the biliary tree due to PSC is a significant challenge. The disease is commonly associated with inflammatory bowel disease, with up to 60% of PSC patients having inflammatory bowel disease if this diagnosis is searched for. The only curative treatment is liver transplantation. Ursodeoxycholic acid therapy is used on the basis that this is a cholestatic disease, but this is not recommended in guidelines and lacks any evidence base.

Autoimmune hepatitis

Autoimmune hepatitis is a disease characterized by persisting liver inflammation with piecemeal necrosis and an infiltrate of predominantly plasma cells. Classically, it presents in young women with a second peak in late middle age with a more even gender distribution. The disease is associated with autoantibodies; the antismooth muscle antibody is positive in 60% with the disease and the antinuclear factor is positive in 40%; both can be positive in other liver diseases at low titre. The liver, kidney and microsomal antibody are associated with a subtype of this disease that affects children. Presentation is often with incidental findings of abnormal LFTs and, on occasion, with jaundice and rarely variceal bleeding. The natural history without treatment is of progression to cirrhosis within 3–5 years; this may represent a historically more narrowly diagnosed disease. Treatment is with steroids and often a second-line immune modulator such as azathioprine (as a steroid-sparing agent); this therapy usually produces a rapid recovery and normalizes with at least 15-year survival.

Congenital and genetic liver diseases

Haemochromatosis

Congenital and genetic liver diseases are listed in Box 24.1.

Both genetic haemochromatosis and neonatal haemochromatosis represent a disorder of iron metabolism that is inherited as an autosomal recessive trait. They are thus distinct from secondary (acquired) haemochromatosis, which develops in patients with polycythaemia and those requiring multiple repeated blood transfusions (chronic haemolytic anaemias).

BOX 24.1 Congenital and genetic hepatic disorders

- Genetic haemochromatosis: defect of iron metabolism
- Neonatal haemochromatosis: defect of iron metabolism
- Wilson disease: defect of copper metabolism
- Cystic fibrosis
- α_1-Antitrypsin deficiency: sequestration of α_1-antitrypsin granules in endoplasmic reticulum
- Hereditary tyrosinaemia type 1: absence/deficiency of fumarylacetoacetate hydrolase
- Crigler-Najjar syndrome: absence/deficiency of uridine diphosphate-glucuronosyl transferase

Genetic haemochromatosis is common. The gene carrier rate in the North European population is 10% and the disorder may affect up to 1 in 300 heterozygotes. The genetic abnormality arises in the *HFE* gene and most commonly consists of a single point mutation, causing a single amino acid substitution from cysteine to tyrosine (C282Y). Another mutation causing an H63D substitution has a much weaker phenotype and usually only causes disease when compounded with C282Y. Together these account for 90% of phenotype haemochromatosis; however, it is important to note that the genotype has poor penetrance so only a minority develop phenotypic disease. The defect leads to an enhanced transport of dietary iron through the intestinal cell, and this is caused by failure of the normal mechanism of downregulation of the villous enterocyte transferrin receptors in response to excess iron stores. The discovery of the candidate gene has led to a simple effective screening method for the disorder.

If unrecognized, genetic haemochromatosis results in progressive iron deposition in the liver, heart, pancreas, joints and endocrine glands with sparing of the spleen, lymph nodes and bone marrow. The hepatic accumulation of iron leads to cirrhosis with an increased risk of HCC, which is one of the commonest causes of death in untreated patients. The classical clinical picture of the full-blown disease is that of a diabetic patient (75%) in whom there is a dusky brown pigmentation of the skin, buccal mucosa and conjunctiva (bronze diabetes) and cirrhosis. About half the patients have a polyarthropathy starting in the small joints, and many exhibit other endocrine dysfunctions including hypopituitarism and hypogonadism. The liver biopsy shows excessive iron deposition in the hepatocytes and the Kupffer cells with fibrosis or macronodular cirrhosis. The deposited iron is thought to induce hepatic injury by peroxidation of the intracellular phospholipid membranes. In addition, these patients are subject to cardiomyopathy.

Early diagnosis is essential to prevent the development of multiorgan disease. Characteristically, the serum ferritin is elevated and the transferrin saturation exceeds 55%, in the presence of which a liver biopsy is essential for establishing the diagnosis. Treatment of the disease entails phlebotomy and reduced dietary intake of iron with long-term follow-up of all patients.

Wilson disease

This is a rare autosomal recessive inherited disorder of copper metabolism leading to copper overload of various organs: liver, cornea, kidneys and the central nervous system (basal ganglia). The gene for Wilson disease (*ATP7B*) is located on the long arm of chromosome 13. Wilson disease is characterized by a low serum caeruloplasmin level. The basic cellular defect underlying the disease is unknown but there is a markedly decreased biliary excretion of copper, which is largely responsible for the progressive copper overload. The hepatic injury results in fibrosis and cirrhosis at a relatively young age and portal hypertension is common. Neurological features are more common in adult patients. The classical clinical feature is that of the Kayser–Fleischer ring of pigment in the cornea. Aminoaciduria and phosphaturia are the result of renal damage following copper deposition in the proximal tubules. Copper studies (serum copper, serum caeruloplasmin and urinary copper levels) should be undertaken in all young patients presenting with chronic liver disease, and slit-lamp examination of the cornea is also carried out. Although there may be difficulty in distinguishing Wilson disease from other chronic forms of liver disorders, as these are often accompanied by increased hepatic copper, the finding of a low plasma caeruloplasmin resolves this diagnostic difficulty.

The treatment of Wilson disease consists of chelation therapy with penicillamine or tientine together with avoidance of food high in copper content. Zinc supplementation is useful because it protects to some extent against the copper-induced hepatocyte injury and reduces the absorption of copper by the enterocytes. Ammonium tetrathiomolybdate is particularly effective for patients with neurological or psychiatric manifestations of the disease.

Cystic fibrosis

As more patients with cystic fibrosis are surviving to adulthood, the incidence of hepatic disease associated with this congenital disorder is increasing. Some 25% of patients with cystic fibrosis have clinical and biochemical evidence of liver disease. Many of these patients have intrahepatic and extrahepatic biliary strictures. Improvement in LFTs may be obtained by therapy with ursodeoxycholic acid, which increases the bile flow and alters the composition of bile such that the proportion of the less toxic hydrophilic bile acids in the bile acid pool is enhanced.

α1-Antitrypsin deficiency

This inherited disorder affects Caucasians of European descent. The deficiency of the α_1-antitrypsin (which acts as an antiprotease) results in pulmonary damage due to lack of inhibition of neutrophil elastase and to liver disease. The latter appears to be secondary to the sequestration of α_1-antitrypsin granules in the endoplasmic reticulum of the hepatocyte. There is no effective medical therapy and progressive disease is treated with hepatic transplantation.

Fibropolycystic diseases

Fibropolycystic liver disease encompasses a spectrum of related lesions of the liver and biliary tract that are caused by abnormal embryological development of the ductal plates. These lesions (congenital hepatic fibrosis, biliary hamartomas, autosomal dominant polycystic kidney disease, autosomal dominant polycystic liver disease Caroli disease, choledochal cysts) can be clinically silent or can cause signs and symptoms such as cholangitis, portal hypertension, gastrointestinal bleeding, infections and space-occupying masses.

Congenital hepatic fibrosis is a disorder that is inherited as an autosomal recessive trait, the importance of which lies in the development of portal hypertension with variceal bleeding in afflicted individuals. In congenital hepatic fibrosis, there is enlargement of the portal spaces by pronounced fibrosis and bile ductule proliferation. The ductules are dilated (ectatic) to varying degrees but still communicate with the main intrahepatic biliary tree. It is generally thought that the bile duct proliferation is the primary abnormality. Some of the bile ductules may become so dilated as to form communicating microcysts. The disease though diffuse is patchy with areas of unaffected liver, and essentially the overall architecture of the liver remains normal, although the portal fibrosis results in a block to the sinusoidal circulation within the liver and hence the development of portal hypertension.

Both sexes are affected and the disease is uncommon with a prevalence of 1:100 000. In most patients the condition is first recognized by the onset of severe gastrointestinal bleeding, which on endoscopy is found to be due to ruptured oesophageal or gastric varices usually between the age of 5 and 20 years. Less commonly, the condition presents with abdominal discomfort caused by an enlarged spleen or because of hypersplenism. In a small minority of patients, the presentation is with bacterial cholangitis. The clinical findings include hepatosplenomegaly with normal LFTs except for a slight elevation of the alkaline phosphatase or γ-GT in some patients. The liver is hyperechoic on ultrasound examination. The diagnosis is established by liver biopsy.

In 50% of cases congenital hepatic fibrosis is associated with Caroli syndrome (ectatic dilatation of the segmental bile ducts causing recurrent bacterial cholangitis). Other associated malformations that may occur include ectatic renal collecting tubules (similar to but distinct from medullary sponge kidney), duplication of the portal vein, cystic dysplasia of the pancreas, pulmonary emphysema, intestinal lymphangiectasia, cerebellar haemangioma, cleft palate and aneurysms of the renal and hepatic arteries.

The clinical course of congenital hepatic fibrosis is that of repeated episodes of variceal haemorrhage and as the liver function remains normal in these patients. A programme of banding therapy to achieve variceal eradication is usually effective at preventing bleeding. Placement of a transjugular intrahepatic shunt, especially a covered stent with improved long-term patency, is a good treatment option and may become the preferred long-term treatment for these patients. With their well-preserved liver function, surgical treatment by selective decompression by Warren shunt after the acute episode has been controlled by endoscopic banding is an option for selected patients.

Gilbert syndrome

Gilbert syndrome is the commonest cause of an isolated hyperbilirubinaemia. It is an unconjugated hyperbilirubinaemia and due to a mutation in the TATA box of the gene for bilirubin uridine diphosphate glucuronosyl transferase. This slows production of conjugated bilirubin leading to mild elevations of bilirubin that are not clinically apparent unless the patient is stressed or dieting. The condition affects 5–10% of the population. It is asymptomatic and is usually an incidental finding with the rest of the LFTs being normal. The diagnosis can be confirmed by genetic testing. In the acute setting it can cause diagnostic confusion, implying any liver problem is of more severity, especially when the acute pathology causes abnormalities in the LFTs.

Hereditary tyrosinaemia type I

This metabolic disorder is characterized by a deficiency of the enzyme fumarylacetoacetate hydrolase (FAH), which is the last enzyme involved in the degradation pathway of tyrosine.

The accumulated products of the amino acid together with various catalytic proteins result in renal, hepatic and neurological involvement. There are two clinical forms of this disorder. The acute type (total absence of FAH) is dominated by failure to thrive and progressive liver failure with death in infancy. The chronic variety (reduced levels of FAH) is characterized by renal tubular dysfunction, rickets, progressive liver disease and the development of HCC. The best treatment of this condition is hepatic transplantation, which abolishes the risk of HCC.

Crigler–Najjar syndrome

This congenital disorder which results in hyperbilirubinaemia is covered in Chapter 25.

Portal hypertension and complications

Portal hypertension arises as the result of obstruction to portal venous outflow; this may result from extrahepatic compression or thrombosis of the portal, mesenteric or splenic veins, from compression of portal venous radicles within the liver from a wide variety of liver diseases or from obstruction to the outflow from the liver (Box 24.2).

Rarely, anomalous arterioportal fistulas result in a massive rise in portal venous flow and pressure (see below). The degree of hypertension depends not only on obstruction to outflow but also on the volume of inflow; for obstructive disease such as portal vein thrombosis the increase in inflow is minimal so the portal hypertension is mild, whereas for cirrhosis there is a massively increased splanchnic blood flow, so even with incomplete obstruction there is significant portal hypertension.

The portal pressure is normally estimated in postsinusoidal cirrhosis by performing a wedged hepatic vein pressure and subtracting the inferior vena cava pressure, giving the wedged hepatic venous portal pressure gradient (PPG). A PPG <7 mmHg is functionally normal, and at 7 mmHg ascites and varices can occur, but varices will only bleed at PPG >11 mmHg. The measurement of PPG is a useful clinical tool but is not widely performed outside major centres. In sinusoidal and presinusoidal portal hypertension the PPG is normal and portal pressure must be measured by direct methods, such as splenic puncture, which these days are rarely done. Most commonly, portal hypertension is post sinusoidal and results from cirrhosis of the liver. Although a precise diagnosis may not be relevant to the immediate management of a patient with variceal bleeding, it may ultimately indicate prognosis and change the choice of subsequent treatment.

BOX 24.2 Pathogenesis of portal hypertension

- Increased blood flow into portal venous system (no obstruction)
  - Hepatic and splenic arterioportal fistulas (rare)
- Extrahepatic outflow obstruction
  - Hepatic vein thrombosis; Budd–Chiari syndrome, veno-occlusive disease; tricuspid incompetence, right heart failure
- Extrahepatic inflow obstruction
  - Congenital malformation of portal vein
  - Portal vein thrombosis
  - Splenic vein thrombosis (sectorial portal hypertension)
  - Portal vein compression, e.g. nodes
- Intrahepatic obstruction
  - Presinusoidal: periportal fibrosis and schistosomiasis
  - Postsinusoidal: cirrhosis (alcoholic, nutritional, postnecrotic, biliary), veno-occlusive diseases, haemochromatosis, Wilson disease, congenital hepatic fibrosis

Cirrhotic portal hypertension is the result of a combination of increased portal venous resistance and an increased splanchnic blood flow. Increased vascular resistance is both a mechanical consequence of liver architecture distortion and a dynamic process involving active contraction of myofibroblasts, activated stellate cells and venous smooth muscle cells. Vascular resistance may be modified by endogenous factors or pharmacological agents. Endothelin, -adrenergic stimulus and angiotensin II increase hepatic vascular resistance whereas nitric oxide, prostacyclin and vasodilating medications (e.g. nitrates, calcium channel blockers) reduce resistance. Splanchnic arteriolar vasodilatation is secondary to elevated circulating levels of vasodilator substances (including glucagon, nitric oxide) and decreased sensitivity of the splanchnic vasculature to endogenous vasoconstrictors. Patients have a hyperdynamic circulation with increased cardiac output, hypotension and hypervolaemia from the resulting sodium retention (discussed further under the section Ascites). Portal hypertension sometimes develops in patients with liver disease prior to the onset of cirrhosis. This has been attributed to intrahepatic arterioportal anastomoses, hyperdynamic circulation and the accumulation of vasoactive humoral factors which alter the resistance to flow.

About 25% of patients will have an extrahepatic cause for portal hypertension, usually a portal vein thrombosis. A proportion of these patients will also have underlying liver disease or hypercoagulability disorders such as polycythaemia. Chronic pancreaticobiliary disease or pancreatic neoplasms may be precipitating factors for portal or splenic vein thrombosis, but only rarely does neonatal umbilical sepsis seem to be an aetiological factor. Extrahepatic outflow block may result from thrombosis or occlusion of the hepatic veins (Budd–Chiari syndrome). Aetiological factors may be protein C deficiency, the contraceptive pill and ingested toxins that include *Senecio* or bush tea poisoning (veno-occlusive disease). Other patients have congenital diaphragms in the suprahepatic vena cava or chronic congestive right heart failure. Such patients rarely present with bleeding varices but suffer with intractable ascites, painful hepatomegaly and rapidly deteriorating liver function. Portal hypertension may also follow thrombosis of the splenic vein from pancreatitis or tumour. In this instance the portal hypertension is left sided (sectorial) and the varices affect the short gastric and gastroepiploic veins.

Obstruction to portal venous flow is followed by enlargement of natural portosystemic communications (Figure 24.6) and by the development of new collateral channels at surgically constructed mucocutaneous junctions (colostomy, ileostomy). Rarely, portal venous blood is shunted away from the liver by an enlargement of the umbilical vein (Cruveilhier–Baumgarten syndrome) and may be detected by a venous bruit in the midline. Though there is a risk of variceal bleeding from the ileum, colon and haemorrhoidal areas, the major risk of haemorrhage is from the oesophagus and stomach. In the oesophagus the varices are large, tortuous and thin walled with a tendency to rupture. However, in the stomach there is venous engorgement of the gastric mucosa with a tendency to erosive gastritis and a widespread diffuse haemorrhage; there is an additional component of proliferative growth of tiny blood vessels, which together cause the appearance of portal hypertensive gastropathy. The predilection of the gastric cardia to develop varices is probably due to the drainage of the left coronary vein after portal hypertension has developed. Instead of draining towards the liver, blood passes along paraoesophageal veins and then via 'perforator' veins to the submucosa of the oesophagus. Three columns tend to develop and run upwards for a variable length, usually communicating with the azygos system. Blood flow from the spleen may course through the short gastric vessels to the gastric fundus and link with enlarged collaterals at the cardia. Fundal varices are only detectable on retroflexion of the flexible endoscope in the stomach. Colonic varices may occasionally be seen on sigmoidoscopy, but not as commonly as may be expected. Nor is the caput medusa or periumbilical plexus of veins at all common. It is most prominent in patients who develop a small paraumbilical hernia into which an omental plug provides the portal flow.

It has to be recognized that not all patients develop portal hypertension as a result of their chronic liver disease; estimates vary from 15% to 40%. Furthermore, only about one-third of the patients with gastro-oesophageal varices (GOV) ever suffer from gastrointestinal bleeding. This is due both to the age of the patients and to the natural history of the underlying liver disease. In those who do develop portal hypertension, they may present with any combination of four clinical syndromes that can be attributed to portal hypertension:

- hypersplenism
- gastrointestinal bleeding
- ascites
- hepatic encephalopathy.

Hypersplenism

Splenomegaly is frequently associated with portal hypertension; it is due not just to passive venous hypertensive congestion but also to a hypertrophy of splenic tissue. This may lead to sufficient sequestration of formed blood elements in the spleen to cause haemolytic anaemia, leucopenia and thrombocytopenia. Only rarely are these features sufficient to produce major symptoms but they do lead to general debility. After portal vein decompression, hypersplenism improves in approximately 50% of patients.

Gastrointestinal haemorrhage

Approximately 70% of cirrhotics will have GOV at disease presentation. Of these patients, 30% will suffer gastrointestinal haemorrhage within 1 year of diagnosis; the index variceal bleed is associated with a 30–50% mortality rate. Bleeding risk is elevated in patients with larger varices, high portal venous pressure (>12 mmHg) and severe liver disease. The prognosis of a bleed is most dependent on the stage of liver disease prior to haemorrhage and to a lesser but important extent on the duration of the bleed and any hypotension, as this exacerbates decompensation of liver function. The following endoscopic findings are predictive of an increased risk of variceal haemorrhage:

- cherry-red spots
- red wale markings
- blue varices (as opposed to white).

Variceal bleeding may present with frank haematemesis, coffee-ground vomitus and/or repeated melaena. Management of oesophageal varices is divided into treatment of acute bleeding, prevention of recurrent haemorrhage and primary prophylaxis.

Management of acute variceal haemorrhage

Patients should be resuscitated with intravenous fluids and blood products as appropriate; those with known liver disease or stigmata of cirrhosis should receive vasoactive drug therapy (terlipressin or octreotide). Blood volume resuscitation should aim to restore haemodynamic stability but must be undertaken with caution; the recommended target haemoglobin is 8 g/dL. Experimental studies have shown that full restitution of lost blood volume results in an elevation of portal pressure above baseline, with increased risk of rebleeding and mortality. Upper gastrointestinal endoscopy should be performed as soon as possible, ideally after the patient has been resuscitated and is haemodynamically stable. On occasion, even with aggressive fluid resuscitation, stability may fluctuate and early endoscopy may stabilize the situation, but this should not slow the resuscitation. Endoscopy should be performed within 12–18 hours of admission.

Endoscopic therapy

Oesophageal varices

Endoscopy has the advantage of allowing specific therapy at the time of diagnosis; it is also important to exclude bleeding from other sources (e.g. peptic ulceration). Variceal haemorrhage may be treated endoscopically, either by injection sclerotherapy or by band ligation. Sclerotherapy involves injecting a sclerosant solution such as 5% ethanolamine oleate directly into the varix, producing vessel thrombosis, or into the overlying submucosa to induce inflammation and subsequent fibrosis. Complications include fever (transient), ulceration, stricture, perforation (rare), chest pain, mediastinitis and pleural effusion.

Endoscopic variceal ligation (EVL) is achieved by attaching a banding device to the tip of the endoscope. The varix is aspirated into the banding chamber and the band placed over the varix using a trip-wire mechanism, ligating the vessel. One to three bands are applied to each varix, resulting in thrombosis. Chest pain or banding-related ulceration may occur following EVL, but there are fewer associated complications than injection sclerotherapy. It has been demonstrated in a meta-analysis of 10 randomized controlled trials (RCTs) that EVL is superior to sclerotherapy in terms of both rebleeding rates and mortality; injection sclerotherapy had higher complication rates, particularly with regards to oesophageal ulceration and sepsis.

Combined endoscopic (either EVL or injection sclerotherapy) and pharmacological (splanchnic vasoconstrictors) therapy has proven superior to endotherapy alone in a meta-analysis of eight trials, with more effective control of initial haemorrhage and 5 day haemostasis without differences in morbidity or mortality. Both the British Society of Gastroenterology and the American Association for the Study of Liver Diseases (AASLD) recommend combination therapy with initiation of vasoactive drugs at the time of admission, prior to diagnostic upper gastrointestinal endoscopy.

Gastric varices

Bleeding from gastric varices only accounts for 10–36% of all variceal haemorrhages, but the bleeding can be more severe and the management more challenging. Gastric varices are classified according to their distribution and whether they are in continuity with oesophageal varices. GOV type 1 (GOV 1), the most common, are in continuity with oesophageal varices, extending <5 cm along the lesser curve. GOV which are in continuity with oesophageal varices but which extend further towards the fundus are classified as GOV type 2 (GOV 2). Isolated gastric varices (IGVs) occur in the absence of oesophageal varices: type 1 are located in the fundus (IGV 1) and type 2 (IVG 2) are located in the body, antrum or around the pylorus. GOV 1, GOV 2 and IGV 1 are most commonly associated with upper gastrointestinal haemorrhage.

Fewer clinical trials exist regarding endotherapy for gastric variceal haemorrhage, thus it is difficult to formulate management guidelines in the absence of robust evidence. GOV 1 constitute extensions of oesophageal varices and the recommended management is the same as for oesophageal varices. Haemostasis and rebleeding rates are reportedly similar in GOV 1 and oesophageal variceal haemorrhage.

Varices in the cardia and fundus (GOV 2 and IGV 1) tend to be more tortuous and complex; management of haemorrhage from these varices is more challenging and requires different endotherapy to GOV 1. Injection sclerotherapy is not recommended for gastric variceal bleeding following reports of inadequate haemostasis, embolization of sclerosant and ulcer haemorrhage at the site of the injection. Alternative therapeutic options are EVL or variceal obturation by injection of tissue adhesive glue or thrombin. Endoscopic variceal obturation (EVO) using cyanoacrylate injection is the current recommended treatment for fundal variceal haemorrhage, providing better control of initial haemorrhage and lower rebleeding rates than EVL. Two RCTs compared outcomes of EVO and EVL in the management of gastric variceal haemorrhage: the first found EVO to be superior both in the achievement of initial haemostasis and in lowering the rates of repeat haemorrhage; the second found no difference in control of bleeding but demonstrated a significant reduction in recurrent haemorrhage in patients treated with EVO. These studies, however, reported outcomes from all patients presenting with gastric variceal haemorrhage, including those with GOV 1. GOV 1 varices, as reported previously, are as well controlled by EVL as oesophageal varices, making these results difficult to interpret. Future studies limited to the management of GOV 2 and IGV 1 variceal haemorrhage are required. Thromboembolic complications including portal vein embolization (PVE), splenic infarction, myocardial infarction and stroke have been reported in case studies and a case series reported non-fatal pulmonary emboli in 4.6% of patients.

Endotherapy using thrombin injection has also been described in the control of gastric variceal haemorrhage but, as yet, this has not been subjected to RCT. Two small trials (patient numbers of 12 and 13) reported haemostasis rates of 100% and 92% and rebleeding rates of 27% and 0%, respectively. Both studies were limited by small patient numbers and short-term follow-up. Potential risks of thrombin endotherapy include allergic reactions or thromboembolic complications.

Vasoconstrictor therapy

Vasoactive drugs restrict portal inflow by splanchnic arterial vasoconstriction, resulting in reduced portal pressure. Therapy should be initiated as soon as variceal haemorrhage is suspected, prior to endoscopy. The most commonly used vasoactive drugs are discussed below.

- *Octreotide* – a somatostatin analogue. Administered as a 50 μg bolus followed by 50 μg/h continuous infusion. Produces splanchnic vasoconstriction without significant systemic vascular effect or complications.
- *Terlipressin* – a synthetic analogue of vasopressin. Administered at an initial bolus dose of 2 mg every 4 hours, titrated down to 1 mg every 6 hours after haemostasis is achieved. Contraindicated in patients with ischaemic heart disease, terlipressin has longer biological activity and fewer side effects than vasopressin (e.g. arrhythmias, hypertension, digital, gastrointestinal or cardiac ischaemia).

A meta-analysis of seven RCTs showed a statistically significant reduction in mortality in patients treated with terlipressin compared with placebo; the number needed to treat to prevent one death was 8.3. Combined vasoconstrictor and endoscopic therapy is superior to endotherapy alone; terlipressin combined with endoscopy showed improved haemostasis and reduced mortality compared with endotherapy plus placebo. UK treatment guidelines recommend initiation of terlipressin therapy in all patients with suspected variceal haemorrhage; treatment should be continued for 48 hours after confirmation of diagnosis.

Terlipressin is not yet available for treatment of variceal haemorrhage in North America; somatostatin and its analogues, most commonly octreotide, are administered as recommended by the AASLD. A systemic review identified 21 RCTs studying somatostatin and its analogues; there was no change in mortality but improved rates of initial haemostasis were demonstrated with drug therapy compared with placebo. A meta-analysis of eight RCTs combining endoscopy with somatostatin and its analogues showed combination treatment was superior to endotherapy alone; initial haemostasis and rebleeding rates were significantly lower with combination therapy but there was no survival benefit. Patients should receive somatostatin and its analogues at initial presentation with variceal bleeding; treatment should continue for 3–5 days following endotherapy.

In summary, combined therapy should be the standard of care for acute variceal bleeding with an immediate pharmacological agent when variceal bleeding is suspected; where available terlipressin is probably the agent of choice and this should be combined with early endoscopy and therapy with EVL for oesophageal varices and EVO for gastric varices.

Management of uncontrolled variceal haemorrhage

Despite urgent pharmacological and endoscopic therapy, uncontrolled haemorrhage or early rebleeding occurs in 10–20% of patients. Initial emergency measures to control massive blood loss should be followed by definitive second-line management of the underlying cause.

Balloon tamponade

This procedure is a temporary salvage treatment for uncontrolled variceal bleeding, two balloon systems are commonly used.

- *Sengstaken–Blakemore tube* – with a gastric balloon of about 60–100 mL capacity, which is meant to anchor the tube at the cardia and an oesophageal balloon which is inflated to 30–40 mmHg and compresses the submucosal veins of the oesophagus.
- *Linton tube* – with a large gastric balloon of 300–700 mL capacity which is pulled against the diaphragmatic hiatus with traction and disconnects the high-pressure portal venous system from the thoracic azygous veins.

Haemostasis with balloon tamponade is achieved in 80–95% of patients with oesophageal or gastric variceal haemorrhage; it is, however, associated with serious complications such as aspiration pneumonia, mucosal ulceration and oesophageal rupture, which lead to mortality rates of 5–20%. As the use of the oesophageal balloon increases the risk of complications with little evidence of additional haemostatic effect, we should discourage its routine inflation. Haemorrhage of the severity to warrant use of a tamponade tube should also prompt consideration of elective tracheal intubation to prevent aspiration. Balloon tamponade should only be used as a temporizing measure (12–24 hours) in patients with uncontrolled haemorrhage; definitive endotherapy or portosystemic shunting can be performed once the patient is stabilized.

Transjugular intrahepatic portocaval shunt

Transjugular intrahepatic portocaval shunt (TIPS) is performed by interventional radiology and creates a channel between the systemic and portal venous systems to divert portal flow into the hepatic vein, thus reducing portal pressure. A guide wire is passed via the internal jugular vein into the right hepatic vein; the wire then passes via a needle through the liver parenchyma into the portal vein. A metal stent is then deployed across the intrahepatic parenchymal tract to form a shunt between the portal and hepatic veins. Procedure-related complications include pneumothorax, puncture site haematoma or arteriovenous fistula formation, cardiac arrhythmias, haemorrhage, arterial and bile duct injury. Postprocedure complications include hepatic encephalopathy, shunt-related haemolysis and stenosis or occlusion of the shunt. Acute alterations in cardiac output and central venous and pulmonary wedge pressure immediately post-TIPS insertion may result in cardiac failure or pulmonary oedema and patients must be monitored closely for these complications.

TIPS is safer for patients with advanced liver disease, avoiding the risks of general anaesthesia and major surgery. A large retrospective study comparing emergency TIPS insertion to oesophageal transection and devascularization showed improved survival with TIPS (42% vs 79%) and recommended this should be the treatment of choice for torrential variceal haemorrhage. Clinicians tend to have a lower threshold for TIPS insertion in gastric variceal haemorrhage: TIPS is recommended after a single episode of rebleeding or in cases where endotherapy is not possible. TIPS achieves haemostasis rates in excess of 90% in patients with uncontrolled gastric variceal haemorrhage.

Additional management of acute variceal haemorrhage

- *Antibiotic prophylaxis* – chronic liver disease patients with acute upper gastrointestinal haemorrhage have a high risk of developing serious bacterial infections such as spontaneous bacterial peritonitis (SBP); severe sepsis is associated with early recurrence of variceal bleeding and increased mortality. A meta-analysis of 12 trials evaluating antibiotic prophylaxis in cirrhotic patients with upper gastrointestinal bleeding demonstrated a significant reduction in infection rates, rebleeding and overall mortality. Short-term (7 days) oral norfloxacin or intravenous ceftriaxone is recommended.
- *Sucralfate* – 1 g four times daily is given to prevent mucosal ulceration following EVL or sclerotherapy.
- *Measures to prevent encephalopathy* – PSE may be precipitated by gastrointestinal haemorrhage; the management is described later in this chapter.

Prevention of recurrent variceal haemorrhage

Following the index episode of variceal bleeding, the risk of recurrence is 60–80% within 1–2 years with a mortality of 20–33%. Secondary preventative measures should be commenced prior to discharge from hospital.

Endoscopic therapy

Repeated courses of endotherapy (at weekly intervals) leads to obliteration of oesophageal varices by fibrous tissue, this usually requires two to four sessions. Once eradicated, patients should undergo surveillance endoscopy every 3–6 months to screen for variceal recurrence. Band ligation (EVL) has been shown to be superior to sclerotherapy in the prevention of variceal recurrence; a meta-analysis of seven trials showed reduced rebleeding rates, mortality and complications with EVL. Complications occur in approximately 14% of patients but are relatively minor, with transient dysphagia and chest discomfort occurring most frequently. Ulceration at the site of EVL is common and treatment with sucralfate and/or esomeprazole is recommended to reduce the risk of banding ulceration and bleeding.

There is no current evidence to support repeat courses of endotherapy in patients with gastric varices. A single RCT compared histoacryl glue obliteration with propranolol secondary prevention and found no difference in rebleeding or mortality rates; endotherapy was associated with more complications than beta-blockade.

Vasoactive drug therapy

Propranolol monotherapy was compared to placebo secondary prevention in a meta-analysis of 12 trials and shown to significantly lower the risk of rebleeding and reduce mortality. Combined beta-blockade and endotherapy was demonstrated to be superior to EVL alone in two RCTs, with rebleeding rates of 23% and 14%, respectively, for nadolol plus EVL compared with 47% and 38% for EVL alone. A combination of beta-blocker and nitrate has been shown to be superior to beta-blockade monotherapy and of equal efficacy to EVL. In practice, however, few patients are able to tolerate dual pharmacotherapy because of side effects, and the current recommended practice is combined beta-blockade plus EVL for secondary prevention.

Transjugular intrahepatic portocaval shunt

The use of TIPS for secondary prevention is currently reserved for patients in whom endotherapy and/or pharmacological therapy has failed or cannot be tolerated. A meta-analysis of 22 trials comparing portosystemic shunts (TIPS and surgical shunts) with endotherapy demonstrated a reduction in recurrent haemorrhage, but this was at the expense of an increased incidence of chronic encephalopathy with no survival benefit.

Standard practice has recently been challenged by researchers in Barcelona who argued that patients with advanced liver disease and high risk of rebleeding would benefit from early TIPS insertion. Patients with Child's C cirrhosis or Child's B disease with active bleeding at endoscopy were randomized to receive standard medical secondary prevention or early TIPS insertion within 72 hours of admission. The early TIPS group showed significantly lower rates of treatment failure, encephalopathy and mortality than patients managed with EVL and vasoactive drug therapy. Use of more modern polytetrafluoroethylene -covered stents is associated with lower risk of encephalopathy and improved rates in patency and rebleeding. The study is limited, however, by selection bias (e.g. exclusion of patients with Child–Pugh score >13) and low patient numbers.

Primary prophylaxis

All patients with cirrhosis should undergo endoscopic screening to detect varices at the time of diagnosis, and if not present at 3 year intervals thereafter. Beta-blockade is recommended in patients with larger varices or in those with small varices and additional risk factors for haemorrhage (e.g. Child's B/C liver disease, presence of red wale marks on varices). EVL has been shown to be as effective as beta-blockade in primary prophylaxis, but much less cost-effective so is reserved for those intolerant of beta-blockade.

Surgical treatment

More than 85% of patients with bleeding varices can be controlled by non-surgical measures and surgical treatment of refractory variceal bleedings has become even more unusual since the introduction of TIPS and of prophylactic endoscopic sclerotherapy.

However patients in whom endoscopic sclerotherapy has failed or the bleeding has recurred early remain problematic. The majority of these patients are high-risk candidates with poor liver function from end-stage liver disease or where liver function has worsened from Child A/B to C as a consequence of the recurrent hypovolaemic episodes. Unless prior information is available on the patient, it is difficult to distinguish between these two categories at the time of emergency presentation. Portosystemic shunting in this group carries a prohibitive mortality and is contraindicated. The aim of surgical management should be to prevent death from exsanguination and not to treat the underlying portal hypertension and therefore an oesophageal transection should be considered instead. This procedure was proposed by Sugiura and Futagawa and consisted of oesophageal transection, extensive oesophagogastric devascularization and splenectomy. Nowadays, the transection and reanastomosis of the oesophagus is performed with a circular stapler introduced through a service gastrotomy (Figure 24.17).

Some other high-risk patients can be considered for surgical treatment of portal hypertension in an elective setting, such as those in whom variceal bleeding has been temporarily arrested and who have good liver function (Child A/'good' B) but remain at high risk of rebleeding and have had several episodes of sclerotherapy. Elective surgical therapy by portosystemic shunting or oesophageal transection with devascularization may be a sensible, cost-effective and safe management approach.

Patients with end-stage liver disease (Child C) who have been definitively controlled by sclerotherapy should be considered

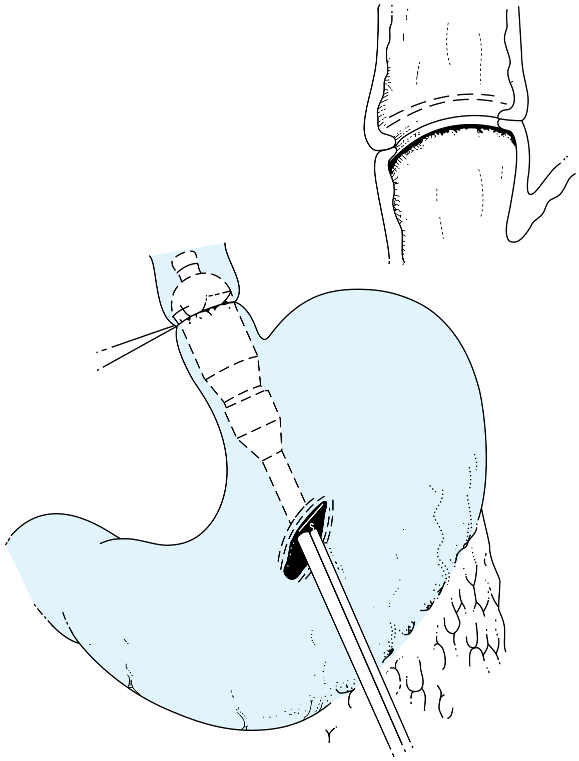

Figure 24.17 Stapled transection and reanastomosis of the distal oesophagus with a circular stapler (28–31 mm) introduced through a small anterior gastrotomy during a Sugiura procedure. A strong suture is tied around the central axle of the stapler gun before it is closed and fired.

for hepatic transplantation. For this reason, surgery should be avoided as it increases the morbidity and mortality of the procedure and TIPSs are more appropriate and successful in achieving portal decompression and thus avoid further bleeding episodes prior to hepatic transplantation.

Portosystemic shunts can be total (total deviation of portal blood flow to the systemic circulation), partial (partial deviation of portal blood flow though the placement of a narrow prosthesis in either the portocaval or mesocaval position) and selective (distal splenorenal, coronariocaval, splenocaval). Selective shunt operations are associated with good control of rebleeding and lower rates of encephalopathy but are less successful in controlling acute variceal bleeds. The indications for such an operation are now limited to non-cirrhotic portal hypertension and patients living in areas where newer therapies (TIPS) are not available. The most commonly performed of the selective shunts, and one that still has a role to play nowadays, albeit infrequently, is the distal splenorenal shunt (DSRS or Warren shunt). In this operation (Figure 24.18), the splenic vein is anastomosed to the left renal vein in an end-to-end fashion with diversion of blood from the cardia via the short gastric veins into the inferior vena cava circulation. The objective is to preserve portal venous flow to the liver and while this is achieved in the postoperative period, it does not seem that it can be maintained in the long term. A multicentre randomized trial of TIPS vs DSRS showed no overall difference in survival and a tendency for TIPS to be more cost-effective in terms of lives saved.

Ascites

Ascites is the commonest complication of hepatic cirrhosis, occurring in 50–60% of patients within 10 years. Ascites is a major cause of hospital admission and its development is an important landmark in the natural history of cirrhosis, being associated with 50% mortality over 2 years. Accumulation of ascites occurs with the development of severe portal hypertension, impaired sodium excretion and water retention. The pathogenesis of ascites has several theories and is not yet fully understood; these have been discussed in great detail in a number of review articles. This chapter will briefly discuss the most accepted mechanisms, the peripheral arterial vasodilatation hypothesis and the forward theory of ascites formation, on which current treatment recommendations are based.

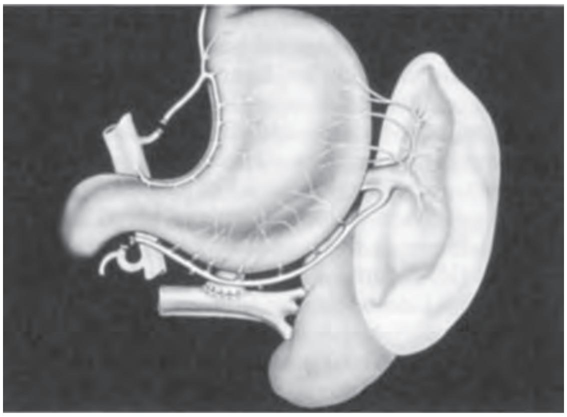

Figure 24.18 The Warren distal splenorenal shunt which results in transplenic decompression of the portal circulation.

The presence of portal hypertension is essential for the development of ascites; it usually occurs when the wedged hepatic venous portal gradient exceeds 12 mmHg but can occur at lower pressures. Portal hypertension disrupts the Starling equilibrium within the splanchnic circulation, resulting in transudation of fluid into the peritoneal cavity.

Peripheral arterial vasodilatation hypothesis

This theory postulates that renal sodium retention occurs as a result of splanchnic arterial vasodilatation secondary to portal hypertension. Nitric oxide is considered to be the putative vasodilator, although other substances (e.g. atrial natriuretic peptide, glucagon calcitonin gene-related peptide and prostaglandins) may also be involved. The reduction in effective arterial blood volume activates the sympathetic nervous system and renin–angiotensin system, thus promoting sodium and water retention. The resultant increase in extracellular fluid volume leads to formation of ascites and oedema.

Forward theory of ascites formation

According to this theory, splanchnic arterial vasodilatation induces ascites formation by simultaneously impairing the systemic circulation, leading to sodium and water retention, and splanchnic microcirculation, resulting in leakage of fluid into the peritoneal cavity.

Assessment and diagnosis

The initial evaluation of the patient presenting with ascites includes a detailed history, physical examination, abdominal ultrasound, laboratory assessment of hepatic and renal function, urine and serum electrolytes and ascitic fluid analysis. Diagnostic paracentesis of 10–20 mL of fluid should be obtained and the following analyses performed:

- cell count – a neutrophil count >250 cells/mm^3 is diagnostic of SBP
- Gram stain and culture
- protein and albumin – the serum–ascites albumin gradient (SAAG) helps differentiate ascites due to portal hypertension from ascites due to other causes; a SAAG 11 g/L is ascribed to portal hypertension with 97% accuracy; total ascitic protein should be measured to assess the risk of SBP, patients with protein <10 g/L have a higher infection risk.
- cytology – to assess for malignant cells
- amylase – to exclude pancreatic ascites.

Management

Treatment of ascites aims to restrict dietary salt intake and increase renal sodium excretion; patients with tense ascites will require paracentesis prior to commencement of medical therapy.

Sodium restriction

Negative sodium balance can be achieved by dietary salt restriction alone in 10–20% of patients; in practice it is usually combined with diuretic therapy during initial management. Sodium restriction [2000 mg/day (88 mmol/day)] is associated with reduced diuretic requirements, more rapid resolution of ascites and shorter hospital stay. Recommended sodium intake for ascitic patients varies between guidelines from 2 to 6.9 g/day; in practice, patients are advised to follow a no added salt diet and to avoid processed foods. This achieves reasonable sodium restriction without impairing nutrition.

Diuretics

Spironolactone, an aldosterone antagonist, acts on the distal tubules to promote natriuresis and conserve potassium. It is the drug of choice for the initial management of cirrhotic ascites and is commenced at 100 mg daily, increasing to a maximum dose of 400 mg. It takes 3–5 days from onset of therapy for the drug to take effect; spironolactone should be increased in 100 mg increments every 3 days until adequate natriuresis has been achieved. The aim of diuretic therapy is to increase urinary sodium excretion so that it exceeds 78 mmol/day (88 mmol intake/day to 10 mmol non-urinary excretion/day). A 'spot' urine specimen with sodium concentration more than potassium concentration correlates with a 24-hour sodium excretion greater than 78 mmol/day with approximately 90% accuracy. Random testing of the urine sodium–potassium ratio is more convenient than the cumbersome 24-hour collection, and gives an indication of whether diuretic dosage is adequate or requires further titration. Common side effects of spironolactone are hyperkalaemia, renal impairment and those related to the drug's antiandrogenic activity (e.g. reduced libido, gynaecomastia). Amiloride, 10–40 mg daily, may be substituted for spironolactone in patients with tender gynaecomastia, but it has been found to be less effective and is more expensive than spironolactone.

Furosemide, a loop diuretic, causes marked diuresis and natriuresis in the normal population but has been shown to be less effective in cirrhosis. It is used as an adjunct to spironolactone therapy with initial dosing of 40 mg daily, titrating to a maximum 160 mg. Higher doses are associated with electrolyte disturbance and metabolic alkalosis. All patients should be monitored closely in the initial stages of management; overdiuresis may result in volume depletion, renal impairment hyponatraemia or PSE.

Spironolactone monotherapy is useful in patients with minimal fluid overload who can be managed in the outpatient setting. Combination therapy is recommended for patients with more marked fluid retention, resulting in faster fluid mobilization and maintenance of normokalaemia.

Refractory ascites

Refractory ascites occurs in patients who fail to respond to sodium restriction and diuretics (diuretic-resistant ascites) or in those who develop complications which preclude the use of effective doses of diuretics (diuretic-intractable ascites). The prognosis is poor in such patients and, if appropriate, referral for liver transplantation should be considered. Other treatment options include paracentesis and portosystemic shunts.

Paracentesis

Patients with refractory ascites are initially managed by serial large volume paracentesis (LVP); total paracentesis is generally safer than repeated smaller aspirations. Volume expansion is given alongside paracentesis to avoid postprocedure circulatory dysfunction, renal impairment and electrolyte disturbance. Several studies have demonstrated the safety and effectiveness of LVP with volume expansion; administration of 8 g albumin/L ascites removed (100 mL 20% albumin/3 L ascites) is recommended.

Transjugular intrahepatic portocaval shunt

TIPS insertion should be considered in patients in whom frequent LVPs are required; prospective RCTs have shown TIPS to be more effective in controlling ascites than LVP, but there is no difference in survival. Hepatic encephalopathy occurs following TIPS insertion in 25% of patients, with a higher risk in patients over 60. It may precipitate pulmonary oedema and cardiac failure in patients with pre-existing heart disease because of increased cardiac preload. Outcomes are poorer in patients with advanced (Child's C liver disease), and TIPS is not recommended in this group. It is also advisable to avoid TIPS in patients with recurrent hepatic encephalopathy, concomitant infection, progressive renal failure or severe cardiopulmonary disease.

Spontaneous bacterial peritonitis

SBP is a monomicrobial infection of ascites occurring in 10–30% of hospitalized patients with cirrhosis. It is a serious complication of ascites with a mortality rate of 20%, despite improvements in early diagnosis and prompt treatment. Patients with SBP are frequently asymptomatic; therefore, diagnostic paracentesis is mandatory in all patients presenting to hospital with ascites and in those with worsening decompensation.

Escherichia coli, Gram-positive cocci (mainly streptococci) and enterococci are the most commonly isolated organisms, accounting for 70% of cases of SBP. Intravenous cefotaxime covers 95% of the flora commonly isolated in SBP and achieves high penetrance of ascitic fluid during therapy. Empirical treatment with cefotaxime is recommended in all patients with ascitic neutrophil count >250 cells/mm^3 until results from culture and antibiotic sensitivity testing are available. Patients with a negative cell count should receive antibiotic prophylaxis, norfloxacin 400 mg daily, while in hospital.

Hepatorenal syndrome

Hepatorenal syndrome (HRS) is defined as the occurrence of renal failure in patients with advanced liver disease in the absence of an identifiable cause of renal impairment (e.g. hypovolaemia, nephrotoxic drugs). HRS is a functional renal impairment resulting from renal hypoperfusion, the pathophysiology is similar to that producing ascites. There are two types:

- type 1 HRS – characterized by a rapid and progressive impairment in renal function (increase in serum creatinine 100% from baseline to >221 mol/L within 2 weeks)
- type 2 HRS – occurs in patients with refractory ascites, characterized by a stable or less progressive impairment in renal function.

Type 1 HRS commonly affects patients with severe alcoholic hepatitis or those with end-stage liver disease following an episode of sepsis such as SBP. Development of type 1 HRS has an extremely poor prognosis with 80% mortality within 2 weeks; management involves plasma volume expansion with albumin and vasoconstrictor therapy. Liver transplantation should be considered in all patients with HRS, as post liver transplantation survival is approximately 65% for patients with type 1; optimization of renal function preoperatively improves outcomes after liver transplantation. Terlipressin and albumin therapy has been shown to improve renal function in 50–60% of patients; however, studies to date show no improvement in long-term survival without liver transplantation. TIPS may offer an alternative to pharmacological therapy but there are insufficient data to support this at present; haemodialysis is currently reserved for patients awaiting transplantation who have failed to respond to medical therapy.

Renal dysfunction in patients with cirrhosis

The classification of renal dysfunction in cirrhotics has recently been expanded, recognizing that many patients develop acute and chronic renal dysfunction without the diagnostic criteria of HRS. Early diagnosis of lesser degrees of renal impairment should improve outcomes as patients will be treated earlier in the natural history of renal dysfunction. The revised classification system has been expanded to include:

- acute kidney injury – rise in serum creatinine of ³50% from baseline or by 26.4 mol/L in less than 48 hours; HRS type 1 is a specific form of acute kidney injury
- chronic kidney disease – glomerular filtration rate (GFR) <60 mL/min for >3 months; HRS type 2 is a specific form of chronic kidney disease
- acute on chronic kidney disease – rise in serum creatinine of ³50% from baseline or by 26.4 mol/L in less than 48 hours in a cirrhotic patient whose GFR is <60 mL/min for more than 3 months.

Portosystemic encephalopathy

PSE is defined as a spectrum of neuropsychiatric disorders in patients suffering from liver disease after exclusion of other known neurological disease. It is characterized by personality changes, intellectual impairment, reduced level of consciousness and abnormalities on psychometric testing. PSE occurs when blood bypasses the liver via portosystemic collaterals, or following portosystemic shunt procedures such as TIPS, and neurotoxic substances cross the blood–brain barrier. It most commonly occurs in the setting of cirrhosis and portal hypertension but a similar acute encephalopathy occurs in FHF.

The encephalopathy in chronic liver disease may be subclinical or overt, either as recurrent reversible episodes or as an overt and persistent condition when PSE may be accompanied by permanent structural central nervous system changes, predominantly cortical atrophy of the brain. Acute onset encephalopathy often has a precipitating factor or may reflect ongoing progressive liver failure: the patient becomes increasingly drowsy, eventually becoming comatose. Factors that may precipitate PSE include infection, gastrointestinal haemorrhage, constipation, central nervous system depressant drugs, TIPS insertion, surgical procedures and fluid and electrolyte disturbance due to paracentesis or diuretics. The acute encephalopathy that occurs in FHF shares many of the pathogenic mechanisms as that of cirrhosis, but cerebral oedema plays a more prominent role.

Pathogenesis

Despite considerable research, the exact mechanisms involved (probably multifactorial) in the pathogenesis of PSE remain uncertain. Animal and *in vitro* models have found evidence of astrocyte swelling and oxidative stress and have demonstrated abnormalities in glutaminergic, serotoninergic, -aminobutyric acidergic (GABA) and catecholamine pathways. Most theories accept that nitrogenous substances derived from the gut adversely affect brain function, producing alterations in neurotransmission that alter consciousness and behaviour. Hyperammonaemia is found in most patients with PSE and reductions in blood ammonia levels are associated with clinical improvement; there is, however, no correlation between laboratory ammonia levels and severity of encephalopathy. In addition there is now mounting evidence for microglial inflammation having a pathogenic role in encephalopathy.

Management

The principles of management of patients with PSE include the search for and correction of any precipitating cause, e.g. withdrawal of sedatives, correction of fluid and electrolyte disturbances, revision or closure of portosystemic shunts, arrest of haemorrhage and treatment of sepsis. Other measures aim to provide supportive care and reduce production and absorption of nitrogenous substances from the gut.

Contrary to widespread belief, patients with chronic liver disease should not be subjected to dietary protein restriction. In the first instance, patients with stable cirrhosis have a higher protein requirement than normal, i.e. 1.2–1.5 g/kg body weight to remain in positive balance. The European Society for Parenteral and Enteral Nutrition recommends a daily protein intake of 1.0–1.5 g/kg depending on the degree of hepatic decompensation. In the rare patients unable to tolerate this amount due to PSE, protein intake is reduced to 0.5 g/kg and the remainder of their requirements is achieved by administration of branched chain amino acids. In practice, the most effective way of achieving a sufficient protein intake in patients with liver disease is by frequent small meals and a late evening meal. This has been shown to improve nitrogen balance without exacerbating encephalopathy.

Non-absorbable disaccharides such as lactulose inhibit intestinal ammonia production by a number of mechanisms. Conversion of lactulose to lactate in the caecum reduces intraluminal pH, inhibiting the growth of ammoniagenic intestinal bacteria; the acidic pH also alters the metabolism of the intestinal flora, promoting uptake of ammonia. Lactulose also has a cathartic effect; the dose should be titrated to produce two to four soft bowel movements daily.

Antibiotics such as neomycin, metronidazole, vancomycin and rifaximin may be administered to reduce ammonia production by intestinal bacteria. Their use is limited by adverse effects including ototoxicity, renal impairment and peripheral neuropathy. Rifaximin, however, has been shown to be as effective at treating PSE as other antibiotics and is better tolerated than both cathartics and other non-absorbable antibiotics.

Liver transplantation

Advances in the field of liver transplantation over the past few decades have resulted in dramatic improvement in outcomes, with 1-year survival rates of 80–95% and 5-year survival rates of 62–80%. Transplantation should be considered in all patients presenting with acute FHF and in those suffering from chronic liver disease in whom life-threatening complications have developed.

Indications for liver transplantation

Acute liver failure

Patients with FHF from any cause should be referred to a transplant centre; hepatotoxicity due to acetaminophen toxicity or idiosyncratic drug reactions is the most common aetiology in the UK and USA.

Chronic end-stage liver disease

Irrespective of the underlying aetiology, development of the following complications warrants consideration of referral for liver transplantation:

- recurrent variceal haemorrhage
- refractory ascites
- SBP
- recurrent encephalopathy
- worsening synthetic dysfunction
- HCC

Special consideration must be given in the following cases:

- Alcohol-related cirrhosis – a 6-month period of abstinence prior to consideration for liver transplantation is recommended; in some cases liver function may improve to such an extent that liver transplantation is no longer required.
- Chronic hepatitis B – recurrence of HBV infection in the graft can be prevented by antiviral therapy pre-liver transplantation and continued treatment post-liver transplantation along with HBV immunoglobulin prophylaxis.
- Chronic hepatitis C – synthetic dysfunction, cytopenias and/or reduced tolerance to side effects often precludes antiviral therapy in end-stage HCV cirrhosis and even if undertaken has a low chance of success. If still HCV RNA positive at the time of transplantation, infection of the graft post-liver transplantation is inevitable, with approximately 50% developing graft cirrhosis within 5 years.
- HCC – disease recurrence post-liver transplantation occurs in patients with larger tumours, mutifocal disease and lymphatic or vascular invasion; this is associated with a high mortality. Liver transplantation is only considered for patients with a single HCC <5 cm or ≤3 lesions with the largest <3 cm, although these criteria are being challenged, with arguments that the biological behaviour of the tumour also has prognostic impact on the outcome of transplantation.

Contraindications

Absolute contraindications to liver transplantation include active sepsis, metastatic or extrahepatic malignancy, cholangiocarcinoma, advanced cardiopulmonary disease and AIDS.

Relative contraindications include HIV infection, HBV DNA positivity, active substance misuse, severe psychiatric disorder, portal venous thrombosis, pulmonary hypertension and age >70 years. All cases should be considered on an individual basis and discussed with a transplant centre if deemed appropriate. These relative contraindications worsen outcomes but if other factors are favourable, then transplantation may be justified.

Patient selection and organ allocation

Unfortunately the number of patients requiring liver transplantation continues to exceed deceased donor organ availability; despite surgical innovations including use of extended criteria donors, split livers, donation after cardiac death and live liver donation, many patients still die on the transplant waiting list. Scoring systems to assess need for liver transplantation and prioritize organ allocation to patients with the highest risk of death without liver transplantation are employed to rationalize resources and reduce waiting list mortality.

Model for end-stage liver disease

The model for end-stage liver disease (MELD) score is based on three variables, (1) serum bilirubin, (2) serum creatinine and (3) international normalized ratio (INR), and has been shown in both retrospective and prospective studies to be a reliable predictor of 3 month mortality in end-stage cirrhosis. It is not used as criteria for listing but is used to prioritize listed patients for organ allocation, in the USA and across Europe with the exception of the UK.

United Kingdom model for end-stage liver disease

The United Kingdom MELD (UKELD) score is derived from the patient's serum sodium, creatinine, bilirubin and INR. Hyponatraemia in cirrhotic patients is associated with neurological dysfunction, refractory ascites, increased risk of development of HRS and a higher mortality. Given the important prognostic value of sodium, it has been incorporated as an adjunct to the MELD score in UK organ allocation.

Minimal listing criteria require that the patient should have projected 1 year liver disease mortality without transplantation of >9%. This is predicted by a UKELD score of 42. Patients should be followed closely after listing for liver transplantation and constantly re-evaluated with regard to their eligibility and fitness to undergo transplantation. Evaluation of patients assesses both physical and psychological health to ensure appropriate patient selection and optimal utilization of this scarce resource.

Hepatic abscesses

Abscesses of the liver are less common in temperate than in tropical regions. There are also differences in the underlying aetiology between the two regions. There are two types: pyogenic and amoebic.

Pyogenic abscesses

Pathogenesis

The incidence of pyogenic liver abscess has remained relatively constant over the past century despite earlier diagnosis and treatment of underlying causes and more aggressive antibiotic therapies. In recent years, the decrease in cases resulting from haematogenous spread from infected foci has been mirrored by an increase in cases secondary to hepatobiliary pathology. The main aetiological factor is bile duct infection with ascending cholangitis commonly due to *E. coli* and anaerobic Gram-negative organisms. In the UK, biliary sepsis will be the predisposing factor in almost half of the patients reviewed. Hepatic abscesses secondary to ascending cholangitis are often multiple due to the distribution of the infecting organism along the biliary ductal system. Early reports implicated choledocholithiasis as the main causative factor; however, more recent series document malignant biliary obstruction as a more common aetiological factor. Other sources of infection include the following:

- Ascending pylephlebitis. While any inflammatory process within the abdomen may initiate pylephlebitis, it is most commonly the result of complicated diverticulitis.
- Some hepatic abscesses of staphylococcal and streptococcal origin arise as a complication of bacteraemia (haematogenous).
- Direct extension from intra-abdominal suppuration, e.g. gangrenous cholecystitis, penetrating peptic ulcer disease and subphrenic collections.
- Trauma to the liver, both penetrating and non-penetrating, may devitalize liver tissue and subsequent infection produces an abscess.
- A significant group of patients are found in the elderly population. No obvious cause is found in many of these patients (cryptogenic). These often have an insidious onset and non-specific symptoms such that, at the time of diagnosis, the abscess is usually very large. In some cases, the chronic abscess erodes through the diaphragm and bursts into the bronchial tree presenting with chest symptoms (Figure 24.19). The infecting organisms for these abscesses are commonly the *Peptostreptococcus* and *Streptococcus milleri*, but other microbes including *Bacteroides fragilis* may be involved.
- Parasitic infestations – *Ascaris lumbricoides.*
- Tuberculous liver abscesses.
- HIV infection – cholangitis/cholangiopathy.

HIV infection is now one of the risk factors, and abscesses due to meticillin-resistant *Staphylococcus aureus* appear to be on the increase. The infection is polymicrobial in 45%. *E. coli* and *S. milleri* are the most frequently isolated organisms. In endemic areas of *Ascaris lumbricoides* infestations, e.g. Kashmir, India, up to 15% of pyogenic hepatic abscesses are associated with this infestation.

Cholangitis/cholangiopathy associated with HIV infection is characterized by chronic abdominal pain, low-grade fever, cholestasis, and sometimes areas of focal or diffuse dilatation of the bile ducts. The disease appears to be the result of immunosuppression and/or secondary opportunistic infections rather than a direct cytopathic effect of the virus itself. Various opportunistic pathogens, including cytomegalovirus, *Cryptosporidium, Campylobacter fetus* and *Candida albicans*, have been implicated in the aetiology of HIV-associated cholangitis.

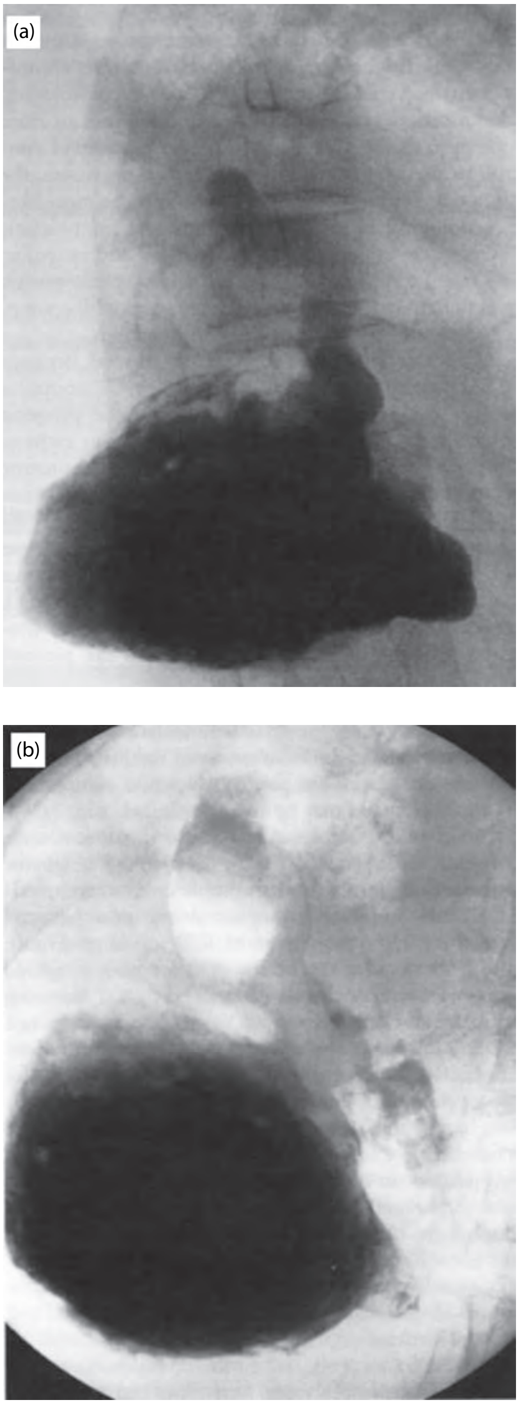

Figure 24.19 Contrast study showing a fistula between the right hepatic abscess and right basal bronchial tree in an elderly patient initially treated with percutaneous drainage.

Pylephlebitis usually occurs secondary to infection in the region drained by the portal venous system, the most common being diverticulitis and appendicitis. Infection is caused by *E. coli* in 54%, followed by *Proteus mirabilis* (23%). The pylephlebitis induces a septic thrombosis of the portal vein and its branches, with multiple microabscess formation in the liver (honeycomb liver). Early recognition of the disease and timely antibiotic therapy are essential for survival. The overall reported mortality is 32%.

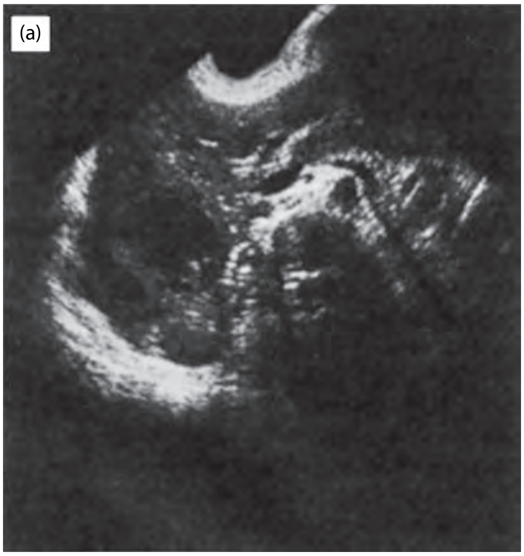
Irrespective of aetiology, liver abscesses are found much more commonly in the right lobe. All abscesses contain areas of liver parenchymal cell necrosis surrounded by polymorphonuclear leucocytes and lymphocyte infiltration with relatively damaged parenchyma and viable bacteria on the periphery. Ultimately a fibrous reaction is initiated which may produce a fibrous capsule containing pus.

Clinical features of hepatic abscesses

Untreated pyogenic liver abscesses carry a high mortality and 10% are diagnosed only at postmortem. The important determinants of mortality are multiple abscesses, hyperbilirubinaemia and comorbid disease. Since most pyogenic abscesses are secondary to other infective processes, the clinical features may be dominated by the primary disorder. Characteristically there is a high fever, rigors, profuse sweating, anorexia and vomiting, with pain as a relatively late symptom. In elderly people pyogenic liver abscess is commoner in women, and the symptoms may be vague. Thus the patients may have minimal abdominal tenderness on physical examination. The clinical features are also less striking in hepatic amoebiasis where the fever is usually low grade. However, pain is a more common feature with amoebic abscess and is aggravated by movement and coughing. An amoebic abscess may reach a very large size before causing pain if situated posteriorly and pointing to the bare area of the liver. About half the patients with amoebic abscesses will have diarrhoea.

Hepatomegaly is common, particularly with amoebiasis. Occasionally with right lobe abscesses there is bulging and pitting oedema of the intercostal spaces. An abscess in the left lobe may present as a painful epigastric swelling. On investigation, anaemia and leucocytosis may be found, and raised levels of acute phase proteins. Disturbances of LFTs are not diagnostic, particularly when complicated by cholangitis, and may be absent in amoebiasis.

Blood cultures are usually positive in patients with pyogenic abscesses when taken during the height of pyrexia. Both aerobic and anaerobic cultures are needed. Clinical suspicion of hepatic abscess must be confirmed by ultrasonography or CT scanning (Figure 24.20). The highest diagnostic yield for both pyogenic and amoebic liver abscess (ALA) is obtained by CT scanning with contrast enhancement. Magnetic resonance cholangiography should be undertaken in patients with biliary symptoms, obstructive LFTs or a dilated common bile duct, and can be combined with cross-sectional MRI to identify any hepatitic parenchymal abnormality. Diagnostic aspiration is a safe and reliable procedure and provides means of identification of the organisms responsible and thus the appropriate antibiotic therapy. Chest radiography is necessary in all cases to outline basal lung changes (consolidation and effusion) and may show direct lung involvement in complicated cases. An elevated immobile diaphragm (radiological screening or ultrasonography) is often encountered, particularly in large abscesses. A plain film of the abdomen may demonstrate gas in the abscess cavity. Barium enema or colonoscopy may be indicated to exclude a colonic source of portal pyaemia.



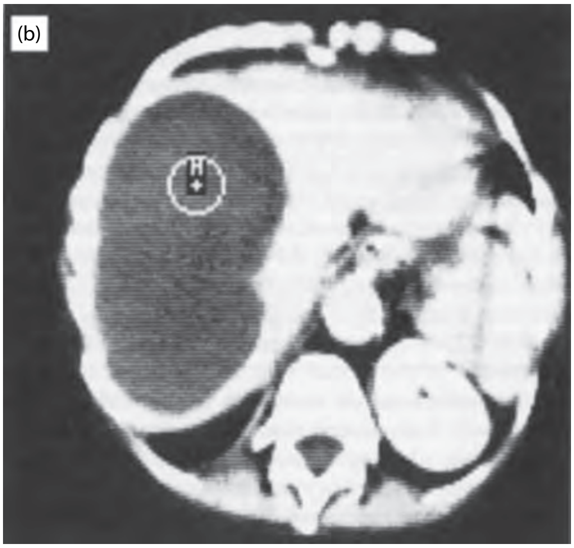


Figure 24.20 (a) An ultrasound of the liver on coronal section shows a cavity within the liver substance. (b) CT scan demonstrates that the abscess cavity occupies most of the right lobe of the liver. Subsequent drainage of the cavity resulted in complete resolution.

Complications

Recurrent bacteraemia is the most common complication of pyogenic abscesses. Extension and rupture of the abscess may occur in any direction. Peritoneal rupture results in widespread peritonitis or in the formation of a subphrenic collection. Extension through the diaphragm may lead to thoracic empyema or to a rupture into the bronchus with expectoration of large volumes of 'anchovy paste' pus from amoebic abscesses and bile-stained pus from cholangitic abscesses. Rarely, the abscess ruptures into the pericardium with high mortality.

Treatment

The key to successful management is drainage of the purulent collection combined with appropriate antibiotic therapy. Precise microbiological identification may result from blood cultures or from aspiration of the abscess cavity under ultrasound or CT guidance. In the event of a failure to isolate organisms, the choice of antibiotic should be based on the most likely aetiological factor, i.e. cholangitic and pylephlebitic abscesses are usually infected with *E. coli* and anaerobes and may be appropriately treated with cephalosporins, gentamicin and metronidazole. Microaerophilic *Streptococcus* infections are sensitive to penicillin. Although antibiotic therapy as the sole treatment is rarely successful, prolonged systemic antibiotic administration may be the only option for patients with multiple microabscesses.

The introduction and refinement of percutaneous drainage techniques have dramatically altered the management of patients with pyogenic hepatic abscesses. Percutaneous drainage has become the first-line therapeutic option in most centres for patients with single or multiple abscesses. Abscess communication with the intrahepatic biliary tree does not prevent pyogenic collections being successfully treated by percutaneous techniques, although the periods of drainage may be prolonged. Some groups have advocated the use of percutaneous aspiration combined with systemic antibiotics; however, in the only randomized trial comparing the two techniques, aspiration was successful in only 60% of patients whereas percutaneous catheter drainage was successful in 100% of patients. Regular irrigation of drainage catheters reduces the risk of catheter blockage with necrotic debris. Percutaneous catheter drainage is monitored by serial ultrasound examination to assess the degree of resolution. As the most frequent cause of hepatic abscess is biliary disease, effective decompression of the biliary tree is as important as abscess drainage where obstruction of the bile duct has contributed to the development of the hepatic abscess.

The factors indicating failure of initial non-operative management are:

- unresolving jaundice
- renal impairment secondary to clinical deterioration
- multiloculation of the abscess
- rupture on presentation
- biliary communication (Figure 24.21).

Deterioration in the general condition of the patient, repeated episodes of septicaemia or a failure of the abscess to decrease in size are indications for open surgical drainage. Posteriorly placed abscesses may be approached by the retroperitoneal route through the bed of the twelfth rib. Larger abscesses require abdominal drainage with wide-bore sump drains and special care being taken to avoid contamination of the peritoneal cavity. Where a pyogenic abscess is secondary to cholangitis, concomitant drainage of the common bile duct with a T-tube and removal of ductal stones may be necessary. Following successful drainage of the abscess, antibiotic administration should be continued for a prolonged period (3–6 weeks) to assist in the complete eradication of the infection.

Hepatic amoebiasis

This results from intestinal amoebiasis. The infection spreads to the liver via the portal vein from an ulcer in the bowel wall. Most amoebae lodge in the interlobular veins and degenerate. Some act by cytolysis to invade the portal tracts and lead to cell necrosis and a coalescence of infected triads to form a larger abscess cavity. Hepatic abscess is the most common extraintestinal manifestation of *Entamoeba histolytica*. There is a male preponderance and the mean age is 40 years. The presenting features include fever (77%), right upper quadrant abdominal pain (72%), cough (16%), chest pain (19%) and chest radiographic abnormalities (57%). The LFTs are often normal. The diagnosis is usually made by ultrasonography and CT where the boundaries of the abscess are usually poorly defined. Patients with amoebic hepatic abscess virtually always have a confirmatory serum antibody titre. Early abscesses are solid but pus appears later, characteristically resembling anchovy paste, though in one-third of patients the pus has the usual creamy appearance. Occasionally, amoebic abscesses become secondarily infected with pyogenic bacteria.

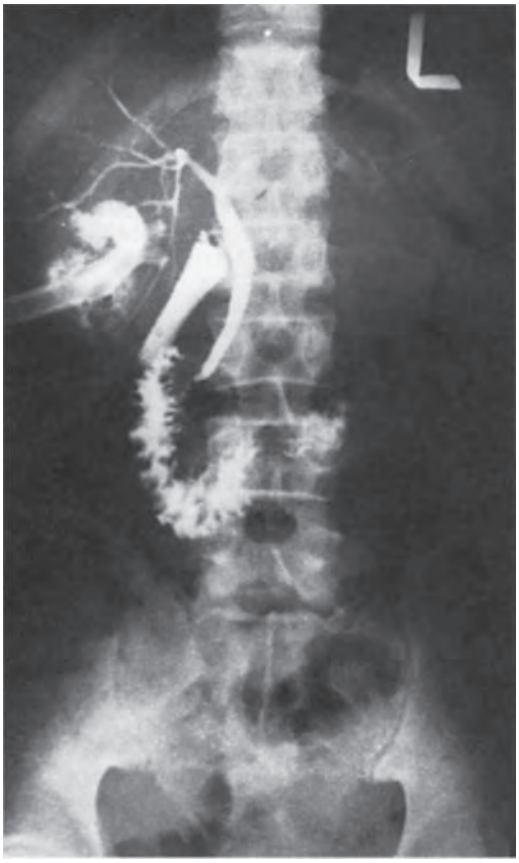

Figure 24.21 Right hepatic abscess communicating with the intrahepatic biliary tree.

In one large series from the USA, patients were divided into groups based on the presumed manner in which they had acquired ALA: (1) those born or raised in the USA, with a history of travel to an endemic area (Tr-ALA); (2) those from an endemic area, but living in the USA for less than 1 year (En-ALA); and (3) those neither from nor having travelled to an endemic area (N-ALA). In this series, there was a distinctive clinical pattern in patients from different epidemiological groups. Thus patients with Tr-ALA were a decade older than those from endemic areas and were more likely to be male, and to have an insidious onset. In addition patients in the Tr-ALA group were more likely to have hepatomegaly and large abscesses. Thirty per cent of patients had no associated travel history or endemic origin as risk factors (N-ALA). The majority of these had severe immunosuppression, such as infection with HIV, malnutrition or chronic infection.

The diagnosis of amoebic hepatic abscess requires confirmation by positive serological tests, demonstration of amoebic trophozoites in abscess fluid and a rapid response to antiamoebicides. Amoebic abscesses tend to occur in younger patients than in those with pyogenic liver abscess. In addition, they are much more likely to have abdominal pain and present with a history of symptoms of shorter duration. Both types, however, have the same high incidence of right lower lung abnormalities (50%). Amoebic abscesses are treated with metronidazole with or without chloroquin. Metronidazole therapy is invariably successful and has lowered the mortality of amoebic abscess, which is now negligible although recurrence after treatment can occur, albeit rarely. Aspiration of the amoebic abscess is not required routinely and is usually reserved for patients where serology is inconclusive or when there is no response within 2 days. Rupture of an amoebic abscess into the lung and bronchus can usually be treated successfully by antibiotics and postural drainage. When the intrapulmonary rupture is associated with cholangitis, bile duct drainage is essential. A persistent bronchopleural fistula may require formal thoracotomy, decortication of the lung and diaphragm with resection of severely damaged pulmonary tissue and diaphragmatic repair. Rupture into the pericardium requires early aspiration of the exudate and occasionally transpleural drainage. In a meta-analysis of 3081 patients with ALA, the mortality rate was 4%, compared with a mortality rate of 46% in patients with pyogenic liver abscess.

Subphrenic extrahepatic abscess

The distribution of intra-abdominal abscesses is directly related to the precipitating lesion and to the potential peritoneal spaces. Abscesses are most common in the right and left lower quadrants as a consequence of appendicitis, diverticulitis and pelvic sepsis. Abscesses around the liver make up the next most common group of intra-abdominal septic collections. Six spaces around the liver are described. Superiorly, the falciform ligament divides the left and right subphrenic spaces, the latter being divided into anterior and posterior spaces by the triangular ligament. In the infrahepatic region, there are also three spaces – the two on the left side including the lesser sac of the peritoneal cavity and the space immediately below the lateral lobe of the left hepatic lobe (Figure 24.22).

Subphrenic collections may contain a mixture of pus and gastrointestinal secretions and may be large. Although any intra-abdominal sepsis may precipitate these collections, most abscesses follow operative intervention with postoperative leaks, spontaneous perforation of hollow organs or accidental abdominal trauma. In the last situation, extrahepatic collections of blood or serous fluid become encysted and infected (Figure 24.23). Primary causes include pancreatitis, cholecystitis, perforated peptic ulcer, perforated diverticular disease and perforated acute appendicitis.

Clinically, suspicion of an extrahepatic collection is aroused by fever with occasional episodes of septicaemia. Non-specific abdominal symptoms and general ill health are common, although

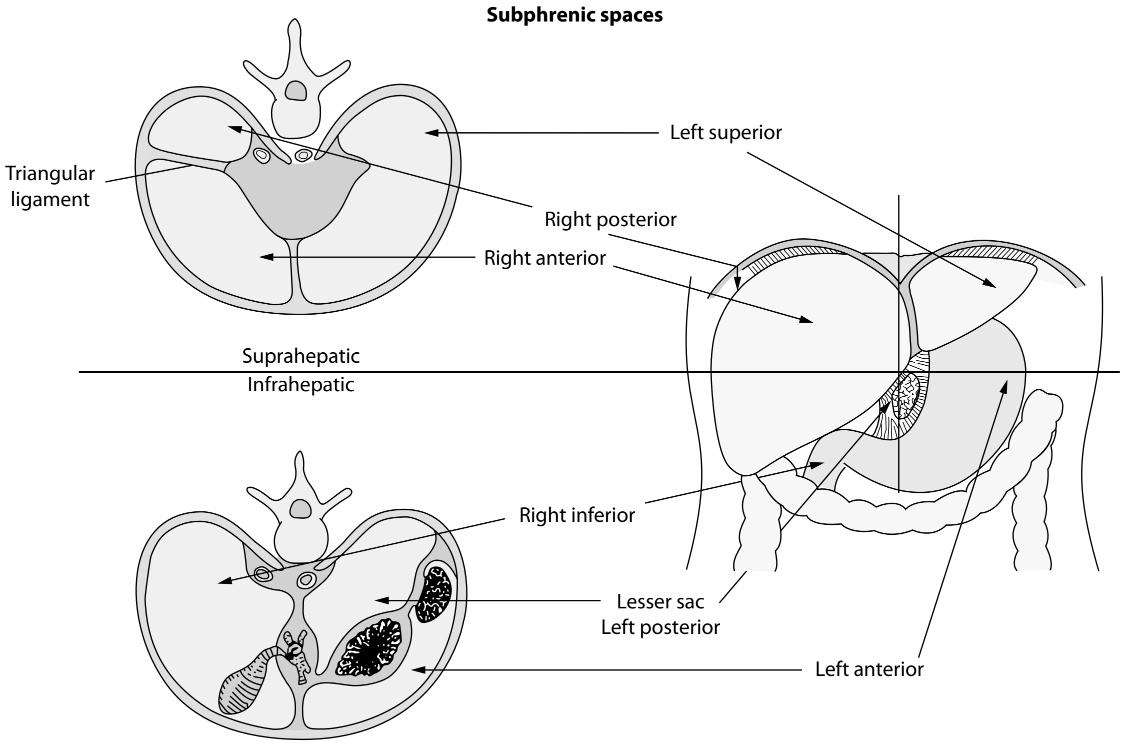

Figure 24.22 The subphrenic spaces may be considered to be supra- and infrahepatic.

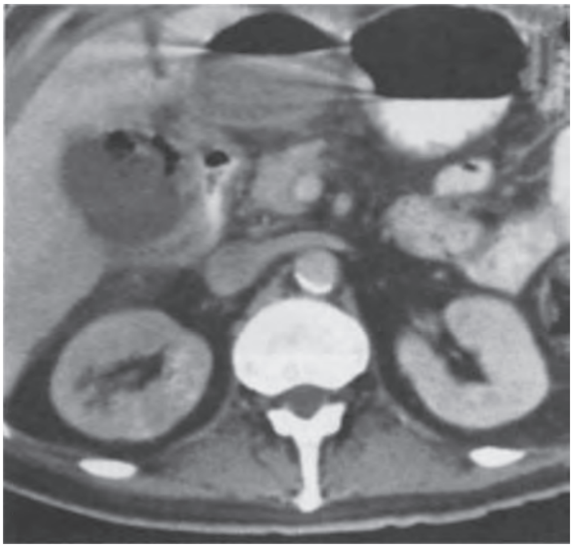

Figure 24.23 CT scan of an infrahepatic abscess with fluid level lying between the gallbladder and gastric antrum. The abscess resulted from the infected gallbladder which contains stones seen on other sections of the CT examination.

in some patients attention is drawn to respiratory symptoms resulting from inflammatory changes induced in the lung by a subdiaphragmatic collection. When an abscess is subhepatic, tenderness is elicited and a mass may be palpated or percussed.

The confirmation of an abscess may be difficult and probably many minor collections ultimately resolve and remain unproven. In right posterior subphrenic space collections there is typically elevation of the diaphragm on chest radiography, with decreased mobility of the diaphragm on screening. Inflammation of the diaphragm leads to pneumonic changes in the overlying lung and a pleural effusion. However, diagnosis and location of subphrenic abscesses is nowadays made by ultrasound and CT scanning. When the patients are stable, CT is the imaging modality of choice for most intra-abdominal processes. CT can detect small volumes of fluid, areas of inflammation and other gastrointestinal tract pathology with high sensitivity.

Management

Complicated intra-abdominal infections are an important cause of morbidity and are frequently associated with poor prognosis, particularly in higher risk patients. Mortality rates associated with complicated peritonitis associated with severe sepsis have a reported mortality of approximately 30%. Factors consistently associated with poor outcome in patients with intra-abdominal infections include increased illness severity, failed source control, inadequate/inappropriate antimicrobial therapy and nosocomial pathogens. The cornerstones in the management of complicated intra-abdominal infections are both source control and antibiotic therapy.

Minor collections may resolve with antibiotics and the frequency of dense adhesions between the liver and diaphragm at elective second laparotomies suggests this is a relatively common event. However, once pus is identified in the subphrenic region, drainage of the abscess is mandatory. Timing and adequacy of source control are the most important issues in the management of intra-abdominal infections, because inadequate or late control may have a negative effect on outcome. With accurate localization using ultrasound or CT scanning, many collections can be drained percutaneously with a catheter left in place. Numerous studies in the surgical and radiological literature have documented the effectiveness of percutaneous drainage to the extent that it is now the standard treatment. In selected cases percutaneous drainage has been shown to be associated with decreased incidence of complications, decreased rates of inadequate drainage and reduced duration of drainage compared with open drainage.

In most instances percutaneous drainage suffices but some require open surgical drainage. These include multilocular collections and the presence of thick pus with necrotic slough. Most subhepatic abscesses may be drained surgically by an anterior approach, as may the right anterior subphrenic collection. Occasionally it is possible to enter the abscess without contamination of the peritoneal cavity. Posterior subphrenic collections are most appropriately drained by the classic extraserous approach through the bed of the twelfth rib. In either approach, the abscess cavity is thoroughly explored and all loculi are broken down. Wide-calibre drains are inserted to the furthermost or most dependent point of the cavity. Gradual withdrawal of the drains is indicated, sometimes with regular saline irrigation. Further cultures (from drain effluent) are often needed especially if resolution is delayed.

Abscesses occurring as a direct consequence of an uncomplicated surgical operation are largely preventable. Prior to abdominal closure, a saline lavage of the peritoneal cavity with special attention to the subphrenic spaces and pelvis will reduce the incidence of postoperative abscesses by removing blood clots and other secretions that may get infected at a later stage.

Liver cysts

These include simple hepatic cysts, choledochal cysts, cystadenoma of the liver, Caroli disease and parasitic cysts. Choledochal cysts are covered elsewhere (Chapter 25).

Non-parasitic hepatic cysts

Within the non-parasitic group there are a variety of clinical conditions that reflect underlying developmental defects of the liver parenchyma or bile ducts. Some cystic lesions follow trauma in which a central rupture has resulted in a collection of bile and serum and these cysts have no epithelial lining. Others are clearly similar to dermoid cysts found in other sites. Most of the remainder are lined by cuboidal or columnar epithelium, contain serous fluid and do not communicate with the biliary tract. These are nowadays referred to as simple cysts and are multiple in 50% of cases. The cysts can grow to a large size and in so doing cause pressure atrophy of the surrounding hepatic parenchyma. They are generally regarded as developmental abnormalities from aberrant bile ducts. The ultrasound incidence of asymptomatic cysts is 1%, but symptomatic cysts are much rarer. Symptomatic cysts are much commoner in females (9:1) and huge cysts are almost exclusively found in women above the age of 50 years (Figure 24.24).

The ciliated hepatic foregut cyst (CHFC) is a rare small to medium size solitary cystic lesion of the liver that is commoner in males (as distinct from the solitary hepatic cysts) and occurs over a wide age range (35–75 years). CHFC is most commonly located in the medial segment of the left hepatic lobe as distinct from the more common solitary hepatic cysts. CHFC is usually found incidentally on radiological imaging or during surgical exploration, although some may present with abdominal pain, and in a collective review of 52 cases one patient presented with portal vein compression. Histologically, the lining of the columnar epithelium is composed of ciliated cells, mucin-secreting goblet cells and endocrine cells positive for chromogranin, synaptophysin, bombesin and calcitonin (similar to respiratory epithelium). The lesion is thought to be a developmental ventral foregut abnormality arising from a bronchiolar bud of the tracheobronchial diverticulum.

Clinical features and treatment

Most simple hepatic cysts are asymptomatic and only become apparent when the cysts reach sufficient size to exert pressure on adjacent viscera, producing non-specific symptoms of vomiting, upper abdominal pain and occasionally diarrhoea. Clinical examination reveals a non-tender smooth mass in the liver. Jaundice is very unusual and LFTs are usually normal. Plain film of the abdomen may show displacement of the colon or stomach but the diagnosis is best confirmed by ultrasonography. Other investigations including CT are not usually necessary. Complications are uncommon and include intracystic bleeding that causes sudden severe pain and increase in size, fistulation with the intrahepatic biliary tract or duodenum, bacterial infection, compression of the bile duct with obstructive jaundice and compression of the vena cava or portal vein. Differentiation is from parasitic cysts and from adult polycystic disease of the kidney where multiple serous hepatic cysts are often present and may indeed replace a substantial part of the hepatic parenchyma.

Only symptomatic cysts require treatment. This consists of fenestration (deroofing), which is nowadays carried out laparoscopically. Percutaneous aspiration of large cysts with introduction of sclerosing agents is followed by a high recurrence rate. In patients with adult polycystic disease of the kidney and liver cysts causing discomfort, multiple fenestration or hepatic resection is followed by improvement but recurrence is inevitable although symptomatic improvement may last for up to 2 years.

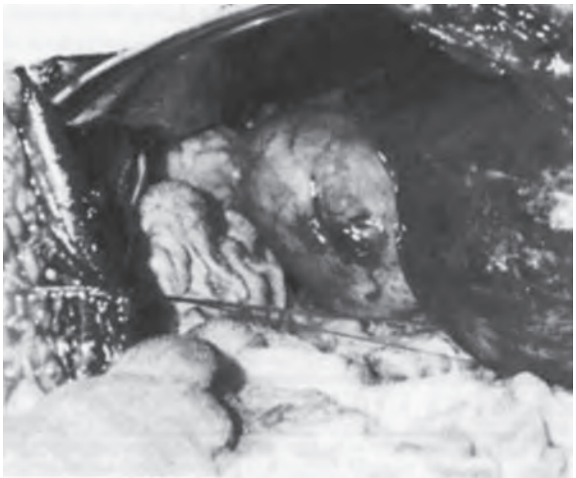

Figure 24.24 This operative photograph shows the undersurface of the liver in which the gallbladder is seen as a whiter structure and lies adjacent to a large lymphogenous cyst of the liver.

Hepatic cystadenoma

This is rare and affects predominantly females. It forms a large multiloculated cyst filled with mucinous fluid and lined by cuboidal epithelium on a basement membrane and thick compact cellular stroma containing foamy macrophages. In places the lining epithelium forms polypoid projections. Although benign, the lesion is liable to complications, notably cholestasis due to compression of the bile duct, intracystic bleeding, infection, rupture and malignant degeneration to cystadenocarcinoma. Hepatic cystadenoma must be excised completely even when asymptomatic. Fenestration/partial resection is inevitably followed by recurrence and increases the risk of cystadenocarcinoma (Figure 24.25).

Caroli syndrome

This is not a single entity and covers a spectrum of disorders characterized by congenital multifocal dilatations of the segmental bile ducts. In 50% of cases Caroli syndrome is associated with congenital hepatic fibrosis, itself an inherited malformation (autosomal recessive). The clinical picture of Caroli syndrome is dominated by recurrent episodes of bacterial cholangitis (Chapter 25).

Hydatid cysts of the liver

Hydatid disease is a parasitic infestation by a tapeworm of the genus *Echinococcus*. It is endemic in certain countries, particularly the southern half of South America, Australasia, New Zealand, France and certain areas of the USA and the UK. Humans are secondary, incidental hosts while dogs and their related species are the definitive host of the parasite. The worm can be found also in intermediate hosts like sheep, goats or swine. Humans become infected by ingesting vegetables or water contaminated by dog excrement or more directly by handling the parasite-

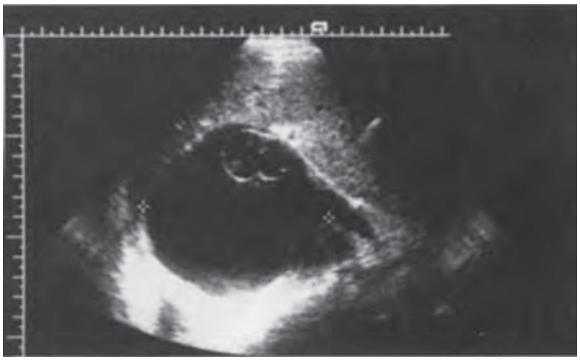

Figure 24.25 Ultrasound scan of hepatic cystadenoma. The lesion recurred following initial deroofing and eventually needed a right hepatectomy.

infested dogs as pets. After ingestion, the egg is destroyed by gastric acid and the embryos hatch within the duodenum and then migrate through the gut wall into the mesenteric circulation to lodge within the liver. Echinococcosis can involve any organs but the liver is the most common site followed by the lungs, which together account for 90% of all cases. The embryo becomes a small vesicle with an inner germinal epithelium that produces secondary or daughter brood cysts containing scolices and hooklets. Some cysts never produce brood capsules or become sterilized by secondary infection or calcification. Hydatid cysts caused by *Echinococcus granulosus* are unilocular as distinct from the multilocular alveolar type due to *Echinococcus multilocularis.* This forms a spongy collection of cysts and carries a poor prognosis.

Clinical features

Since the growth of the parasite is slow, many years elapse before the cyst reaches significant size (Figure 24.26). Palpable cysts are therefore rare in children. At all ages, pain, jaundice and ascites are uncommon and, in most patients, general health is good. On physical examination, an anteriorly located cyst presents as a smooth rounded tense mass. Secondary infection results in tender hepatomegaly, rigors and pyrexia associated with a deep-seated continuous pain. Further clinical features are the result of cyst complications. Intrabiliary rupture may give biliary colic and usually causes jaundice and fever. Intraperitoneal rupture produces severe pain and shock classically associated with pruritus and urticaria. Some of the implanted brood cysts induce a profound fibrous reaction that sterilizes the infection, but other cysts reappear in various parts of the peritoneal cavity years later. Intrathoracic rupture may be preceded by symptoms of diaphragmatic irritation, and rupture into bronchus leads to a partly blood-stained sputum which frequently becomes bile stained. Hydatid allergy is manifested by urticaria or, very rarely, anaphylactic shock.

Investigations

An unruptured cyst may show on plain radiograph as a calcified reticulated shadow or by displacement of the diaphragm and stomach if not calcified. Following intrabiliary rupture, gas may enter the cyst leading to partial collapse of the cyst wall (Camellotte sign). Ultrasonography reveals an echogenic cyst.

Although the cyst is isolated from the liver by an adventitial layer, there is absorption of parasitic products, which acts as an antigenic stimulus. This is reflected in eosinophilia in 25% of patients, and a positive complement fixation test which is accurate in 93% of patients. The Casoni test has been largely abandoned. Some cysts never leak and tests are never positive in these patients.

Treatment

The treatment of hydatid cysts of the liver is surgical or radiological. There is no guaranteed response to drug treatment with mebendazole/albendazole and the cyst is a potential source for serious complications. Surgical treatment involves removing the cyst without contaminating the patient. Where there are

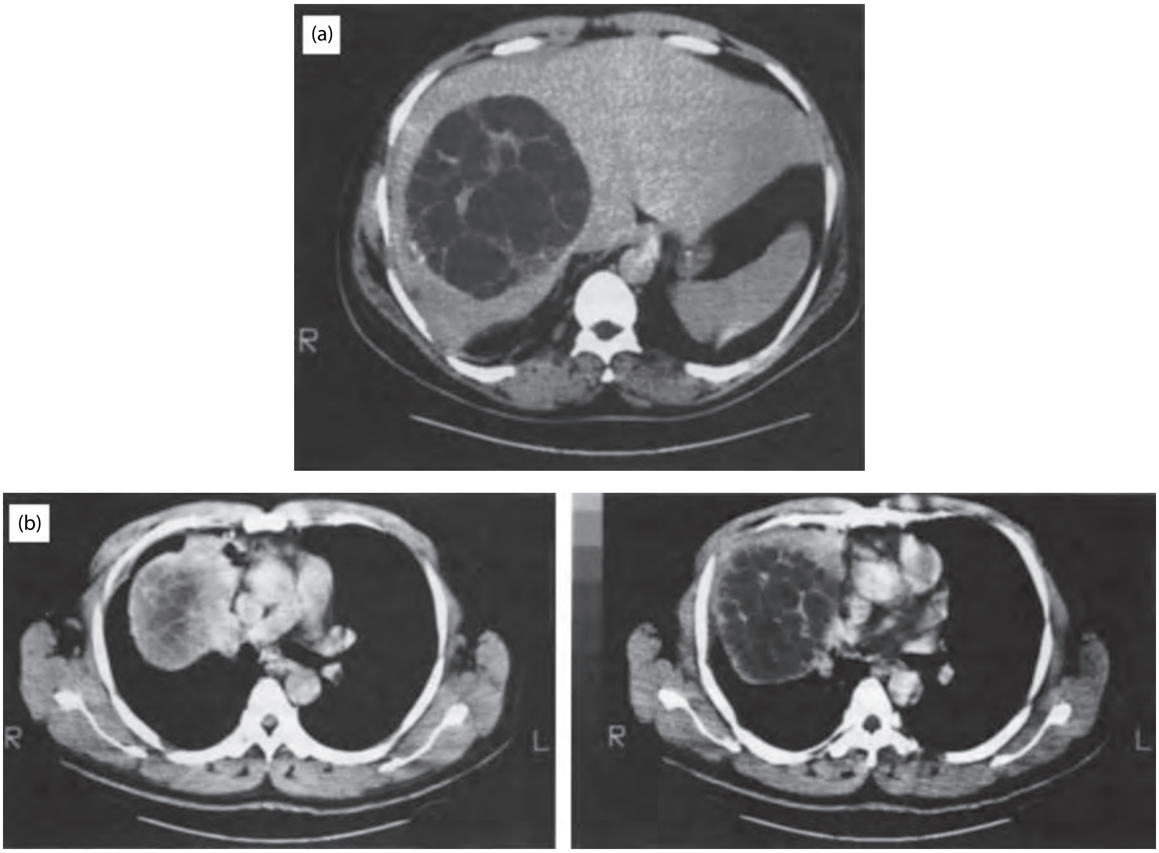

Figure 24.26 CT scan showing multiseptate hydatid cyst (a) in the right lobe and (b) projecting above the right liver surface in the subphrenic space.

multiple cysts, several procedures may be necessary. Large cysts found on the anteroinferior and posteroinferior aspects of the liver are approached abdominally. Cysts in the dome may be reached by the posterior extraserous approach or transpleurally through the bed of the ninth rib.

The initial stage involves protection of the operative field against live cysts using multiple coloured towels soaked in hypertonic saline which isolate the main cyst from the exposed serous cavity. Since hydatid fluid is under high pressure, the cyst is decompressed by aspiration as completely as possible, although daughter cysts tend to block the needle frequently. The main cyst is injected through the same needle with 20% hypertonic saline and left for 5 minutes, after which the main cyst is opened and all daughter cysts are removed. In large cysts it is not feasible to remove the cyst wall and the cavity is drained for a few days and partially occluded by an omental plug which is sutured to the rim of the cyst.

Marsupialization of large cysts may be indicated when secondary infection has occurred but prolonged purulent drainage results and a secondary omentoplasty may be necessary. Cysts with extensive calcification are usually sterile and best left alone. Jaundice after intrabiliary rupture requires choledochotomy and clearance of cysts followed by T-tube drainage. Peritoneal rupture is managed by laparotomy and careful toilet followed by lavage. Providing that rupture has not occurred and careful surgical techniques are applied, the prognosis is excellent.

There have been good reported results of percutaneous ultrasound-guided treatment of hepatic hydatid cysts. The treatment involves puncture, aspiration, injection (of scolicidal agents), and reaspiration (PAIR). In patients with cysts larger than 6 cm in diameter, PAIR is followed by percutaneous drainage (PAIR-PD). In one recent large reported series no recurrence of hydatid disease after PAIR or PAIR-PD was observed during a follow-up period of 72 months (mean 26 ± 27 months).

Medical treatment with mebendazole and albendazole is unreliable as penetration of the drug into the cyst cavity is uncertain. Thus although many cysts decrease in size, not all scolices are killed. Nowadays medical treatment with these drugs is started before surgery or radiological intervention (PAIR).

Liver tumours

Benign solid tumours

Benign tumours of the liver are commonly asymptomatic and discovered accidentally during investigation usually by ultrasound, and during laparotomy for other conditions. More rarely, they reach sufficient size to cause symptoms or complications that can be quite dramatic. Although the classification of these tumours is not sharply defined several types are identified:

- haemangioma
- infantile haemangioendothelioma
- neoplastic angioendotheliomatosis
- hamartoma
- FNH
- adenoma
- cholangioma
- biliary cystadenoma.

Haemangiomas

Haemangiomas are the commonest benign tumour of the liver most commonly found in adults between the ages of 30 and 70 years, but only rarely produce symptoms. They are frequently situated just beneath the liver capsule and are normally of the cavernous type. Histologically the lesion is composed of blood-filled endothelium-lined spaces separated by a variable degree of fibrous tissue and inflammatory changes, both of which result from episodes of spontaneous thrombosis.

Infantile haemangioendothelioma is the most common mesenchymal tumour in this age group and the majority present in the first few months of life. The lesion may be solitary or multicentric and often extends over a wide area. Histologically it consists of numerous arteriovenous channels, endothelium-lined vascular lakes in a fibrous stroma containing bile ducts. The tumour is locally aggressive and presents with hepatomegaly, coagulopathy (due to thrombosis in the tumour), extramedullary haemopoiesis, cardiac failure (commonest presentation), bleeding and liver failure. Most deaths are due to cardiac failure. A related but histologically different condition is *neoplastic angioendotheliomatosis.* Although essentially benign these diffuse subcapsular haemorrhagic lesions in children have a variable course. They may mature to a cavernous haemangioma or regress spontaneously, but rarely they may undergo sarcomatous change. In children the condition may present as high-output cardiac failure and is often associated with cutaneous haemangiomas (85%). Other complications are attributed to recurrent thrombotic episodes in the tumour. These include microangiopathic anaemia, thrombocytopenia and hypofibrinogenaemia.

In adults, some of these cavernous haemangiomas, having grown to significant size (>4.0 cm), will eventually produce pain or dyspepsia and may develop a palpable abdominal mass. A bruit is heard in about 15% of patients. The pain is usually dull but acute posterior pleuritic pain lasting a few weeks may develop and has been attributed to episodes of intratumoral thrombosis and inflammation. In general symptomatic cavernous haemangiomas are more common in females and have been documented to enlarge during pregnancy. Intratumoral thrombosis may be precipitated by oral contraception.

Rupture of cavernous haemangioma is rare. The reported incidence of this complication varies from 0 to 10%. Nonetheless, it is a serious complication in view of the major intra-abdominal haemorrhage with shock and collapse. Cavernous haemangiomas have characteristic appearances on the various imaging modalities:

- hyperechoic lesion on ultrasound
- hypodense on CT without contrast, halo edge enhancement on high-dose contrast helical CT which then fills the centre of the lesion
- dark on T_1 and intensely white on T_2 weighted MRI images.

The need for arterioportography (Figure 24.27) seldom arises nowadays. A biopsy is not indicated.

The majority of these tumours do not require any treatment except for follow-up liver ultrasound examination. The preferred treatment for clinically significant/symptomatic haemangiomas

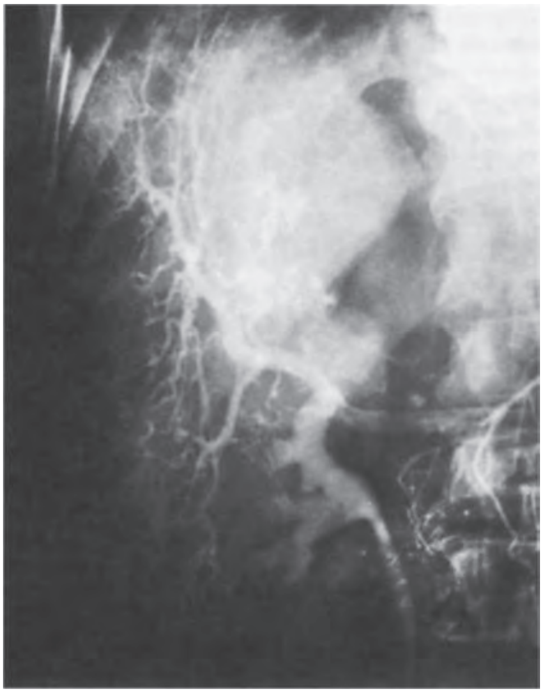

Figure 24.27 This selective arteriogram shows an apparent tumour circulation arising from the left hepatic artery. Subsequent resection of a tumour in the left lobe showed this to be a benign cavernous haemangioma.

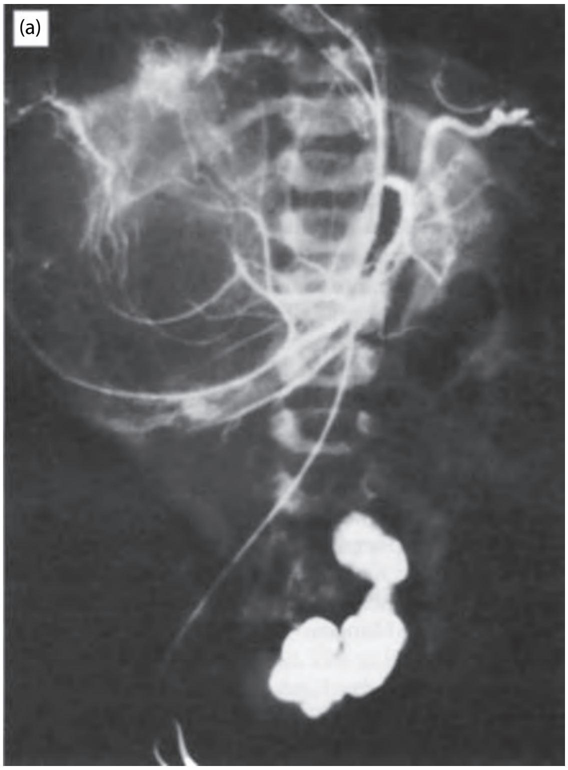
is segmental/wedge excision where possible, with lobectomy being reserved for large/multiple lesions confined to one lobe. In such cases the residual liver may contain further haemangiomas. Supervoltage radiotherapy is used for symptomatic lesions in adults who are unfit for surgery.

Children presenting in the first year of life have a poorer prognosis. Hepatic angiography in this age group may demonstrate a major feeding vessel from the hepatic artery, when ligation of this vessel or the main hepatic artery may reduce the blood flow through the lesion. With more diffuse lesions, radiotherapy and steroids result in significant shrinkage and a reduction in the volume of arteriovenous shunting. It is nowadays the preferred management in this age group. After the first year, the angioendotheliomatosis may regress, as do the cutaneous lesions. Resection of vascular tumours is no longer advocated in children, but liver transplantation is the correct treatment for infantile haemangioendothelioma that fails to respond to radiotherapy.

Mesenchymal hamartomas

Hamartomas are tumour-like malformations of congenital origin and consist of normal tissues in a disorderly arrangement. The lesions vary from minute nodules to large solid tumours and may be single or multiple. The tumours are not encapsulated, the fibrous periphery is a pseudocapsule of compressed parenchyma (Figure 24.28) and the histological picture demonstrates irregular distorted hepatic plates, vascular channels, bile ducts, cysts and extensive fibrosis. Children are commonly affected and present with an expanding abdomen and a large palpable mass. Large tumours may displace the stomach and produce vomiting and elevate the diaphragm compressing the right lung. As the tumour expands, inferior vena caval compression occurs.



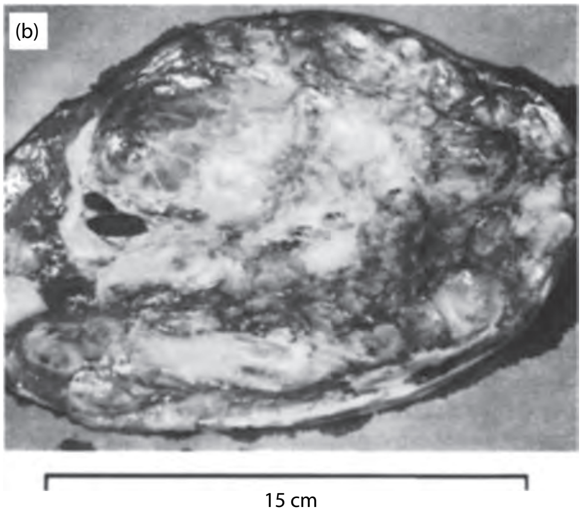


Figure 24.28 (a) A 3-year-old child presented with an expanding liver tumour. Selective arteriogram showed the hepatic vessels to be stretched around the tumour and there is little evidence of tumour circulation. (b) The excised lesion proved to have a distinct capsule and to be multilocular. Histology showed this to be a hamartoma of the liver.

Mature hepatic teratomas have been reported. All have mesodermal, endodermal and ectodermal components (tridermal). They may be associated with chromosomal abnormalities, e.g. trisomy 13. Hamartomas show as filling defects in angio-CT or scintiscans as they are relatively avascular tumours. Large tumours should be removed, usually by formal lobectomy. Occasionally, large tumours may show evidence of sarcomatous change and have a poor prognosis.

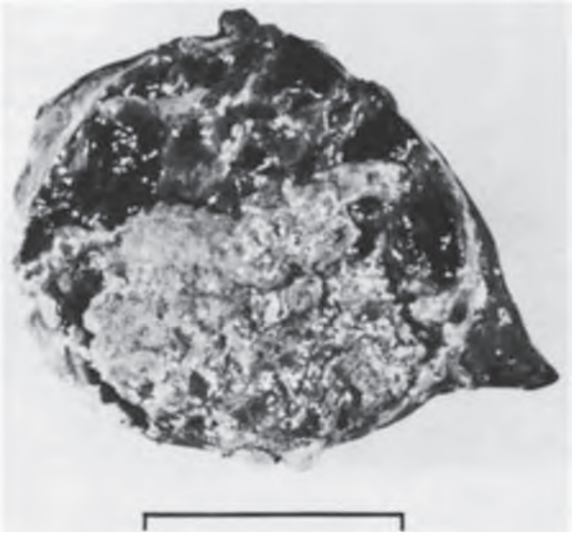

Figure 24.29 This operative specimen of the right lobe of the liver has been cut to show the necrotic contents of a hepatic adenoma into which a major haemorrhage has occurred. The patient presented with severe upper abdominal pain and evidence of massive blood loss.

Benign lesions have an excellent prognosis and when small and multiple should be kept under observation.

Liver cell adenomas

Adenomas are variable in size (4–30 cm). They are rare and tend to occur most commonly in children and postmenopausal women. There is an established increased incidence related to use of the contraceptive pill. The risk rises after 4 years of pill usage, particularly in women over 30 years on pills of high oestrogen content. Liver cell adenoma can also occur in patients with type I glycogen storage disease and galactosaemia. Up to one-third of adenomas are multiple.

Macroscopically liver cell adenoma forms a pale soft smooth lesion without a fibrous capsule. Histologically the tumour consists of sheets of hepatocytes containing glycogen, venous lakes and necrotic ghost cells. The differentiation between liver cell adenoma and well-differentiated hepatocellular (lamellar) carcinoma may be difficult and the two may coexist. Furthermore HCC may develop in patients with biopsy-confirmed liver cell adenoma. In the absence of a well-defined central scar, the differentiation between an adenoma and FNH can also be difficult. In this case technetium-99 sulphur colloid scintigraphy can be useful. Liver cell adenomas do not take up the Tc-labelled tracer and have a typical photopenic appearance, explained by their supposed lack of reticuloendothelial cells. Altered blood flow (secondary to intratumoral infarction and haemorrhage) or decreased activity of Kupffer cells may also help explain the appearance of adenomas on scintigraphy. More recently the sensitivity of a Tc-colloid scan can be increased with the use of simultaneous single photon emission computerized tomography.

The symptoms of liver cell adenoma include upper abdominal pain and mass. The lesion carries an ever-present risk of rupture and haemorrhage, a complication that occurs in 30% of cases (Figure 24.29). A specific diagnosis of liver cell adenoma cannot be made by CT, ultrasound or MRI. Although they have a distinctive arteriographic appearance (enlarged tortuous vessels, peripheral and central feeding), this is also encountered in HCC. Nowadays diagnosis is established by ultrasound or laparoscopically guided biopsy. The true incidence of malignant degeneration of hepatic adenoma is not known. It has however been widely reported that malignant transformation can occur after an interval period of 2–5 years and that foci of HCC can often be found in surgical specimens of liver adenomas (10–35%), but its reported frequency seems to be around 5% when observed prospectively. It appears to be 10 times more common in males than females, which would suggest a different carcinological pathway, and seems to be a very unusual complication in females with lesions smaller than 5 cm.

Treatment

If the diagnosis is certain and the lesion is asymptomatic, it may be monitored by ultrasound and AFP for 6–12 months for at least 10 years. In addition, oral contraception should be stopped. Adenomas that diminish in size can be managed expectantly, whereas those that do not regress on follow-up should be excised. If the patient becomes pregnant, the risk of rupture may be increased.

Ruptured and bleeding tumours are excised as emergency procedures and, since many of these tumours are near the surface, local excision with a thin rim of parenchyma is sufficient, although whenever possible the resection should be anatomical. Intracapsular haemorrhage may produce an extremely large tumour necessitating formal lobectomy.

Focal nodular hyperplasia

FNH (Figure 24.12b) is nowadays regarded as a separate entity from liver cell adenoma on aetiological and pathological grounds. FNH is best considered as a response to parenchymal injury or to an anomalous arterial supply to a local area of liver tissue. The lesion is usually small and may be multiple (20%), although large lesions presenting as an abdominal mass may occur especially in pregnant females and in children of both sexes. There is no aetiological association with oral contraception and the incidence of FNH has not increased since the introduction of the contraceptive pill. Macroscopically FNH consists of a firm mass, the cut surface of which reveals a central scar with radiating fibrous septa. The microscopic findings are akin to cirrhosis with regenerating nodules and fibrosis. The vast majority of FNH cases are discovered accidentally during surgery or investigation. FNH is not premalignant and the natural history is such that it may be observed without serious risk.

Adenomatous hyperplasia

This ill-defined pathological entity refers to sizeable nodules that develop in chronic liver disease. In cirrhosis, adenomatous hyperplasia forms part of the spectrum of morbid pathological change which includes small benign regenerative nodules, large size regenerative nodules (adenomatous hyperplasia), atypical adenomatous hyperplasia (dysplastic borderline lesions, considered as low-grade HCCs by some pathologists) and frank HCC. There is some debate as to the malignant potential of adenomatous hyperplasia as some reports have indicated that cancer can develop from the intervening hepatic parenchyma, whereas others consider the transition from regenerative nodules to adenomatous hyperplasia, dysplasia and carcinoma to be the norm.

Cholangioma (Von Meyenburg complexes)

These are derived from bile duct epithelium and form small greyish white nodules consisting of mature bile ducts and fibrous tissue with a cystic component. The condition is entirely asymptomatic and requires no treatment. Most are diagnosed on biopsy for nodules found accidentally during surgery. Von Meyenburg complexes (VMCs) do carry a small risk of malignant transformation (only 11 cases of neoplastic transformation of VMCs have been reported). The malignant tumour that may develop from VMCs is cholangiocarcinoma usually in patients over 60 years of age.

Primary malignant tumours of the liver

The primary malignant tumours of the liver are dominated by HCC. By comparison, other primary tumours are rare or very rare. They include hepatic cholangiocarcinoma, angiosarcoma and epitheliid haemangioendothelioma.

Hepatocellular carcinoma, hepatoma

Primary HCC is the commonest malignant tumour worldwide and its geographical distribution parallels closely the incidence of hepatitis B and C viral infection. Although the highest prevalence is encountered in the Far East and sub-Saharan Africa, it is also common in selected populations within the USA and Europe. The disease usually develops on a background of cirrhosis (cirrhomimetic) but can originate in normal or non-cirrhotic hepatic parenchyma (non-cirrhomimetic). In the South African black population, where the incidence is high (HCC accounts for 80% of all cancers in the Bantu), 37% of primary hepatic carcinoma occur in patients without cirrhosis. This is a much higher incidence of non-cirrhomimetic disease than anywhere else in the world, including Japan (11%). In general, there are no marked differences between patients with and without cirrhosis in the symptomology, size of tumours at presentation, serum markers and HBV status, although a lower incidence of HBsAg is reported in some countries in non-cirrhomimetic cases. It is important to stress that a significant cohort of non-cirrhotic patients have histological evidence in the portal tracts of ongoing chronic liver disease.

The disease is more common in males and, although slow growing, it is associated with a poor prognosis and a frequently fatal outcome with a median survival of 4 months in patients with symptomatic disease. The outcome is not influenced by racial origin or the presence of chronic liver disease and is largely determined by the stage of the disease.

Aetiological factors

The exact pathogenesis remains unknown but the development of the disease seems to occur in stages with initiation by a genotoxic event followed by transformation due to the action of co-carcinogens. There is no evidence for a genetic predisposition, and the high incidence in certain ethnic groups and regions is explained by the correspondingly high prevalence of chronic viral liver disease in these populations.

There is undoubtedly an association between the development of HCC and the presence of chronic (necroinflammatory) liver disease with or without a background of HBV/HCV disease. One hypothesis, suggested by Dunsford *et al.*, is that, irrespective of the aetiology, chronic liver cell injury induces a series of events (cell death, regeneration, cellular metabolic dysfunction and release of inflammatory mediators) which collectively increase the risk of transforming mutations. Chronic liver disorders which are particularly prone to the development of HCC are haemochromatosis, ALD and hereditary tyrosinaemia.

The importance of HBV infection in the development of HCC is undoubted. The risk is increased 94-fold in HBsAg-positive males. In the Far East, 90% of patients who develop HCC are HBsAg positive, although the corresponding figure in the West is substantially lower (10–30%). It is now known that hepatitis B viral DNA and RNA are present in tissue extracts of the tumour and the viral DNA is commonly integrated in the host genome. However, since the non-neoplastic parenchyma adjacent to the tumour also contains viral DNA, integration alone does not account for the carcinogenesis, and the molecular mechanisms by which the hepatitis B viral DNA induces mutation remain obscure. It has been suggested that, subsequent to integration, promoting cofactors are important and these include specific carcinogens and the known risk factors, i.e. male sex, alcohol, iron overload and cigarette smoking. Again the molecular mechanisms involved in the action of these cofactors are not known. The other hypothesis concerning the development of HCC in HBV disease implicates the insertion of the viral DNA close to a cellular proto-oncogene, which is then stimulated to produce cellular transformation. Alternatively, the integration of the viral DNA is followed by chromosomal rearrangement leading to carcinogenesis.

Since the identification of hepatitis C, there have been several reports, particularly from southern Europe (Italy and Spain) and the USA, that have shown a significantly high incidence of antibodies to HCV in patients with HCC. The mechanism is obscure since HCV is not a retrovirus. It is assumed that its oncogenic action is the result of a chronic necroinflammatory state along the Dunsford hypothesis. Many, but not all, of these patients have had alcoholic or HBsAg chronic liver disease. It is now generally accepted that hepatitis C disease predisposes to the development of HCC.

Coinfection with HBV and HCV is not uncommon and results in more severe liver disease and with a significant increased risk for the development of HCC. In one recent study from Japan, 59% of patients with HCV disease and who developed HCC had evidence of past HBV infection and were anti-HBc positive. The mechanism for this synergy between coinfection with HBV and HCV is not known but it has been suggested that the HBV-encoded X protein that regulates both cell proliferation and apoptosis on a background of increased hepatocyte turnover present in patients with chronic HCV infection may be involved.

Of the mycotoxins, the most important is aflatoxin B, produced by a fungus that contaminates grain and nuts, particularly in West Africa. Recently, aflatoxin B has been detected histochemically in patients with HCC. The aetiological role of hepatic helminthosis remains obscure and the only firm association is between infestation with *Clonorchis sinensis* and the development of cholangiocarcinoma as distinct from HCC.

Pathological features of hepatocellular carcinoma

From a macroscopic viewpoint HCCs are described as follows:

- *Expanding* – sharp demarcation between tumour mass and the compressed (sometimes atrophied) surrounding parenchyma. Some have a definite capsule. Further classified into single nodular or multinodular.
- *Pedunculated* – predominantly extrahepatic growth. This has two subtypes: type I intrahepatic origin, or type II extrahepatic tumour mass that becomes nourished by a branch of the right hepatic artery (not true HCC).
- *Spreading* – lack of demarcation between tumour and surrounding hepatic parenchyma. May involve the whole liver as nodules (usually in cirrhotic livers) or be diffusely infiltrating (non-cirrhotic livers), sometimes referred to as Engel's massive form.
- *Multifocal* – several unconnected small tumours of similar size that appear to have arisen synchronously rather than as metastatic foci from an initial single tumour.
- *Indeterminate* – no distinct pattern, different features in different parts.

Another perhaps more important distinction is *small HCC*. According to the *Japanese General Rules for Clinical and Pathological Study of Primary Liver Cancer*, this is an HCC of a diameter that is less than 2.0 cm. However, during the last 10 years, this limit has been extended by surgeons to tumours smaller than 3.0–5.0 cm. In any event small HCCs are nodular and well differentiated. A capsule is not identified when the lesion is smaller than 2.0 cm, but larger tumours possess a definite capsule. Histologically, small HCCs are difficult to diagnose and in particular to differentiate from large regenerative nodules. A suggestive histological picture with a rising AFP is the basis for establishing the diagnosis. Small HCCs are slow growing and have an excellent prognosis with resection or *in situ* ablation. Recurrence and prognosis are influenced by size, extracapsular growth and involvement of the portal venules.

Some large tumours may have necrotic centres. On cut section there may be a pale appearance with satellite projections into the surrounding liver tissue but some tumours have a homogeneous appearance and merge with the normal cut appearance of the parenchyma. Histologically the tumour cells resemble the normal polygonal hepatocytes and often contain inspissated bile between cells especially when well differentiated. The most commonly used classification of HCC is that of Gibson and Sobin employed by the World Health Organization.

- *Trabecular or sinusoidal* – tumour cells grow in cords or lamellae of variable thickness and are separated by sinusoids.
- *Pseudoglandular or acinar* – in addition to the basic trabecular pattern, areas of the tumour exhibit glandular pattern and canaliculi with or without bile plugs.
- *Compact* – tumour cells grow in solid masses compressing the sinusoids, which thus become indistinct.
- *Scirrhous* – cords of tumour cells are separated by fibrous septa.

All HCCs (and secondary tumours) lack a Kupffer cell population. This is important because some imaging tests, e.g. MRI using superparamagnetic ferric oxide contrast agents, are based on this characteristic. Various histological subtypes are recognized: the most common is the clear cell variant which accounts for up to 10%. The tumour cells appear 'clear' because they are laden with glycogen or lipid in the foamy cytoplasm and are sometimes associated with hypoglycaemia or hypercholesterolaemia respectively. The strong male prevalence seen with other HCCs is not shared by this histological subtype which has a male–female ratio of 1.6:1.0. Histological grades (I–IV) are used as an index of differentiation by some, but it has to be stressed that, in general, there is poor correlation between the histology and the prognosis of HCC. AFP-secreting tumours may show periodic acid–Schiff-positive staining.

HCC may spread to other segments of the liver. In this situation there is usually a large tumour mass with smaller separate satellite nodules. This is different from multifocal cancer where the nodules are of similar size. Spread through the liver is along the lumina of the hepatic and portal veins with the formation of tumour thrombus, which then embolizes to other parts of the liver. HCC is a highly vascular tumour as the neoplastic cells promote angiogenesis. Even tumour thrombus within the portal veins becomes vacularized by arterial tumour vessels and this mechanism is held responsible for the development of arteriovenous shunts that characterize this tumour. HCC can grow into and obstruct the biliary tract causing jaundice (icteric hepatoma).

Fibrolamellar HCC is a distinct variant with specific histological, histochemical and clinical features that occurs in young adults. This tumour has a better prognosis with cures rates of 50% after resection. The histology shows large polygonal cells in a dense fibrous stroma that forms bands or lamellar structures. The histology is similar to that of FNH and differentiation by imaging between the two may be difficult. The current consensus is that the two are not related aetiologically and that the FNH represents a hyperplastic response to the HCC. The AFP is not elevated in fibrolamellar carcinoma, but the serum vitamin B_{12} binding is usually elevated and this has been suggested as a tumour marker for fibrolamellar HCC. Also, some patients have elevated plasma neurotensin.

The pattern of recurrent disease after apparently successful resection suggests that direct infiltration along the hepatic veins and suprahepatic vena cava is common. Lymphatic spread to the portal tract is also common and distal lymphatic metastases are seen later in the natural history. Bloodborne metastases in the lungs are common.

Rarer malignant hepatic tumours

Hepatocellular cholangiocarcinoma combines histological features of both types of tumour and probably represents a coincidental occurrence. *Cystadenocarcinoma* occurs as a large lesion usually in adults. Microscopically, cystic spaces are lined in part with cuboidal epithelium with papillary projections.

Angiosarcoma (malignant haemangioendothelioma) consists of proliferating endothelial cells with fibrotic and haemorrhagic areas and large cavernous sinuses lined with dedifferentiated endothelium. The tumour cells may express factor VIII-related antigen. The tumour usually forms multiple nodules throughout the liver rather than a single mass. There is an established association with vinyl chloride production (as soluble monomer and solid PVC) or exposure to arsenic, Thorotrast or anabolic steroids. Angiosarcoma can occur in both children and adults. It usually metastasizes within the peritoneal cavity and carries a very poor prognosis. Presentation with life-threatening intraperitoneal haemorrhage is common. The related *epithelioid haemangioendothelioma* also expresses factor VIII-related antigen and, although it has a somewhat more favourable prognosis, it too can bleed intraperitoneally and develop extrahepatic metastases.

Adult hepatoblastoma is now referred to as malignant hepatic mixed tumour. Although composed of both epithelial and mesenchymal elements, these tumours are different from teratomas. They can form very large tumours.

Hepatic tumours in childhood

Primary liver tumours account for about 15% of abdominal tumours in childhood.

They include:

- hepatoblastoma
- HCC
- infantile haemangioendothelioma
- undifferentiated embryonic sarcoma (embryonal rhabdomyosarcoma)
- mesenchymal hamartoma
- malignant rhabdoid tumour
- mature teratomas.

Hepatoblastoma is the most common liver tumour in children and usually occurs below the age of 5 years with a male predominance. This is an aggressive, rapidly enlarging tumour. Metastases are present in 50% of patients at the time of presentation. The right lobe of the liver is involved in 70%. Various histological types are recognized: HB epithelial, HB mixed epithelial and mesenchymal, and HB NOS (not otherwise specified). The HB mixed type includes the teratoid hepatoblastoma which contains elements of the three germ layers. Irrespective of type, the AFP is elevated in the majority of cases. Large tumours may rupture with massive intraperitoneal haemorrhage that is often fatal.

Infantile HCC has similar morphological features to the adult type except for the absence of chronic liver disease/cirrhosis. It may occur in infants. Fibrolamellar HCC is encountered in older children

Undifferentiated embryonal sarcoma is usually diagnosed in children between the ages of 6 and 10 years and shows no male preponderance. Histologically the tumour consists of undifferentiated spindle cells and multinucleated giant cells in loose connective tissue. Differentiated components (cartilage, osteoid, striated muscle, etc.) are infrequent. Where possible, liver resection is indicated and about one-third of patients survive long term.

Mesenchymal hamartoma may form a lobulated multicystic or solid, at times pedunculated mass usually in the right lobe of the liver. It presents in infants (usually about 10 months), but may develop in older children, as a progressively enlarging mass. The tumour consists of epithelial line structures resembling bile ducts in a fibrous/myxoid stroma. The lesion is benign and cure is achieved by resection.

The rare *malignant rhabdoid tumour* is a very aggressive tumour consisting of sheets of cells containing eosinophilic intermediate cytoskeletal filaments. It is almost invariably fatal.

Clinical features of hepatic tumours

The incidence of HCC shows wide geographical variation with high-prevalence regions (Mozambique, South Africa, Far Eastern countries) and low-prevalence countries (1–2/100 000) such as the USA and UK. Some races seem to be at a higher risk, e.g. black population of South Africa and Chinese. HCC exhibits a male dominance with an average sex ratio of 3:1. In the early stages of the disease, HCC is asymptomatic; and is only discovered by screening (by ultrasound and AFP) in individuals at risk of the disease.

The predominant symptom results from an abdominal mass, which produces a dragging sensation on exercise. Other symptoms include anorexia, weight loss, abdominal or chest pain, vomiting, fever and, more rarely, changes in bowel habit and weakness. Jaundice and peripheral stigmata of chronic liver disease may be present in patients with HCC in a cirrhotic liver or arising in childhood biliary atresia. Also, jaundice may supervene from the growth of HCC into the bile ducts (icteric hepatoma). Some liver tumours at all ages present acutely with rupture and massive intraperitoneal bleeding.

Physical findings include obvious abdominal distension due to hepatomegaly or the presence of a hepatic mass. A bruit is heard in about 10% of patients. Ascites is common and is sometimes bloodstained. Additional infrequent clinical features include hypoglycaemia, hypercalcaemia, hyperlipidaemia and hyperthyroidism. Laboratory studies frequently show abnormalities of LFTs, but these may reflect underlying chronic liver disease. Haematological abnormalities may include anaemia due to intratumoral haemorrhage or polycythaemia due to anomalous erythropoietin release. Serum AFP levels are elevated in about one-third and are a useful cancer marker after resection. However, it is more commonly elevated in the US, Chinese and African populations. Serum AFP is more likely to be elevated in undifferentiated cancers and is a valuable marker for screening the cirrhotic population for HCC development. The reported sensitivity of serum AFP in the detection of HCC in patients with cirrhosis varies from 29% to 87%. Despite this, a rising level of AFP or a level greater than 500 ng/mL in patients with chronic active hepatitis or cirrhosis should be followed by real-time ultrasonographic examination of the liver and other imaging techniques to exclude HCC.

Hepatitis B and C should be looked for in all patients. For patients undergoing surgery a study of the coagulation parameters is necessary, as these may be abnormal and certainly will be affected by a major hepatic resection. Rarely there is hyperlipidaemia or hypercalcaemia with demineralization of the skeleton and spontaneous fractures.

Tumour localization and evaluation

Most patients are initially evaluated by ultrasound scanning to demonstrate size and position of lesions. More detailed information is obtained by helical high-dose CT or MRI, which reveals lesions greater than 1.0 cm in size. A chest radiograph may suggest direct diaphragmatic involvement or show pulmonary metastases. Both ultrasound and CT-guided biopsy are practised to obtain histological confirmation, but this practice is ill advised in patients with resectable tumours, as it encourages local implantation and may thus jeopardize cure. Occasionally all imaging modalities (ultrasound, spiral CT, MRI) fail to demonstrate a lesion in a cirrhotic patient who has other indications of the presence of an HCC, e.g. raised AFP. In these cases, laparoscopy with laparoscopic contact ultrasonography may be helpful. For large posteriorly placed tumours, cavography is essential to exclude invasion of the inferior vena cava but simple compression or deviation of the inferior vena cava does not preclude a successful resection. There is probably no place for a trial dissection of a HCC and the surgeon should have fully assessed the probability of a successful resection before embarking upon it.

With the advent of monoclonal antibodies, newer immunoscintigraphic methods are being developed. These include labelled antibodies against AFP and antibodies to surface antigens of human HCC (XF-8, AF-20). Preliminary results look promising.

Surgical treatment

Preoperative preparation

Disturbance of LFTs, particularly with regard to serum levels of bilirubin and albumin, may indicate the seriousness of liver damage in patients with chronic liver disease and tumour. Child's classification is used to judge the operative risk prior to resection. Patients classified as grade B or C have effectively lost 50–60% of their liver parenchyma. ICG clearance is used in many centres to evaluate the hepatic reserve and thus the ability to withstand major resection. The arterial ketone body ratio (KBR) of acetoacetate/ -hydroxybutarate is a good indicator of the hepatic mitochondrial redox potential and for this reason is used in some centres in the preoperative evaluation. Resection is poorly tolerated in patients with a KBR <0.4.

In some patients with large tumours of the right liver requiring an extended right hepatectomy (segments IV–VIII), the residual left lobe (segments II and III) may be too small and in these patients resection will be followed by acute liver failure even if the liver parenchyma is healthy. In these patients preoperative right PVE (see below) is used to achieve substantial hypertrophy of the left lobe before the resection is undertaken 4 weeks later. Patients with normal liver parenchyma will regenerate the liver bulk but patients with cirrhosis are not able to regenerate further liver tissue. Hence major resections are contraindicated in cirrhotic B and C patients.

Fluid and electrolyte disturbances should be corrected prior to surgery and vitamin K is given routinely. Nutritional supplementation with the maximum protein load tolerable by the patient may elevate the serum albumin though albumin infusions are usually required postoperatively. Patients should receive an intravenous glucose load (1 L of 10% dextrose) prior to surgery in order to ensure that hepatic glycogen is maximal.

Resection

Surgical resection remains the first-line treatment of HCC even in patients with cirrhosis, provided their hepatic reserve is good. The best results are obtained in patients with lesions less than 2.0 cm and in those with encapsulated well-differentiated tumours. The 5 year survival rate after resection averages 35–38%. Recurrence after resection is common and reaches 55% at 5 years. The risk of intrahepatic recurrent disease after curative resection is enhanced by the presence of a macroscopic portal thrombus at the time of surgery, indicating possible spread of cancer cells from the thrombus during the surgical intervention. Thus only 21% of intrahepatic recurrences are situated near the hepatic resection line and the majority (79%) are located away from the hepatic stump. For this reason, some surgeons advocate intraoperative embolization (with starch microspheres) of the portal branch supplying the tumour at the time of the resection.

The predictors of survival by univariate analysis are vascular invasion, advanced age, multiple tumours and lack of capsule but only vascular invasion remains significantly predictive on multivariate analysis.

The objective of surgical resection is to excise the lesion safely with a margin of healthy liver tissue (Figure 24.30). This can be achieved by careful operative assessment. Even so, intraoperative ultrasound is used to locate the lesion in relation to major structures (hepatic veins) and to ensure that no other satellite foci are present. Small liver tumours are amenable to segmental resection providing a tumour-free margin of at least 1.5 cm (Figure 24.31). This approach, i.e. segmentectomy, is most suited to patients with chronic liver disease where tumours have been detected relatively early by screening.

Large tumours require a formal dissection along major planes. Where the tumour is localized to segments V–VIII, a right hepatectomy is required. If it encroaches on segment IV, an extended right hepatectomy (including segment IV of the left liver) is necessary. Lesions in segments II and III are excised by left lobectomy but where, as is often the case, the tumour approaches the falciform ligament and segment IV, then a left hepatectomy (segments II–IV) is necessary. Some cancers extend across the

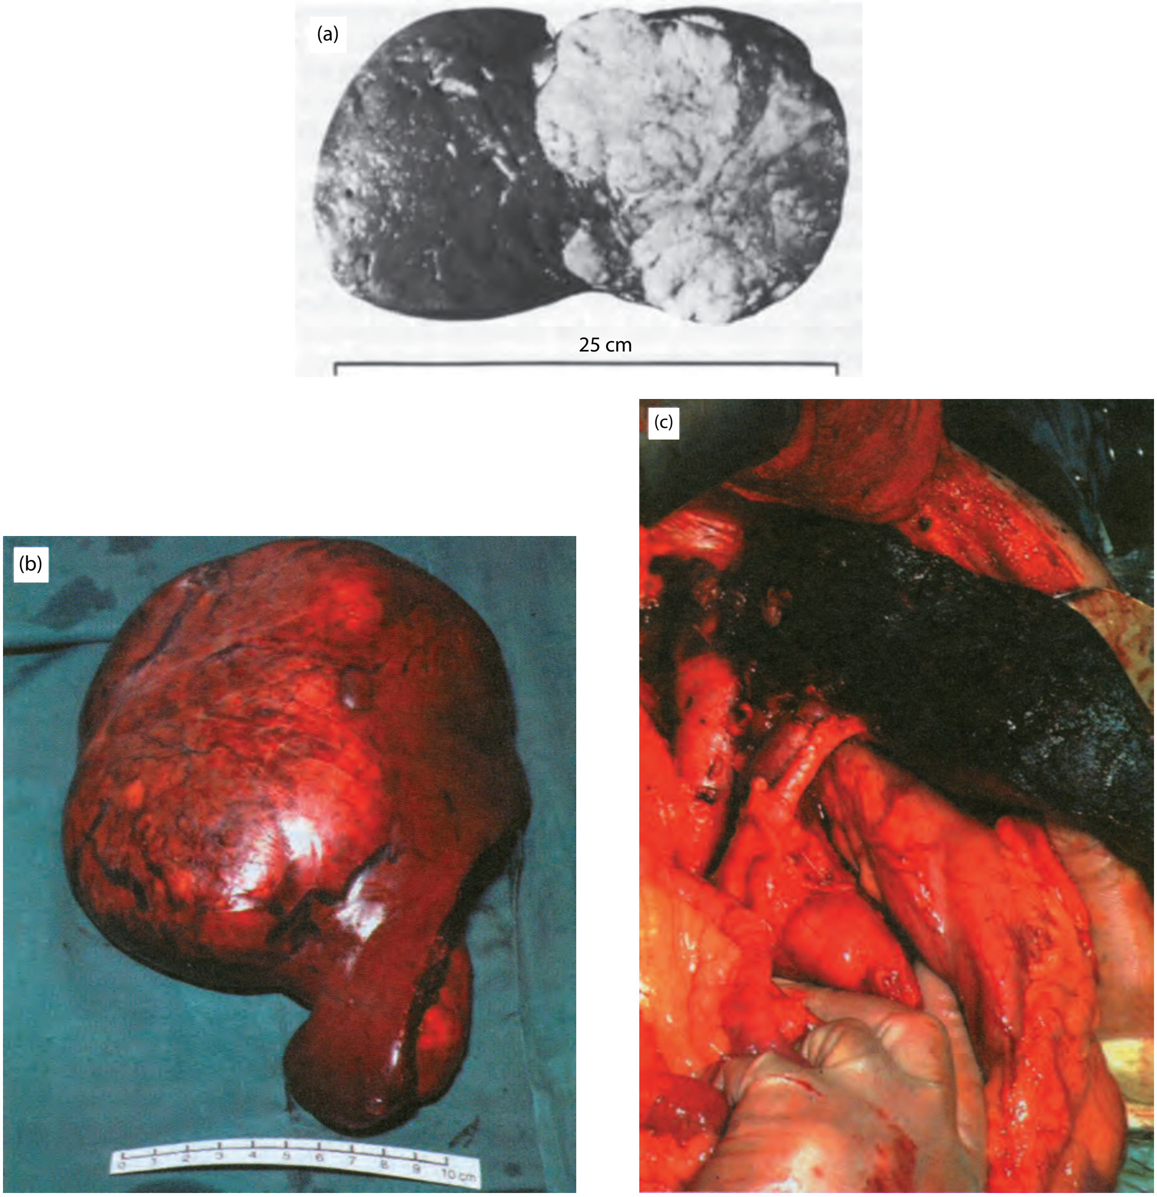

Figure 24.30 (a) Transected surgical specimen showing a large bulky tumour which appears lobulated and to have necrotic areas. There is evidence of satellite nodules in the periphery of the main tumour. (b) Surgical specimen after extended right hepatectomy (right trisectionectomy) and caudate lobectomy for a large hepatoma. (c) Intraoperative view at the end of the resection. The transected liver surface on the residual segments II-III has been treated with an argon-beam coagulator.

plane between the two livers particularly from the right into segment IV. In some patients requiring major resection for both primary and secondary hepatic tumours, e.g. especially extended right hepatectomy, the residual liver parenchyma (segments I–III) is too small. Avoidance of major blood loss during major hepatic resections underlies a good postoperative outcome. Bleeding is considerably reduced during the hepatectomy if the central venous pressure is reduced to around zero by ante-Trendelenburg position, epidural anaesthesia and vasodilator therapy.

Hepatic transplantation

The results of hepatic transplantation for HCC have improved with recurrence rates of 20% and survival rates of 45% at 5 years. The best results have been in cirrhotic patients with small tumours where partial resection could have been considered as an alternative. Thus, aside from occult small lesions (<2.0 cm) in patients requiring transplantation for chronic liver disease and cirrhosis, the indication for this surgical treatment is limited to a selected group of patients with fibrolamellar carcinoma. Even in this group, some consider that, if the tumour is too large to resect, the outcome following transplantation is not good.

Postoperative care after liver resection

Patients after liver resection require major parenteral support with diminishing daily requirements as liver regeneration takes place. Following hepatectomy/lobectomy there is transient portal hypertension and a sizeable sequestration of blood in the portal venous system.

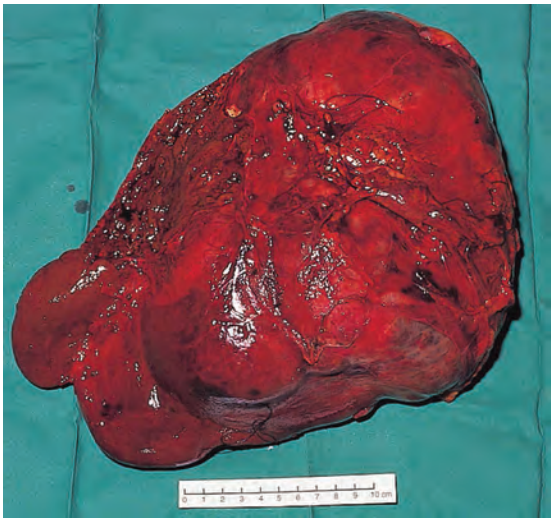

Figure 24.31 Bisegmentectomy V and VI for metastatic carcinoid tumour.

Jaundice is minimal and lasts about 1 week. More profound and persistent hyperbilirubinaemia may indicate bile duct obstruction and the need for further surgery. Hypoglycaemia can occur in the early postoperative course. Regular monitoring of blood glucose levels is thus necessary. Usually this complication can be avoided by infusing 5–10% glucose during and after operation. Intra- or postoperative coagulation defects can also be countered by the prophylactic use of fresh frozen plasma (at least two units daily during the first 4 days) and vitamin K injections. Since the half-life of albumin is 8–24 hours, hypoalbuminaemia is universal after a major hepatic resection and only partly correctable by plasma infusion. Repeated plasma or albumin infusion may be necessary for at least 1 week postoperatively until hepatic regeneration is sufficient to maintain plasma levels. Regeneration of liver documented by imaging occurs by 3 months if the parenchyma is normal.

Non-surgical management of primary hepatic cancer

Chemotherapy

Chemotherapy is used in some patients with unresectable lesions although the results are generally poor. The chemotherapy may be administered systemically or regionally with hepatic arterial infusion using either external or implantable pumps. Only one report has demonstrated that hepatic arterial infusion with floxuridine, doxorubicin and mitomycin C is associated with increased survival compared with systemic intravenous therapy, with the vast majority showing no difference. In general, a higher objective response is obtained by regional chemotherapy but this is offset by a higher rate of post-treatment complications (chemical hepatitis, biliary sclerosis, peptic ulceration and gastritis/duodenitis). A recent retrospective large series of chemotherapy for hepatic malignancy documented an overall response rate of 13% in patients with HCC. Thus it is doubtful whether this poor response justifies the morbidity and costs of this treatment. The results of adjuvant immunotherapy with cytokines such as interleukin (IL)-2 and interferons have been equally disappointing to date. Some response to -interferon can occur in patients with HCC arising on a background of cirrhosis due to hepatitis B or C.

Chemoembolization

TACE with gelatin sponge and/or ethiodized oil (with or without added chemotherapeutic agents such as cisplatin or doxorubicin) imparts some objective response and symptomatic improvement in patients with unresectable disease. TACE has also been used in the preoperative setting before surgical resection but there is no evidence that this combined approach improves the survival or reduces the recurrence rates.

Radiotherapy

Supervoltage radiotherapy has been used in unresectable disease but the treatment is limited by the dose-related radiation-induced hepatitis. Thus dosages greater than 30 Gy are not tolerated. Nonetheless, symptomatic relief of pain can be obtained by this therapy. A more recent approach is interstitial radiation using ^{131}I-labelled antibodies to ferritin and AFP with the aim of targeting the radiation dose to the tumour. The early results with this targeted interstitial radiotherapy seem promising, with 50% partial response rates.

Metastatic liver tumours

Direct invasion of the liver may result from locally advanced cancers of the stomach, pancreas and hepatic flexure of the colon. More commonly, hepatic metastases are the result of vascular spread from the primary tumour via either the portal vein or hepatic artery. The liver is by far the commonest site of metastatic disease from gastrointestinal, bronchial and breast cancers. In part this is due to its dual blood supply. Although many of the secondary deposits appear necrotic on cut section, there is sufficient blood supply to allow multiple deposits to expand, and livers weighing in excess of 10 kg at autopsy have been recorded. Although the histological picture normally reflects the primary tumour, there is a general tendency towards dedifferentiation.

Hepatic metastases are often asymptomatic, but patients with widespread involvement or large superficial deposits may suffer abdominal and back pain secondary to stretching of the Glissonian capsule or haemorrhage and necrosis within the tumour. Although many patients appear physically well when liver metastases are first detected, as the disease progresses, malnutrition, jaundice, ascites and cachexia are inevitable. By the time liver metastases become symptomatic, there is usually massive involvement of the liver. Thus the objective of modern management is the detection of early asymptomatic disease in patients at risk of secondary hepatic deposits, especially with colorectal cancer, when the results of surgery or *in situ* ablation are better and can even be curative.

Colorectal cancer liver metastases

Colorectal cancer is the commonest gastrointestinal malignancy and the second commonest cause of cancer death in the Western world. It is estimated to cause 57 100 deaths per annum in the USA and 17 000 deaths per annum in the UK. The liver is usually the first site of metastatic disease and may be the only site in 30–40% of patients with advanced cancer. At the time of initial diagnosis of colorectal cancer, 20–25% of patients will have clinically detectable liver metastasis. A further 40–50% will develop liver metastases, most commonly within the first 3 years of follow-up after resection of the primary tumour.

The median survival of untreated colorectal liver metastasis (CRLM) is around 6–8 months, varying with the extent of disease at presentation. Although overall survival of patients with CRLM has improved with modern chemotherapy agents and median survival of 18–20 months can be achieved with the most aggressive protocols including 5-fluorouracil (5FU), oxaliplatin and irinotecan, surgery remains the only treatment modality that offers the prospect of cure. A recent systematic review has shown that 30–40% of patients will achieve 5 year survival after liver resection and, although relapse may still occur between 5 and 10 years, 20% will still be alive at that point. Further relapse is unlikely after 10 years. Some tertiary referral centres have achieved 5 year survival in excess of 50% after liver resection in subgroups of patients with more favourable prognostic factors, and survival has continued to improve steadily during the last two decades. A recent epidemiological study in the UK showed that the outlook for patients with CRLMs who had surgical resection was no different from that of patients with primary colorectal tumour in stage III (Dukes's C). Until recently, however, only 10–20% of patients were considered suitable for attempted curative resection with the remaining patients being offered palliative and symptomatic treatments.

Criteria for resection

In the past, the decision to resect CRLMs was relatively straightforward. Liver resection was considered appropriate only in patients who had one to three unilobar metastases, preferably presenting at least 12 months after resection of the primary tumour, whose disease was resectable with at least a 1 cm margin of healthy liver tissue and who had no hilar lymphadenopathy or extrahepatic disease.

More recently, with advances in surgical technique, preoperative and postoperative care and chemotherapy, indications for liver resection have expanded and even patients traditionally expected to have poor prognosis have been reported to have long-term survival following liver resection. A shift has occurred in the criteria used for assessing resectability, from mere morphological criteria to new ones based on whether complete resection (R0) can be achieved. Instead of resectability being defined by what is removed, resectability should now be determined by what will remain. CRLMs are nowadays considered resectable if (1) the disease can be completely resected, (2) two adjacent liver segments can be spared with adequate vascular inflow and outflow and biliary drainage and (3) the future liver remnant (FLR), calculated on preoperative CT scan with volumetry software, is adequate. The safe FLR will vary from patient to patient depending on body mass index and underlying disease. Patients with an otherwise normal liver can survive with a FLR as low as 20–25% of the initial volume; a FLR of 30% is desirable following chemotherapy and this increases to 40% in the presence of chronic liver disease. Some conditions remain relative contraindications to surgery like invasion of a first-order division branch of the hepatic pedicle, contact with the contralateral branch, contact with the inferior vena cava, invasion of all three hepatic veins, presence of coeliac trunk lymph nodes and presence of non-treatable extrahepatic disease.

The presence of bilateral metastases has also traditionally been considered as a contraindication to surgical treatment. More recently, however, resections in two or more stages have been successfully performed for bilobar disease with good short- and long-term results. In a 'staged resection', one lobe of liver is resected or otherwise cleared of disease first followed by a period of regeneration, usually 2–3 months, after which the contralateral side is operated on. This strategy can be adopted for bilateral lesions in which a one-stage resection would leave an insufficient liver remnant with consequent liver failure or where the metastatic disease cannot be completely cleared with a single resection. Radiofrequency ablation or other techniques of *in situ* liver ablation have also been used in combination with resection surgery with the aim of increasing resectability and temporarily controlling disease progression. In this clinical setting, PVE and two-staged resection can often be used together with PVE employed to induce hypertrophy of the future remnant following clearance of metastatic disease (see section Embolization of portal vein prior to major hepatectomy).

When assessing resectability, it is important to observe that a positive liver resection margin remains a predictor of poor prognosis. However, although the minimum resection margin has historically been >1.0 cm, this has significantly reduced in recent years, and recent studies have shown that the width of surgical margin has no effect on long-term survival and even a margin of 1 mm is sufficient and is associated with long-term survival. A microscopic resection margin of 1 mm is nowadays considered acceptable, particularly if the liver transection has been performed with modern surgical devices like CUSA (Cavitron Ultrasonic Surgical Aspirator) or radiofrequency devices. It should also be recognized that several millimetres worth of resection margin may be removed with the CUSA and that a radiofrequency ablation of the transected liver surface for a depth of several millimetres (0.2–0.8 mm) is achieved with devices like Tissuelink or Aquamantis (Salient Surgical), increasing the safety of a smaller resection margin.

Synchronous metastases

At the time of diagnosis with colorectal cancer, 15–25% of patients already have liver metastatic disease (synchronous metastases). These patients pose a significant therapeutic challenge and the optimal treatment strategy is still uncertain. Recent data, however, indicate that a simultaneous colon–liver resection is technically feasible, safe, cost-effective and entails additional patient benefits in terms of psychophysical recovery and quality of life. It has been demonstrated that a resection of fewer than three hepatic segments can be performed in association with any type of colorectal resection without any increase in mortality or morbidity and with significant reduction in total operative time and total hospitalization. The combination of a major hepatectomy (four or more segments) with a colorectal resection seems however to be associated with an increased mortality and therefore remains unadvisable.

Survival at 3 and 5 years after a synchronous colon–liver resection has been found to be improved in a recent meta-analysis when compared with a classic procedure in two stages; an increased number of liver recurrences has however been observed at 1 year, caused by occult liver disease becoming overt and by the lack of patient selection operated by the time interval between colectomy and hepatectomy, where up to 30% of patients can show progressive disease even despite chemotherapy and hence never proceed to liver resection.

Embolization of portal vein prior to major hepatectomy (trisectionectomy)

Removal of more than 60–65% of the liver parenchyma in adults carries an increased risk of liver failure and mortality, particularly in obese patients, postchemotherapy patients and patients with underlying chronic liver disease. This problem is quite common in patients undergoing an extended right hepatectomy (trisectionectomy) and in some patients undergoing a right hepatectomy where only a very small left lateral sector (left lobe – segments II and III) is present.

Preoperative PVE, by redistributing the portal venous blood in the liver, induces atrophy of the liver to be resected and hypertrophy of the prospective liver remnant. PVE is usually well tolerated with virtually no symptoms and barely measurable liver function disturbance. Occasionally, however, some may develop liver failure or ascites. This technique increases the FLR thus significantly expanding the pool of resectable patients: up to 85% of patients previously judged irresectable on the basis of an insufficient FLR can undergo attempted major hepatectomy after PVE while only 15% had to be definitively turned down (inadequate hypertrophy of FLR or tumour progression being the most common reasons), as shown in a recent meta-analysis.

Notes on imaging and staging

CT

Contrast CT of the chest, abdomen and pelvis is commonly used as the initial imaging modality. Iodinated contrast allows characterization of hepatic lesions based on enhancement patterns. During the portal venous phase, normal liver enhances uniformly while liver metastasis appear hypodense. This can be attributed to the largely arterial blood supply of these lesions. Smaller lesions may appear more evident in images acquired during the arterial phase scan; however, for subcentimetre lesions, MRI has a higher sensitivity.

MRI

MRI has several advantages over CT such as no risks from radiation exposure and no adverse reactions to iodinated contrast agents. CRLMs are hypo- to isointense on T_1 and iso- to hyperintense on T_2 weighted images. MR contrast agents provide critical tumour characterization and can be safely used in patients with iodine contrast allergy and renal failure. Other agents, including gadolinium chelates or iron oxide agents, may provide additional benefits in selected applications. The degree and nature of tumour vascularity form the basis for liver lesion characterization based on enhancement properties. It is particularly useful in evaluating indeterminate subcentimetre hepatic lesions and lesions in livers with fatty infiltration.

CT-PET

This is commonly used in patients with liver metastasis being considered for resection. PET is an imaging modality which images metabolic activity via the distribution of positron-emitting tracers that are incorporated into metabolic processes. In practice, this translates into the parenteral administration of a metabolically radioactive (positron emitting) tracer into the body which is then incorporated into a metabolic pathway. The emissions of positrons are then imaged with the PET scanner. CT-PET combines the advantages of CT with the functional ability of PET, by the fusion of PET images and CT images acquired at the same time, helping to accurately localize the area of increased metabolic activity. This modality is highly sensitive however and any focal area of hypermetabolism can give a false-positive result. It is also expensive and has a questionable role in determining lesions less than 1 cm in size.

Laparoscopy

Laparoscopy with or without intraoperative ultrasound has also been used in the preoperative assessment. Its role has evolved as radiological detection has improved. It has high sensitivity in detecting surface CRLM and peritoneal carcinomatosis. Overall, the yield of laparoscopy for metastatic colorectal cancer ranges from 6% to 36%, with 10% in the largest published series. The yield of detection has been shown to be related to duration of disease-free survival, number of hepatic lesions, size of hepatic lesions, nodal stage of primary tumour and prehepatectomy carcinoembryonic antigen level (<200 ng/mL) as part of a clinical risk score assessment.

Operative techniques

Transection techniques

Blood loss during liver resection is associated with increased postoperative complications. Technological innovations in the transection of liver parenchyma have been developed with the aim of reducing blood loss to which reduced morbidity, mortality and safety can at least partially be attributed. Haemorrhage during hepatotomy can be controlled or prevented by a Pringle manoeuvre, which temporarily interrupts all blood inflow to the liver, although this may be associated with ischaemia–reperfusion injury. Reduction of the central venous pressure, with continuous infusion of vasodilating drugs, like glyceryl trinitrate or epidural anaesthesia, has also been advocated to reduce blood loss during hepatic resection because the hepatic veins are in direct continuity with the inferior vena cava.

Numerous techniques and devices are now available for the transection of the liver parenchyma. Historically, liver resections were performed with the finger fracture technique, whereby the liver was crushed between the operating surgeon's fingers preserving the robust fibrous structures which would then be divided in turn. This brutal and imprecise technique was then replaced by the crush-clamping techniques and more recently by the newer and more technologically advanced techniques involving often expensive surgical devices like radiofrequency dissecting sealers, CUSA, hydrojet and others.

With meticulous transection technique and with the help of these devices, hepatic resections are now routinely performed with minimal blood loss in specialized centres and without the need of routine Pringle clamping.

For additional notes on the surgical strategy during liver resection see section Techniques of anatomical liver resection and intraoperative ultrasound.

Chemotherapy

Historically chemotherapy has been reserved for patients with unresectable CRLM where its survival benefits are well documented. Response rates of 48–78% have been reported with protocols combining multiple agents like 5FU, oxaliplatin, irinotecan, with median survival ranging from 16 to 31 months and survival at 3 years of 44–55% in selected groups.

More recently however these chemotherapy regimens have also been applied in neoadjuvant settings prior to liver resection in cases where resectability was borderline or downstaging desirable. It has been demonstrated that some 10–30% of patients with unresectable disease can be downstaged successfully and become suitable for definitive surgery with 5 year survival of 30–35%. Indeed, conversion to operability is now being considered a surrogate endpoint in trials of stage IV colorectal cancer.

The role of perioperative chemotherapy in outright resectable liver metastases remains controversial despite the results of a recent RCT (EPOC) and no definitive benefits have been demonstrated yet. Patients who received FOLFOX4 had improved 3 year progression-free survival (36.2% vs 28.1%) compared with patients who had surgery alone, but this came at the price of a reduction in resection rate in the chemotherapy group, mainly caused by tumour progression, poor patient condition and patient refusal (overall 12.1% vs 4.4%). Furthermore an increase in postoperative complications (25.2% vs 15.9%) was observed after neoadjuvant chemotherapy. Overall, despite a 7–9% increase in survival in resected patients who received neoadjuvant chemotherapy, these results do not seem to justify the routine adoption of it in outright resectable liver metastases and more evidence is needed.

It would appear sensible, however, despite the current lack of absolute data, to routinely offer postoperative chemotherapy after liver resection, which may yield the same survival benefits of neoadjuvant treatment without determining increased surgical morbidity and risking disease progression. After all, the survival benefits of adjuvant chemotherapy for colorectal cancer with lymph node metastases are well established and it is reasonable to assume that similar benefits may be achievable in patients with liver metastases.

The spreading of neoadjuvant chemotherapy presents challenges as well as benefits. Chemotherapy-associated steatohepatitis has become increasingly common and its consequences are well recognized. This refers to the bluish discoloration, oedema and spongiform consistency of the liver similar to that in early cirrhosis. In studies which have compared the short-term outcomes of patients who received chemotherapy prior to resection to those patients who did not, significantly more postoperative complications have been observed in the chemotherapy group. Moreover, the postoperative morbidity is associated with the number of chemotherapy cycles.

Monoclonal antibodies

Cancer cells can proliferate through the uncontrolled production of growth factors, or an increased number of growth factor receptors on their cell membranes. For example, epidermal growth factor receptor (EGFR) is overexpressed in around 75% of colorectal cancers, with K-ras one of the better known downstream pathways. Mutation and upregulation of this pathway is associated with increased cell proliferation. Conversely, inhibition reduces the growth of cancers expressing this receptor. Such activation or inhibition of EGFR is dependent on normal or wild-type K-ras expression. However, mutations in the *KRAS* gene, found in 30–50% of patients with colorectal cancer, can lead to cell proliferation that is independent of the action of EGFR, hence they show no response to EGFR inhibitors.

The growth of primary tumours and metastases also depends on the formation of new blood vessels (angiogenesis) to supply these tissues once they reach a critical size. Vascular endothelial growth factor upregulation has been found in many human tumours, including colorectal cancer, and is important in tumour angiogenesis. However, it also plays a crucial role in liver regeneration in patients undergoing liver resection.

Cetuximab

A recent meta-analysis analysed data from seven RCTs of chemotherapy with or without cetuximab, involving a total of 4617 people with metastatic or advanced colorectal cancer. It found that cetuximab increased the likelihood of a response to treatment and also improved progression-free survival. One study of 1217 previously untreated patients received chemotherapy with or without cetuximab. The median progression-free and overall survival times were said to be longer with cetuximab (8.9 vs 8.0 months; and 19.9 vs 18.6 months, respectively). The rate of resection of liver metastases after chemotherapy has been used as a surrogate outcome measure. Cetuximab increased the number of patients who had resection of their liver metastases (7.0% vs 3.7) and the rate of R0 resection with curative intent before disease progression (4.8% vs 1.7%). The National Institute for Health and Clinical Excellence (NICE) recommends that for patients with the wild-type *KRAS* gene cetuximab is used with chemotherapy as first-line treatment for metastatic colorectal cancer. In addition, the following criteria must also be met: the primary colorectal tumour has been resected or is potentially operable; the metastatic disease is confined to the liver and is unresectable; and the patient is fit enough to undergo surgery to resect the primary colorectal tumour and to undergo liver surgery if the metastases become resectable after treatment with cetuximab.

Bevacizumab

A meta-analysis of data from five RCTs, involving 3103 patients with metastatic colorectal cancer, assessed chemotherapy with or without bevacizumab. Compared with the combination treatment, chemotherapy alone was associated with shorter progression-free survival (median 7.1 vs 9.7 months) and overall survival (median 17.7 vs 20.5 months). Only one of the studies included in the meta-analysis provided information on the number of participants whose liver metastases became resectable (8.4% with bevacizumab vs 6.1% without). NICE guidance, published in December 2010, has not recommended bevacizumab in combination with oxaliplatin-containing regimens, as it was not considered to be a cost-effective use of NHS resources for first- or second-line or later treatment of patients with metastatic colorectal cancer.

In situ ablative therapies

In essence, *in situ* ablation consists of local destruction of the tumour without resection. This is achieved by thermal methods aimed at heating the tumour to a temperature above 42.5°C for several minutes or by rapid freezing to −40°C or by chemical denaturation. The various ablating technologies include:

- rapid freezing – cryotherapy
- radiofrequency heating probes
- microwave heating
- interstitial laser hyperthermia
- heating by high-intensity focused ultrasound
- chemical ablation by alcohol injection; biochemical ablation by p53-induced apoptosis (developmental).

Currently *in situ* ablation of liver tumours is used

- when the disease is inoperable either because of multiple deposits in both lobes, or in the case of HCC because the functional reserve of the liver precludes safe resection (Child B, C)
- in conjunction with resection for bilateral disease
- whenever the patient comorbidities would not allow a safe hepatic resection.

In situ ablation can be carried out at open surgery, percutaneously or via the laparoscopic approach. The major advantage of the percutaneous and laparoscopic routes is that the procedure can more easily be repeated several times. This is an important consideration in patients with metastatic liver disease, as the majority of these patients develop fresh lesions in time. The laparoscopic approach carries advantages over the percutaneous technique – more accurate ablation and reduced risk of collateral damage to adjacent organs. The actual ablation is monitored by laparoscopic contact ultrasonography.

The initial results of phase II and III studies comparing *in situ* ablation with surgery are promising but the experience is still limited. It appears however that, for lesions of a maximum 3–3.5 cm in diameter, *in situ* ablation may well achieve long-term survival similar to surgery in case-matched settings and in experienced hands. For larger lesions, the risk of incomplete ablation and recurrence seems to be higher and therefore long-term results are worse.

Radiofrequency ablation

With this modality, a high-frequency alternating current (100 000–500 000 Hz) is passed through the tissue to cause intense ionic agitation resulting in frictional heating. Normal and neoplastic tissue is destroyed if heated to above 43°C for 5 minutes. Multielectrode probe systems increase the ablative power of radiofrequency generators. Even so the ablative zone rarely exceeds 3.5 cm. This is because of charring around the electrodes, which increases the impedance and thus limits current flow in the tissue. This problem has been overcome by the introduction of 'cool-tip' electrodes. These are hollow and are kept cool (below 30°C) by closed cold water circulation. Because of the absence of charring around the electrode during use, the ablative capacity is considerably enhanced (Figure 24.32). Radiofrequency thermal ablation has been used in patients with inoperable primary and secondary hepatic tumours. Most of the reported experience has been on the use of radiofrequency ablation by the percutaneous route under radiological or external ultrasound guidance. The laparoscopic/contact ultrasound approach carries a number of potential distinct advantages over the percutaneous route. In the first instance the positive pressure pneumoperitoneum by reducing liver blood flow decreases the heat sink, resulting in a larger ablative zone. Second, the approach permits precise visual and contact ultrasound-guided insertion of the electrode in the hepatic lesion; and, third, the risk of collateral damage is minimized.

Microwave

This is similar in principle to the above but uses microwave energy instead. It seems to be accompanied by a higher morbidity rate, especially of biliary fistula, than radiofrequency ablation. It is popular in Japan, where it is also used during open surgery for inoperable liver tumours.

Cryotherapy

Cryotherapy is the oldest *in situ* ablation modality and has been used in the treatment of inoperable liver tumours for more than 25 years. The principle is very rapid freezing followed by a slow thaw. The tumour must be frozen to −40°C for complete destruction. Modern cryo-units use high-efficiency liquid nitrogen (boiling temperature −190°C) recirculating through implantable probes (2–4 mm) that are impaled in the lesion under ultrasound control. The objective is to achieve an ice-ball that totally encompasses the tumour and extends into the surrounding normal parenchyma for at least 1.0 cm (Figure 24.33).

Non-colorectal cancer liver metastases

The recent success of an aggressive surgical approach to the management of CRLM has, in part, provided the impetus for stimulating the use of liver resection for non-CRLM disease. Extrapolating surgical strategies from one malignancy to another is reasonable in some cases; however, fundamental biological differences between various neoplasms dictate careful consideration and understanding of the tumour's

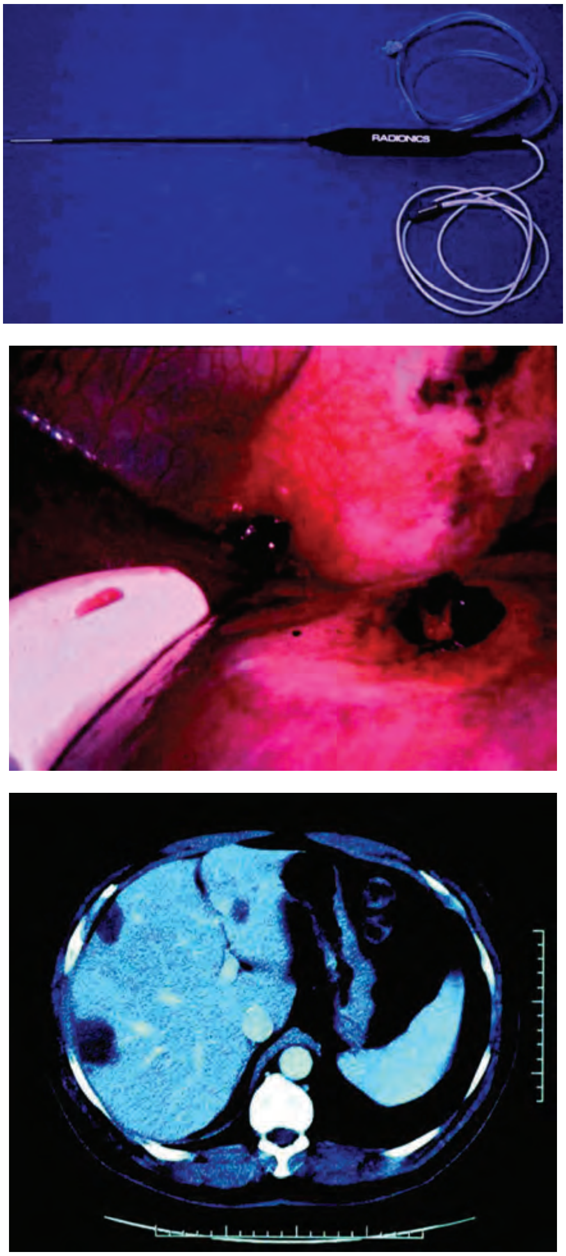

Figure 24.32 (a) Cool-tip electrode for radiofrequency ablation (Radionics); (b) laparoscopic thermal ablation of secondary hepatic deposits; (c) postoperative CT scan showing satisfactory incorporation of ablated tumours (dark areas in liver parenchyma).

natural history and prognosis. Treatment decisions must take into account clinical surrogates of tumour biology. Patients with synchronous liver metastases or short disease-free interval or with extrahepatic disease may have more aggressive tumours and may be less likely to gain significant survival benefit from liver resection. In most cases, liver resection should be performed with curative intent and the ability to achieve negative resection margins is a significant prognostic factor. The majority of patients with non-CRLMs have disseminated disease and are not candidates for hepatectomy. Exceptions include liver metastases for NETs, epithelial ovarian cancer and testicular malignancies, where debulking is considered useful as a palliative manoeuvre to improve overall survival. Ablative strategies and systemic or locally delivered chemotherapy can be used as adjuncts to resection. Radiofrequency ablation has been reported to be safe and successful at achieving local control in patients with breast cancer, ovarian cancer and NETs. Its major limitation is the inherent difficulty of achieving complete necrosis in tumours larger than 3 cm.

Transarterial embolization (TAE) and TACE take advantage of the differential blood supply of liver metastases, which depend mainly on the hepatic arteries, and the normal parenchyma, which relies more heavily on the portal circulation.

Breast

The case for resection of breast cancer metastases is evolving, with some liver surgeons advocating resection as one of various cytoreductive therapies for this disease. Response to chemotherapy appears to be an important predictor of overall survival following liver resection for metastatic breast cancer. In the largest series, patients whose disease remained stable or progressed during prehepatectomy chemotherapy were 3.5 times more likely to die than responders. Preoperative chemotherapy has been recommended in all cases, with hepatectomy reserved for those who show objective response.

Ovarian

Although the liver is rarely the only site of metastatic disease in ovarian cancer, hepatectomy can be an important component of a primary cytoreductive strategy. Ovarian cancer can involve the liver through the development of peritoneal lesions on the surface of the liver (stage III) or intraparenchymal (stage IV). Survival is improved for patients with stage IV disease who have undergone adequate debulking surgery including hepatectomy.

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) represent a group of mesenchymal malignancies that originate from the interstitial cells of Cajal of the gastrointestinal tract. Primary GISTs arise in the stomach (60%), small intestine (25%), colon and rectum (10%), with the remainder found in various other sites (gallbladder, appendix, omentum, mesentery). Surgery is the treatment of choice for resectable primary GISTs. Commonly, the primary tumour is classified into four prognostic categories, ranging from very low to high risk, according to size of lesion and the number of mitotic figures identified. Between 40% and 60% of resected patients with primaries in the intermediate- to high-risk categories recur with two patterns of recurrence: local recurrence with peritoneal disease or intraparenchymal liver metastases. Liver metastases are frequently multiple, large and bilobar making curative resection unlikely. The treatment of unresectable primary and metastatic GISTs has been revolutionized by imatinib, a selective tyrosine kinase inhibitor. Most patients with metastatic GISTs will receive imatinib as first-line treatment with a clinical response in 80%. The response is durable, with a reported median survival greater than 24 months. Eventually, though, many patients develop imatinib resistance and disease progression. Second-line agents (sunitinib and nilotinib) are currently being tested.

Neuroendocrine tumours

Gastrointestinal NETs are a diverse group of tumours that originate throughout the gastrointestinal tract and can be classified into carcinoid and pancreatic histological subtypes. Most NETs of gastrointestinal origin demonstrate indolent growth. Nonetheless, the majority will have disseminated disease at the time of diagnosis and 5 year survival is 50–80%. NETs metastasize preferentially to the liver, and in many patients the liver remains the only site of metastatic disease for a prolonged period of time. The majority of patients have multifocal, bilobar disease and more than half will have >50% liver involvement. Liver resection may be performed with curative intent, for symptom control or prolongation of survival in the palliative setting. A review article demonstrated that hepatic resection for metastatic NETs resulted in almost double 5 year survival rates over the unresected group (30–40% to 47–82% respectively). In addition, cytoreduction offers the most effective and durable palliation of symptoms. Radiofrequency ablation used in isolation can achieve symptomatic relief and local control in 60–80% of NETs with liver metastasis, but the duration of response is variable. TAE and TACE have also been shown to achieve reasonable palliation for very bulky or symptomatic unresectable tumours. However duration of response can be short and repeat embolizations are often required.

Laparoscopic liver surgery

Since the introduction of laparoscopic cholecystectomy in 1987, the laparoscopic approach has been applied to the full spectrum of abdominal procedures. However, liver resections have for long remained resistant to the onslaught of laparoscopic surgery, despite a first report as early as 1992. Concerns regarding the difficult mobilization and transection of the liver and the risks of major haemorrhage, gas embolism and dissemination of malignant tumours have been responsible for this initial slow development. More recently, however, increased experience in laparoscopic cancer surgery and the contribution of improved technology have fuelled the enthusiasm for laparoscopic liver surgery. Increasing numbers of reports and a recent meta-analysis suggested that the laparoscopic approach to the anteroinferior segments of the liver (II–VI) is a suitable alternative to open surgery, being as safe as open surgery. Laparoscopic liver surgery is associated with reduced blood loss, reduced postoperative morbidity and shorter hospital stay, and these findings are now well recognized. This has culminated in the recent acclamation of the laparoscopic approach as a gold standard, at least for selected procedures such as left lateral sectionectomy. Together with a shift in practice towards more limited, anatomic, segmental resections and parenchyma-sparing surgery, laparoscopic liver surgery is now a well-established technique routinely employed in specialized liver surgery units.

CHAPTER 25

Disorders of the biliary tract

SIR ALFRED CUSCHIERI

Surgical anatomy

Biliary tract

The right hepatic duct is formed by the intrahepatic union of the dorsocaudal and ventrocranial branches draining the two sectors of the right liver (segments V–VIII) (Figure 25.1). The ventrocranial duct is in direct line with the right hepatic duct and crosses in front of the dorsocaudal branch as this arches downwards before reaching the confluence of the two ducts. The left hepatic duct, which is formed by medial and lateral branches draining segments II–IV, is longer than the right hepatic duct. It follows a partial extrahepatic course (of variable length depending on the width of the quadrate lobe) and, therefore, dilates readily in the presence of distal obstructive disease.

The extrahepatic portion of the left duct and its segment III branch can be accessed surgically at the hilum by following the insertion of the round ligament (ligamentum teres) in the depths of the recessus of Rex (Figure 25.2). This 'round ligament' approach is an effective method of bilioenteric bypass for inoperable cholangiocarcinoma (CC) of the extrahepatic ducts.

The union of the right and left hepatic ducts is usually extrahepatic (90% within 1.0 cm of liver parenchyma), high up in the porta hepatis. The resulting common hepatic duct receives the cystic duct lower down, whereupon it becomes the common bile duct. It is customary, however, in surgical anatomy to use the term 'common bile duct' or simply 'bile duct' for the entire extrahepatic conduit as it obviates difficulties in nomenclature, especially when there is a low insertion of the cystic duct. The junction of the right and left hepatic ducts is also referred to as the *hilar bifurcation*. Together with the hepatic artery to its left and the portal vein behind, the common bile duct is surrounded by fibrous tissue known

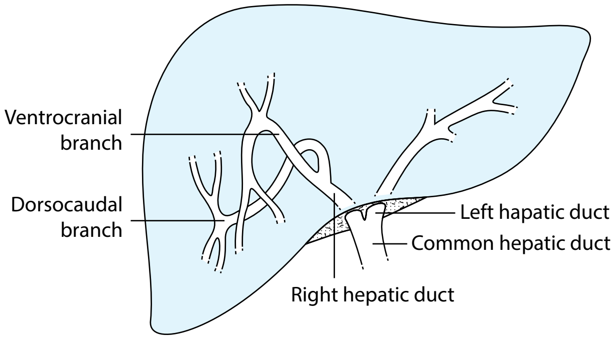

Figure 25.1 Frontal schematic view of the liver illustrating the intrahepatic biliary tree and the ductal arrangement at the hilus. Note the left duct has a longer extrahepatic course. Within the liver, the dorsocaudal branch of the right hepatic duct curves acutely posterior to the ventrocranial branch.

Figure 25.2 Diagrammatic representation of the round ligament approach to segment III duct: (a) the round ligament leads to the umbilical fissure between segment IV and segment III which are often joined by a bridge of liver tissue that overlaps the terminal insertions of the round ligament into the left branch of the portal vein; (b) the bridge of liver tissue has been divided to expose the vascular terminations of the round ligament to the left branch of the portal vein; (c) the terminations of the round ligament have been suture ligated and divided to expose the left branch of the portal vein; (d) downward traction displaces the left branch of the portal vein with exposure of the segment III duct which is divided longitudinally for anastomosis to a loop of jejunum.

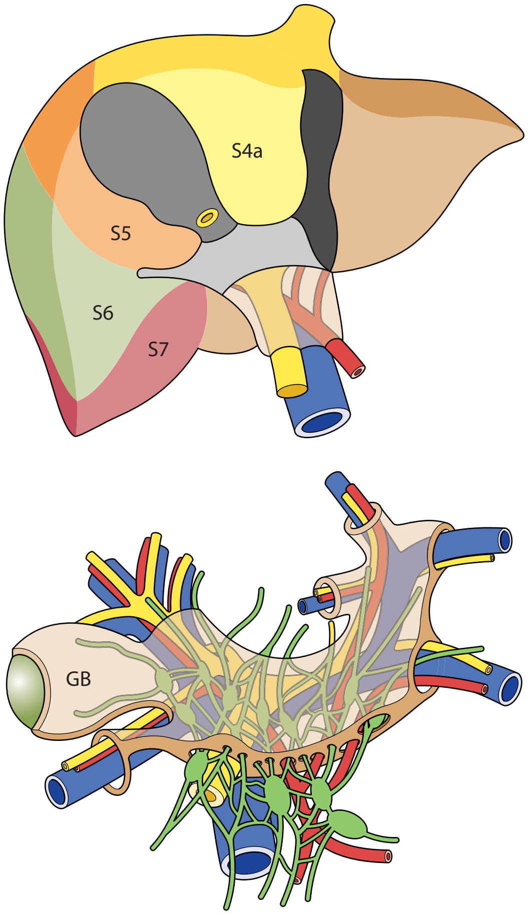

Figure 25.3 Hepatic plate system. (a) Location of the different plates; (b) components of the plate system. GB, gallbladder; G, Glisson's sheath (From Kawarada, *J Hepatobiliary Pancreat Surg* 2000;**7**:580–586, with permission.)

as the Glissonian sheath. At the hilum this is thickened and forms a condensation that is often referred to as the *hilar plate*. If the liver is incised anteriorly and posteriorly (between the hilum and the caudate lobe) to the hilar plate, finger dissection enables the mobilization of the main divisions of the hepatic duct, hepatic artery and portal vein (Figure 25.3). This manoeuvre allows inferior displacement and thus access in case of high bile duct strictures. It is also used for segmental resections of the liver.

Hepatic plate system

The hepatic plate system consists of bile ducts and blood vessels (arteries and veins) surrounded by a fibrous sheath which intrahepatically is continuous with Glisson's capsule and extrahepatically with the hepatoduodenal ligament. In addition, the sheath contains meshwork lymphatic vessels, nerves and a scant vascular network. Whereas the plate system surrounds the bile ducts and hepatic artery, i.e. they are located within the plate system, the portal vein is not and is simply covered by a loose connective tissue sheath. This is the reason for the easy dissection and separation of the extrahepatic bile duct and hepatic artery from the portal vein at the hilum of the liver.

The limits of the hilar plate are *above* by segment 4a (the inferior part of the medial segment), Rouviere sulcus (demarcating the junction between S6 and S5) *on the right* and continuous with the cystic plate (beneath the gallbladder), whereas *on the left* it is continuous with the umbilical plate. As the anterior Glisson's sheath generally runs behind the junction between the cystic plate and the hilar plate, and the posteroinferior Glisson's sheath runs behind the Rouviere sulcus, the bile ducts and blood vessels of the right side can be dissected easily without widely opening the hilar plate. Rouviere's sulcus is a surface fissure between the right lobe and the caudate process present in the vast majority of patients. It corresponds to the level of the porta hepatis where the right pedicle enters the liver.

Ductal anomalies

The intrahepatic arrangement outlined above applies in 75% of cases. A different arrangement is encountered in the remainder when either the right dorsocaudal or ventrocranial ducts join the left hepatic duct, or the common hepatic duct forms a trifurcation (Figure 25.4). The majority (75–80%) of intrahepatic calculi are located in the left hepatic duct, and right-sided calculi, which are far less common, are usually found in the ventrocranial branch of the right hepatic duct.

Important extrahepatic anomalies sometimes referred to as 'aberrant ducts' are encountered in 15–19% of patients. In fact, these 'anomalous/aberrant ducts' represent an extrahepatic confluence of a segmental duct and in the vast majority (95%) affect the right system, when the aberrant duct joins the right hepatic duct (extrahepatically), or common hepatic duct or cystic duct and, very rarely, the gallbladder.

Gallbladder and cystic duct

The gallbladder is a pear-shaped sac about 10 cm in length and is situated on the inferior surface of segment V of the right liver. It is covered with a layer of peritoneum that contains many small veins that require coagulation during cholecystectomy. It is customarily divided into the fundus, which has the poorest blood supply, especially when the organ is distended, the body and the neck or infundibulum, which leads to the cystic duct. Not infrequently, the neck has an abnormal sacculation, which is referred to as Hartmann's pouch. This may become adherent to the surrounding structures of the porta hepatis, particularly the common bile duct, seriously obscuring anatomical relationships during dissection of this region.

The cystic duct runs a variable course from the neck of the gallbladder to join the common hepatic duct. Its mucosa is arranged in a spiral fold or valve (valve of Heister), which often causes difficulties in cannulation during operative transcystic cholangiography. Although most anatomical textbooks indicate that the cystic duct joins the bile duct along its right margin, several large series of surgical dissections and analyses of operative cholangiograms demonstrate clearly that this arrangement is rare and is only encountered in 15–20% of cases. Much more commonly, the cystic duct enters the bile duct either posteriorly or anteriorly (40%). It may also pursue a spiral or a parallel course with the bile duct, with the two structures being enclosed in a common fibrous sheath that tends to obscure the exact location of the entry of the cystic duct into the bile duct (Figure 25.5). The spiral cystic duct runs down and behind the common hepatic duct to enter on its medial aspect (35%). The parallel cystic duct runs parallel to the bile duct for a variable distance before entering it. This is the rarest arrangement and is encountered in 5–7% of patients. Rarely, the cystic duct joins the right hepatic duct and very infrequently the left duct.

Anomalies of the gallbladder

The most common anomaly of the gallbladder encountered during surgery is the Phrygian cap, where the fundus is constricted and turned back on itself. The fully intrahepatic gallbladder is rare. The so-called floating gallbladder, which has a complete serosal covering and a dorsal mesentery, is relatively uncommon, as is malposition of the gallbladder and double gallbladder.

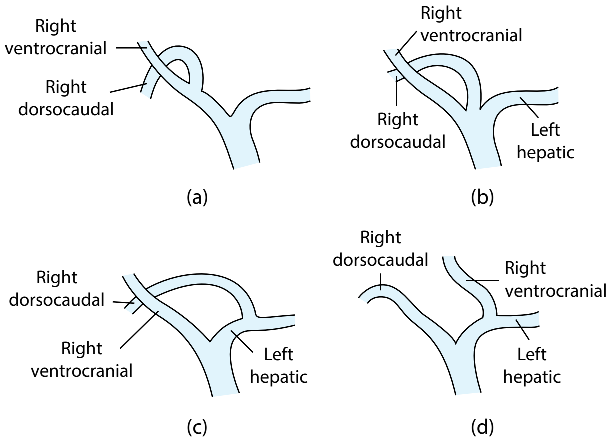

Figure 25.4 Variations in the confluence of the major intrahepatic ducts: (a) normal arrangement which is found in 75% of cases; (b) trifurcation where the right ventrocranial, right dorsocaudal and the left hepatic ducts arise simultaneously from the common hepatic duct, there being no right hepatic duct; (c) termination of the right dorsocaudal branch into the left hepatic duct; (d) termination of the right ventrocranial duct into the left hepatic duct.

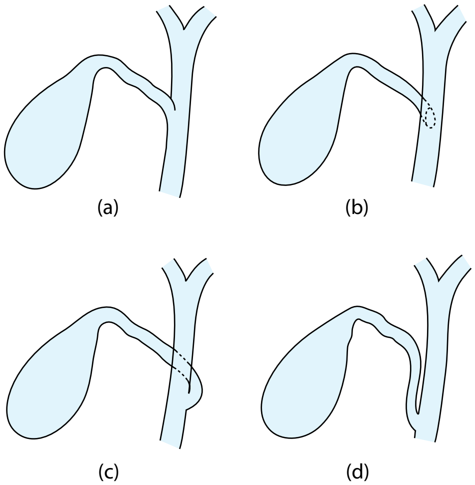

Figure 25.5 Schematic representation of the termination of the cystic duct: (a) lateral insertion often depicted as the usual arrangement but which is only encountered in 15–20% of patients; (b) anterior or posterior termination – this is the most common type and accounts for 40% of cases; (c) spiral cystic duct which courses behind the bile duct to open on its medial aspect – this is fairly common and is found in 35% of patients; (d) parallel cystic duct – this is the rarest arrangement and is encountered in 5–7% of patients.

The floating gallbladder predisposes to torsion, which simulates acute cholecystitis. An elongated sausage-shaped gallbladder frequently accompanies congenital cystic disease of the bile ducts. Agenesis (congenital absence) of the gallbladder is very rare and the condition can only be diagnosed at laparotomy in a patient who has not undergone previous biliary tract surgery. Another rare anomaly is the trabeculated gallbladder, but this usually causes symptoms similar to chronic cholecystitis and is associated with abnormal gallbladder emptying.

A left-sided gallbladder is an integral component of *situs inversus.* In the absence of this condition, malposition is generally regarded as a very rare anomaly. Thus a collective review of the Western literature yielded only 24 cases of left-sided gallbladder. Two types of gallbladder malposition have been described – *medioposition* of the gallbladder and *sinistroposition* (transposition). In medioposition, the gallbladder is displaced medially to lie on the undersurface of the quadrate lobe (segment IV) but still on the right side of the round ligament. In sinistroposition, the gallbladder lies under the left lobe (segment III) to the left of the round ligament (Figure 25.6). Despite its alleged rare incidence, the authors of a joint two-centre (Dundee and Eindhoven) study have encountered five cases of sinistroposition in a consecutive series of 1764 patients undergoing laparoscopic cholecystectomy (LC), a prevalence of 0.28%. The resulting pathological anatomy has implications for the safe conduct of LC. Despite the left-sided location of the gallbladder, the biliary pain experienced by these patients is always on the right side. The preoperative diagnosis of this anomaly is made only rarely despite routine preoperative external ultrasonography and selective recourse to endoscopic retrograde cholangiopancreatography (ERCP).

In sinistroposition, the cystic artery always crosses in front of the common bile duct from right to left. The cystic duct may open on the left or right side of the common hepatic duct. The anomaly does not preclude safe LC but modifications of the port sites and the use of the falciform lift facilitate the procedure in these cases.

The arterial supply of the gallbladder is by means of the cystic artery, which usually arises from the right hepatic artery. The cystic artery is an end artery and its occlusion is followed by gangrene of the gallbladder. There are several congenital anomalies of the arterial supply of the gallbladder (Figure 25.7), the most important of which is a short cystic artery arising from a looped right hepatic artery. All these arterial anomalies are however important and must be recognized during cholecystectomy before ligature of the 'cystic artery'. Careful display and verification of the anatomy is the single most important factor in the prevention of arterial bleeding and iatrogenic injuries during cholecystectomy and biliary tract surgery.

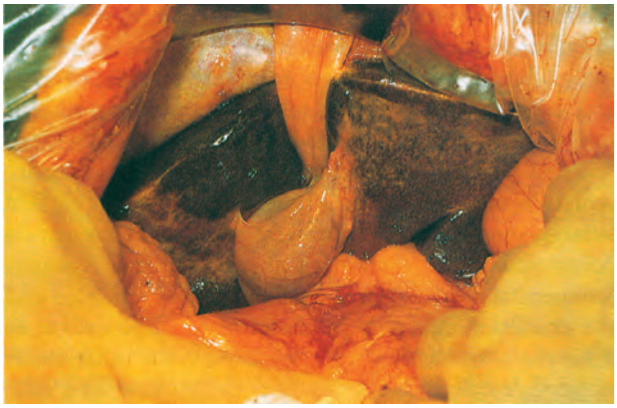

Figure 25.6 Operative photograph of sinistroposition of the gallbladder which lies under the left lobe (segment III) to the left of the round ligament. Despite the left-sided location of the gallbladder, the biliary pain experienced by these patients is always on the right side.

Common bile duct

The bile duct (choledochus) is formed by the union of the right and left hepatic ducts each draining the respective hemiliver. It is joined at a variable distance along its course by the cystic duct. In strict anatomical terms, the segment between the hilar bifurcation and the cystic duct is referred to as the common

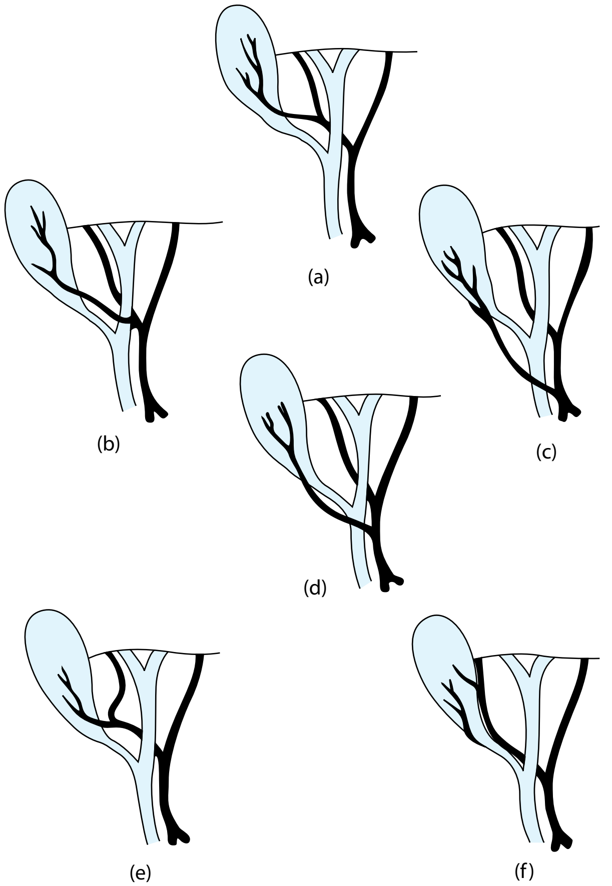

Figure 25.7 Anomalies of the cystic artery: (a) normal arrangement where the cystic artery arises from the right hepatic artery soon after this emerges from behind the common hepatic duct; (b) origin of the cystic artery from the right hepatic to the left of the bile duct, the cystic artery then crossing in front of the common hepatic duct; (c) low origin of the cystic artery from the common hepatic or gastroduodenal arteries; (d) accessory cystic artery arising from the hepatic artery – this second artery can also arise from the left hepatic, right hepatic and gastroduodenal arteries; (e) looped right hepatic artery with a short cystic artery arising from the summit of the right hepatic arterial arch; (f) the right hepatic runs close to the cystic duct and the neck of the gallbladder before giving anterior and posterior cystic branches – this anomaly is the most dangerous since the right hepatic is easily mistaken for a large cystic artery.

hepatic duct and the term common bile duct is reserved for the portion distal to this junction. From the surgical standpoint, however, it is best to consider it as one structure, which is divisible into the *supraduodenal*, *retroduodenal*, *intrapancreatic* and *intraduodenal* segments. It serves as a conduit of bile from the liver and gallbladder to the duodenal papilla and in the adult measures 11–12 cm in length with an average diameter of 7 mm (range 4–10 mm).

The supraduodenal segment is important surgically because it is the area that is most commonly explored. It lies in the free edge of the hepatoduodenal ligament to the right of the hepatic artery and anterolateral to the portal vein. The retroduodenal segment curves to the right away from the portal vein behind the first part of the duodenum before entering the head of the pancreas – intrapancreatic segment. However, in 20% of patients the duct has a partial or complete extrapancreatic course. The transduodenal segment (also known as the infundibulum), which traverses obliquely the duodenal wall and usually joins the pancreatic duct, opens into the duodenal lumen at the summit of the major duodenal papilla. The lower end of the common bile duct, therefore, deviates to the right before entering the lumen of the duodenum almost at right angles. This is an important practical consideration since forcible probing through this area may perforate the bile duct and result in a haematoma, postoperative pancreatitis, choledochoduodenal fistula or stricture of the lower end of the bile duct.

The main pancreatic duct (Wirsung) joins the posteromedial wall of the transduodenal segment of the bile duct to form a common channel in 90% of cases. A localized dilatation of the common channel to form an ampulla of Vater is uncommon (10–20%) and in 10% of patients the two ducts open separately into the duodenum (Figure 25.8).

The Vaterian segment includes the lower 2.5–3.0 cm of the common bile duct, the distal part of the pancreatic duct, the ampulla or common channel and the major duodenal papilla. These structures are surrounded by a condensation of circular and longitudinal smooth muscle fibres often referred to as the sphincter of Oddi, although it was Boyden who described the detailed anatomy of the various components of this sphincteric complex. The inferior sphincter is the strongest component and is also known as the papillary muscular ball (Figure 25.9). It surrounds the terminations of the bile and pancreatic ducts and the common channel. The middle sphincter is the longest and the thinnest of the components and surrounds the transduodenal and a variable portion of the transpancreatic segments of the bile duct and the duct of Wirsung. The superior sphincter consists of localized thickenings of the middle sphincter around the bile and pancreatic ducts at the proximal end of the sphincter complex.

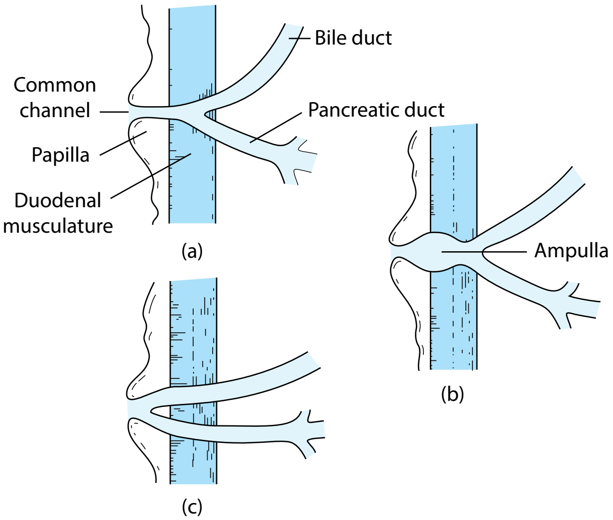

Figure 25.8 Configuration of the lower end of the common bile and pancreatic ducts: (a) the two ducts join to form a common channel, which opens at the summit of the duodenal papilla – this is the most common arrangement; (b) there is a localized dilatation of the common channel to form the ampulla of Vater; (c) the two ducts open separately into the duodenum.

An important variation of the anatomy of the Vaterian segment is the condition known as *pancreas divisum,* which results from failure of fusion of the ventral and dorsal pancreas during embryological development. The duct of the ventral pancreas, which normally forms the main pancreatic duct, remains rudimentary and drains the lower portion of the pancreatic head and the uncinate process. The rest of the pancreas is drained through the duct of the dorsal anlage (duct of Santorini), which opens through the small accessory papilla above the major duodenal ampulla. The incidence of pancreas divisum in the general population is 5–8% but the condition is much commoner in patients with idiopathic recurrent pancreatitis (approximately 25%) and an aetiological relationship has been suggested.

The rest of the common bile duct contains few muscle fibres. Its epithelial lining rests on a loose stroma containing elastic fibres, which disappear with age or disease. Thus, stone impaction, prolonged distension or cholangitis may lead to rigidity of the common bile duct. The narrowest portion of the common bile duct occurs at its point of entrance into the duodenal wall and this area is often indicated by a notch on the cholangiogram. The diameter of the transduodenal segment is normally 5 mm and that of the major duodenal papilla varies from 0.5 to 1.5 mm. The commonest site for calculus arrest or impaction is just proximal to the transduodenal segment. The major duodenal papilla is situated on the posteromedial aspect of the second

Duodenal musculature

Figure 25.9 Diagrammatic representation of the components of the sphincter complex (sphincter of Oddi) surrounding the Vaterian segment. The bile and pancreatic ducts are illustrated splayed apart to facilitate the demonstration. Normally the terminal portions of both ducts are contiguous.

part of the duodenum about 7.0–10.0 cm from the pylorus. Its appearance may vary from the usual well-defined papilla with varying degrees of projection to a flattened depression between the mucosal folds. Irrespective of its exact configuration, the major duodenal papilla frequently has a dorsal mucosal fold. The papilla is more easily located by ERCP than by direct inspection during surgical intervention. The minor (accessory) papilla is more proximally situated and assumes clinical importance only in patients with pancreas divisum.

The activity of the choledochal sphincteric complex is independent of the duodenal musculature but may be influenced by it. Thus, the effect of certain drugs on the choledochal sphincter differs from their action on the duodenal wall, and duodenal muscular peristaltic activity has no significant effect on the common bile duct pressure. The choledochal sphincter is an active structure and measures up to 2.5 cm in length. It consists of well-developed longitudinal and circular smooth muscle. Contraction of the longitudinal muscle tends to open the duct lumen, whereas the circular muscle has the opposite effect. These contracted (systolic) and relaxed (diastolic) states of the choledochal sphincter lead to quite distinct appearances of the lower end of the common bile duct at cholangiography. During contraction, contrast often forms a meniscus with the concavity facing downwards simulating a stone (the pseudocalculus phenomenon) (Figure 25.10).

Cystohepatic triangle of Calot

The cystohepatic triangle is important in biliary surgery especially in the performance of cholecystectomy. It is a triangular fold of peritoneum containing the cystic duct, cystic artery, cystic node and a variable amount of fat. It also often contains the right hepatic artery, which usually enters the triangle behind the common hepatic duct and before it gives off the cystic artery, after which it curves upwards along the right hepatic duct to the liver. The cystic lymph node is most commonly situated at the junction of the cystic with the common hepatic artery. The vast majority of aberrant/anomalous bile ducts arise from the right ductal system (especially the dorsocaudal branch of the right hepatic) and 80% are located in the cystohepatic triangle of Calot (Figure 25.11). The cystohepatic triangle is virtually obliterated in the presence of Mirizzi syndrome (see below).

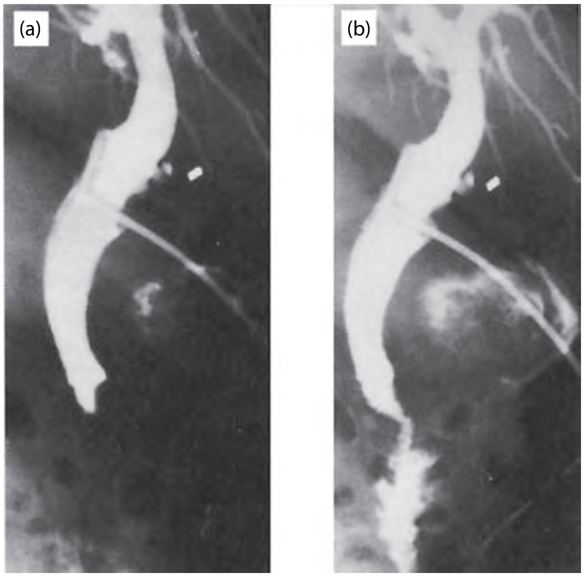

Figure 25.10 The pseudocalculus phenomenon: (a) during the systolic phase of choledochal sphincter action, there is an apparent detachment of the lower end of the common bile duct outline from the duodenal contrast shadow with an inverted meniscus effect, the appearance simulating a stone impacted at this site; (b) this 'filling defect' disappears when the same bile duct is visualized during diastole (relaxation) of the sphincter.

Lymphatic drainage of the gallbladder

Proximally, the lymphatic channels of the gallbladder communicate with those of Glisson's capsule of the liver. The hepatic capsular lymphatics drain into the thoracic duct except those on the superior surface of the liver, flow from which reaches the retrosternal lymph nodes via several channels. Distally, the gallbladder lymphatics and those of the extrahepatic bile ducts drain into the cystic lymph node, which is situated near the cystic artery close to its origin from the right hepatic artery, and to other nodes lateral to the lower end of the bile duct, particularly the retroduodenal segment. The distal lymphatic drainage of the gallbladder follows three routes: (1) cholecystoretropancreatic lymphatics, which run downwards anterior and posterior to the common bile duct to end in the retroportal nodes at the posterior surface of the head of the pancreas; (2) cholecystocoeliac lymphatics, which run to the left through the hepatoduodenal ligament and drain in the coeliac nodes; and (3) the cholecystomesenteric lymphatics, which run to the left in front of the portal vein and drain in lymph nodes at the root of the superior mesenteric vessels. The cholecystoretropancreatic drainage is considered the main pathway with respect to nodal spread from cancer of the gallbladder. The three lymphatic pathways ultimately drain in the abdominal aortic nodes.

Hepatic artery

The adult hepatic artery is derived from the middle of the three primordial arteries that supply the fetal liver. The usual arrangement is for the common hepatic artery to arise from the coeliac axis. After giving off the right gastric and gastroduodenal

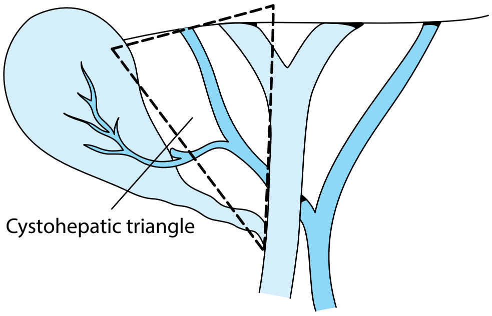

Figure 25.11 Cystohepatic triangle of Calot formed by the cystic duct and neck of the gallbladder inferiorly, the liver edge superiorly and the common hepatic duct medially. It contains the cystic artery and lymph node and the right hepatic artery as it emerges from behind the common hepatic duct. The vast majority of aberrant/anomalous bile ducts arise from the right ductal system (especially the dorsocaudal branch of the right hepatic) and 80% are located in the cystohepatic triangle of Calot.

arteries behind the antroduodenal region, it arches upwards along the left side of the bile duct and in front of the portal vein. It then bifurcates into the right and left hepatic arteries usually quite close to the liver. The right hepatic artery usually crosses behind (rarely in front of) the common hepatic duct before giving rise to the cystic artery. Low division of the hepatic artery is encountered in 15% of patients when the right hepatic artery courses behind the portal vein.

The important anomalies are the result of persistence of the left or right primordial hepatic arteries. The most common (20%) is persistence of the left primordial artery. This anomalous vessel then arises from the left gastric artery or directly from the aorta and traverses the lesser omentum to enter the liver in the umbilical fissure. It is very rare for a persistent left primordial hepatic artery to be the main or only arterial supply to the liver; usually it is present in addition to the normal hepatic artery. Persistence of the right primordial artery results in an anomalous right hepatic artery originating from the superior mesenteric. It ascends to the liver behind the pancreas and duodenum to reach the free edge of the hepatoduodenal ligament. Again it is very rare for a persistent right primordial hepatic artery to provide the sole arterial blood supply to the liver.

Portal vein

The portal vein which measures 8.0 cm in length is formed by junction of the superior mesenteric and splenic (lineal) veins, the union occurring in front of the inferior vena cava behind the neck of the pancreas. The portal vein then courses upwards behind the superior part of the duodenum and ascends to the liver in the right border of the lesser omentum behind the common bile duct on the right and hepatic artery on the left to the right extremity of the porta hepatis, where it bifurcates into the right and left portal veins which accompany the corresponding branches of the hepatic artery into the hepatic parenchyma. The portal vein bifurcation can be intrahepatic or extrahepatic (roughly equal incidence). The portal vein is surrounded by the hepatic plexus of nerves and numerous lymphatic channels and some lymph nodes. The right branch of the portal vein (3.0 cm length) receives the cystic vein before it enters the liver. The left portal vein (3.5 cm length) is of smaller calibre and is joined by the ligamentum teres (obliterated umbilical vein) and may be united by a fibrous cord (ligamentum venosum), the remains of the obliterated ductus venosus. The left portal vein gives branches to the caudate lobe before it enters the liver.

Variant anatomy of portal vein

Many anatomical variants of the portal vein have been described, including duplications, congenital absence and absence of portal vein branching (single portal vein enters the right liver and courses into the left, giving only segmental branches), but all these are rare. An important CT portography-based study of 200 patients has shown that subtle variants are much more common in practice, and these may easily be overlooked with important adverse surgical consequences. In this study, 35% of patients had variant portal vein anatomy (significantly greater than the 10–15% reported in the sonography literature). The findings of this important study are summarized as follows:

- normal bifurcation (standard anatomy) 65%
- trifurcation 9%
- right posterior portal vein as the first branch of the portal vein (Z configuration) 13%
- segment VII as a separate branch of the right portal vein 1%
- segment VI branch as a separate branch of the right portal vein 6%
- other anomalies 6%.

The common abnormal variants affect predominantly the right portal vein, with abnormalities of the left portal vein being rare. Knowledge of abnormal portal vein anatomy is important in surgical resections of the liver, hepatic transplantation and many percutaneous interventional procedures, including transhepatic portal vein embolization to induce contralateral liver hypertrophy in patients, transjugular intrahepatic shunt, etc. If missed, some of these variants may have very serious consequences. Thus for example, failure to recognize a Z-type portal vein variant during a left liver resection or when harvesting a living donor liver transplant may result in loss of perfusion to the right anterior sector. Trifurcation of the portal vein may require two separate anastomoses when the right liver is transplanted.

Surgical biliary physiology

Hepatic cholesterol and bile acid physiology

The liver plays a key role in the metabolism of cholesterol. It regulates the uptake of dietary cholesterol, its *de novo* synthesis and the excretion of this lipid in bile either as free cholesterol or as bile acids. There is increasing evidence for metabolic compartmentalization of cholesterol within the hepatocyte, i.e. cholesterol derived from extrahepatic sources is metabolized differently from that synthesized in the liver, the latter being destined for bile acid synthesis via the 7-α-hydroxylation step, after which it is no longer available for esterification.

Under normal conditions, sufficient bile acids are synthesized to make up for the enteric losses, and to this extent the synthesis of bile acids by the liver is generally believed to be controlled by the circulating bile salt concentration, although there is some debate on the importance of this feedback control mechanism. The primary bile acids are conjugated within the hepatocyte with the amino acids glycine and taurine, before being secreted into the bile canaliculi. Toxic relatively insoluble secondary bile salts (reabsorbed from the small intestinal pool) such as lithocholic acid are sulphated prior to excretion. Cholesterol is transported into the bile canaliculi as phospholipid–cholesterol vesicles. The formation of phospholipid–cholesterol–bile acid micelles is a postcanalicular event induced by the high concentrations of bile acids in the hepatic bile. There is evidence that high concentrations of deoxycholic acid may promote the hepatic secretion of cholesterol saturated bile and thereby induce the nucleation of cholesterol crystals.

Bile secretion

The secretion of bile by the liver is largely dependent on the influx of bile acids, which consist of a large component made up of bile salts that have been reabsorbed from the small intestine into the portal venous blood, and a smaller component of newly synthesized bile acids. There is a small bile acid-independent fraction of bile secretion, which is reduced in experimental cholestasis, whereas the bile acid-dependent fraction increases under these conditions.

Somatostatin decreases both bile acid flow and bile ductular secretion, indicating a suppression of *de novo* bile acid synthesis by the hepatocytes. By contrast, vasoactive intestinal polypeptide (VIP) increases the bile flow in man by a mechanism which is similar to that of secretin. The basal or resting (interdigestive) common bile duct pressure that averages 6.0 mmHg ensures the continued patency of the lumen of the choledochus but is insufficient to overcome the resistance of the choledochal sphincter. The hepatic bile is stored and partitioned in the gallbladder, although the patterns of gallbladder filling and emptying are incompletely understood. Eating results in the cholecystokinetic response, consisting of contraction of the gallbladder and relaxation of the sphincter of Oddi; this results in the timely delivery of bile salts into the intestinal tract. This response is mediated by known hormonal mechanisms [cholecystokinin (CCK)] and poorly understood neural reflexes. Studies have shown that gallbladder emptying occurs before the onset of gastric emptying of a meal, suggesting a cephalic neural reflex. Gallbladder contractions also occur during the interdigestive period, and, in humans, these are coincident with phase II duodenal activity of the intestinal migratory motor complexes.

Biliary motility

The existence of an independent choledochal sphincter is now recognized by electrophysiological criteria. It results in a high-pressure zone just within the papilla. Apart from being responsive to various hormonal influences, the choledochal sphincter has a rich nerve supply via the hepatic vagal plexus, which consists predominantly of motor fibres derived from the left abdominal vagus. The sympathetic component is derived from the spinal segments T8 and 9 via the coeliac and periarterial plexuses. In addition, the lower end of the common bile duct exhibits phasic peristaltic activity with opening (diastolic) and closing (systolic) movements that correlate with pressure waves demonstrated in man. In the fasting state, these phasic contractions are cyclical and parallel the duodenal migratory motor complexes. They are considered to regulate the flow of bile and pancreatic juice into the duodenum. The sphincter is in a contracted state and offers a significant resistance to bile flow in between these phasic contractions.

Effect of hormones

CCK is the main stimulus to gallbladder contraction in response to a meal and CCK administration increases gallbladder pressure, decreases the resistance through the sphincter of Oddi and enhances bile flow in man. CCK-induced gallbladder contraction is largely inhibited by atropine. In humans, the gallbladder is less sensitive to CCK than the exocrine pancreas since the dose of exogenous CCK required to induce trypsin secretion is lower than that necessary for gallbladder contraction. CCK action on the extrahepatic biliary tract is not mediated by the nervous system, although the atropine effect in reducing CCK-mediated contraction suggests that its action may be mediated by the release of acetylcholine from intrinsic cholinergic nerves. CCK administration results in the activation of cyclic adenosine monophosphate. CCK induces relaxation of the sphincter of Oddi, which is concomitant with contraction of the gallbladder, resulting in an efficient delivery of bile into the duodenum in response to a meal. CCK and motilin may be involved with the phasic activity of the choledochal sphincter, which is associated with duodenal migratory myoelectrical complexes during the interdigestive stage.

The activity of CCK depends on the COOH-terminal heptapeptide, a sequence found in gastrin which has a cholecystokinetic activity one-fifteenth that of CCK. Thus, this effect of gastrin is a pharmacological phenomenon in both dog and man, and gastrin has no effect on the biliary pressure of cholecystectomized patients. The synthetic hepta-, octa- and decapeptides of CCK are more potent than the various molecular forms of naturally occurring CCK. In humans, 20 mg/kg of the COOH-terminal octapeptide of CCK (OP-CCK) reduces the gallbladder size by 40%. Caerulein, a peptide of similar composition to CCK extracted from amphibian skin, has a marked cholecystokinetic effect about three times that induced by CCK in the dog. Both the gallbladder contraction and the relaxation of the sphincter of Oddi are produced by a direct action on the smooth muscle. The synthetic derivative, ceruletide, has been used in the relief of biliary colic and to promote passage of retained ductal stones during saline infusion of the common bile duct through the T-tube.

Secretin does not appear to have a significant cholecystokinetic response in humans. Its effects on the gallbladder muscle vary with the species studied. Glucagon relaxes both the gallbladder musculature and the choledochal sphincter in man and dog, probably by direct action. VIP, which has been demonstrated in nerve fibres and neurones within the gallbladder wall, induces relaxation of the gallbladder and inhibits gallbladder contraction induced by CCK. These findings suggest that VIP may act as a local neurotransmitter in the physiological neural regulation of gallbladder function. Somatostatin-containing cells have been demonstrated in the human extrahepatic biliary tract. Somatostatin interferes with gallbladder emptying and reduces bile flow in man. The mammalian tachykinin substance P has been detected in the biliary tract. It is a potent stimulator of gallbladder contraction by direct action and indirectly by inducing the release of a cholinergic transmitter.

Impaired gallbladder emptying

Impaired gallbladder contraction with poor emptying leads to biliary sludge formation, increases the risk of stone formation and in certain susceptible patient groups may lead to acute acalculous cholecystitis. Emptying of the gallbladder is disturbed in:

- patients after vagotomy
- morbidly obese patients
- patients with chronic pancreatitis and exocrine insufficiency
- patients on long-term parenteral nutrition
- diabetics with visceral neuropathy
- critically ill patients.

In the morbidly obese, both fasting gallbladder volume and emptying rates are lower than normal and are associated with precipitation of cholesterol crystals. The cause–effect relationship between these two abnormalities (which precedes which) remains debatable.

One study has shed some light on the mechanism underlying the poor contractile activity of the gallbladder in vagotomized patients. These patients exhibit an abnormally elevated CCK release after a triglyceride meal compared with normal subjects. This has been interpreted as a compensatory response to a reduced sensitivity of the gallbladder to CCK following vagal denervation. In patients with chronic pancreatitis, impaired contractility of the gallbladder is encountered in those patients who develop malabsorption. Impaired gallbladder emptying is thus attributed to reduced fat digestion and inadequate triglyceride absorption leading to defective secretion of CCK. Lack of oral alimentation and abrogation of the postprandial CCK response is involved in impaired motility of the gallbladder encountered in patients on parenteral nutrition.

Delivery of bile into the duodenum

Studies in humans have demonstrated that the bile salt output through an intact choledochal sphincter is significantly lower than that obtained from the T-tube in patients after common bile duct exploration. Whereas peak bile salt output is significantly increased after cholecystectomy, total bile salt output is unaffected by this operation when compared with normal. The exogenous administration of CCK results in the production of a more stable bile secretion than the endogenous release of this hormone induced by the intraduodenal infusion of essential amino acids, and the rhythmic release of bile which follows is related to the concentration of bile salts in the duodenal lumen. The delivery of bile into the duodenum is predominantly influenced by the choledochal sphincter, the activity of which is controlled by complex neurohormonal mechanisms that are as yet incompletely understood. Alcohol ingestion induces spasm of the choledochal sphincter and intraduodenal instillation of 0.1 N HCl produces the same effect in dogs.

Neural influences on biliary motility

In man the results of vagal stimulation by insulin-provoked hypoglycaemia suggest that the parasympathetic nervous system is involved in the maintenance of gallbladder tone. Vagotomy causes dilatation and some delay in gallbladder emptying when studied by cholescintigraphic techniques. Vagotomy also results in a decrease in the nerve fibres within the gallbladder wall. However, the increased prevalence of gallstones after vagotomy suggested by some retrospective reports remains controversial. Vagal activity appears to influence the tone of the choledochal sphincter. Electrical stimulation of the vagus nerve in the dog has been reported to result in no change or in decreased bile flow through the sphincter and an increase in its electromyographic activity. In humans, hepatic plexus vagectomy has been reported to lower the passage pressure (the pressure head which opens the sphincter and permits bile to flow into the duodenum), indicating a lowering of sphincteric muscular activity/contractility.

The role of the sympathetic system remains undefined. An increased threshold for pain induced by biliary distension has been reported in humans following sympathetic blockade. Stimulation of the right splanchnic nerve induces a contraction of the sphincter, which is abolished by α-blockade, and gallbladder dilatation that is inhibited by β-blockade.

Effect of cholecystectomy and sphincterotomy/sphincteroplasty

On *a priori* grounds, removal of the gallbladder would be expected to alter the delivery of bile into the duodenum as this would then depend on the hepatic secretory pressure (maximum 25–30 cmH$_2$O) and the resistance of the choledochal sphincter which is expressed by the passage (yield) pressure. In practice, cholecystectomy in humans does not lead to any alterations in the total bile salt output compared with the normal situation, but there is a redistribution of the pool of bile salts between the gut and the portal venous system. The effect of cholecystectomy on cholesterol saturation of bile is uncertain, with some reports indicating a reduction and others showing no effect on bile composition.

Although no changes in biliary cholesterol content, gallbladder filling and response to CCK are observed after division of the sphincter (endoscopic or surgical), the concentration of lecithin and bile salts in the gallbladder is decreased, as is the concentrating ability of the gallbladder. In addition, the results of animal experiments have shown an increase in monohydroxy and dihydroxy bile salts in the gallbladder, which becomes colonized by bacteria and develops histological changes of chronic inflammation. In humans, cholecystitis develops in 6% of patients with an *in situ* gallbladder within 6 months of an endoscopic sphincterotomy. A further 30% will develop cholecystitis and biliary symptoms during subsequent years.

Investigation of patients with biliary tract disorders

Plain abdominal radiology

Plain abdominal film is of limited use in the diagnosis of gallstones in the elective situation, as only 10% of gallstones are radio-opaque. However, a plain film of the abdomen can provide useful diagnostic information in the acute situation. It may demonstrate gas in the biliary tract in patients with bilioenteric fistulas. The demonstration of this gas together with dilatation of the small intestine provides good evidence of gallstone ileus (intraluminal distal small bowel obstruction by a large gallstone), although the stone itself is rarely visualized on the film. Plain film also provides valuable diagnostic information in patients with emphysematous cholecystitis. Finally, calcification within the gallbladder wall, which is an established risk factor for carcinoma of the gallbladder, is best detected by a plain abdominal film.

Oral cholecystography and intravenous cholangiography

Both techniques can provide adequate visualization of the gallbladder if the serum bilirubin is below 40–50 μmol/L. Oral cholecystography can also demonstrate gallbladder contractility after a fatty meal or after the injection of CCK/ceruletide. Failure of the gallbladder to opacify is followed by repeated investigation using a double-dose cholecystogram. Non-visualization by this method is indicative of a diseased gallbladder if ingestion and absorption of the oral contrast agents (Telepaque) can be reasonably assumed (probability exceeds 90%). The sensitivity of a technically satisfactory oral cholecystogram for the detection of radiolucent stones exceeds 90%. However, visualization of the ducts is poor and is obtained in only 20% of patients after a fatty meal, although CCK or ceruletide cholecystography enhances the visualization of the ducts considerably (80% of patients). In practice, oral cholecystography is very rarely used in the diagnosis of gallstones nowadays and has been replaced by external ultrasound scanning. Oral cholecystography may be useful in the diagnosis of polypoid lesions of the gallbladder.

Likewise intravenous cholangiogram is very rarely used for outlining the extrahepatic biliary tract. Although infusion cholangiography is an accurate technique for the diagnosis of cystic duct obstruction (acute cholecystitis, where the gallbladder is not opacified but the ducts are outlined), this technique has been largely replaced by biliary scintigraphy, which is more accurate. In addition, there is a small but definite incidence of severe hypersensitivity reactions. In practice, preoperative intravenous cholangiogram has been abandoned in most centres.

External abdominal ultrasonography

This is now the first-line investigation for biliary tract and pancreatic disease in most hospitals. Aside from its non-invasive nature and lack of any radiation exposure, ultrasound scanning can provide simultaneous information on the following:

- detection of gallstones
- detection of gallbladder disease and its complications
- dilatation of the biliary tract and hepatic parenchymal disease, e.g. tumour deposits
- detection of neoplasms and disorders of the biliary tract, liver and pancreas.

Detection of gallstones

Real-time ultrasound in experienced hands can detect gallstones in over 90% of cases (Figure 25.12).

Gallstones are detected by ultrasound as gravity-dependent, mobile, echogenic foci within the gallbladder lumen which cast a posterior acoustic shadow. Despite the reported high diagnostic yield, gallstones that are too small (<1 mm), soft stones which lack strong internal echoes and gallstones impacted in the gallbladder neck or in the cystic duct may be missed by external abdominal ultrasound scanning. A special technique which employs harmonic imaging has been shown to improve detection of small gallstones. With this technique, the insonating ultrasound beam is at the fundamental frequency (2.5 or 3 MHz), but the receiving (returning) echoes are both at the fundamental frequency and at the second harmonic frequency (twice the fundamental frequency), enabling the imaging software to significantly reduce degradation of the image by noise. Hence, harmonic imaging, by increasing the echogenicity of gallstones and strengthening their posterior acoustic shadows, permits visualization of small stones. However some stones, e.g. soft brown pigment stones, are often not visible even by harmonic imaging. These stones, because they lack acoustic shadowing, are often misinterpreted as sludge or debris.

Detection of ductal calculi

The sensitivity of external ultrasound for ductal calculi is much less and varies considerably from centre to centre. Ductal calculi are easy to visualize by external ultrasound only when surrounded by anechoic bile in a dilated duct and when they are sufficiently large to cast an acoustic shadow. Stones impacted in the distal duct are thus often difficult to detect as their margins are inseparable from the adjacent ductal walls and surrounding echogenic fat. Ductal calculi smaller than 5 mm are missed unless special techniques such as harmonic imaging are used. With harmonic imaging

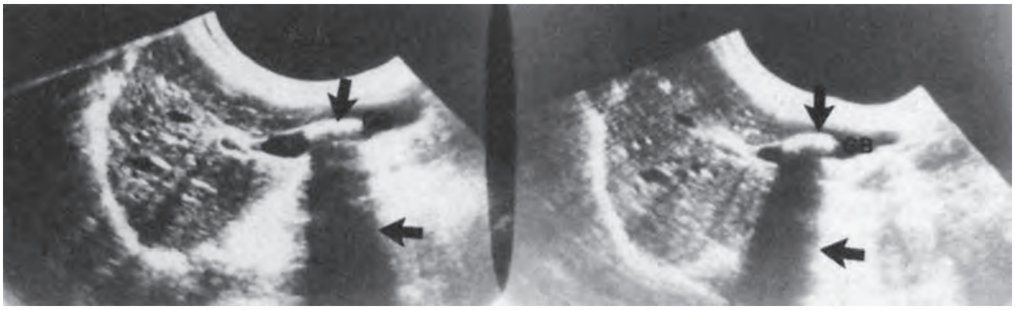

Figure 25.12 Ultrasound examination demonstrating a large gallstone (vertical arrow) with the associated acoustic shadows (transverse arrow) which are characteristic of gallstones. GB, gallbladder.

and related special techniques, the overall reported sensitivity of ultrasound for the detection of ductal calculi is 75%. Difficulties are still encountered in patients without dilatation. In this respect, one-third of common bile duct calculi are found in patients with non-dilated bile ducts. These patients require magnetic resonance cholangiopancreatography (MRCP) or ERCP.

Diagnosis of acute cholecystitis

The diagnosis of acute cholecystitis is established by the presence of a positive sonographic Murphy's sign in patients with documented gallstones by external abdominal ultrasound. Secondary ultrasound findings which support the diagnosis of acute cholecystitis include gallbladder wall thickening (>3 mm), a distended gallbladder and presence of pericholecystic fluid. The sonographic Murphy's sign is defined as a point of reproducible tenderness over the gallbladder elicited by application of pressure by the transducer head. A sonographic Murphy's sign is reported to be 87–92% accurate for the diagnosis of acute cholecystitis. However, the sonographic Murphy's sign may be absent in patients with denervated gallbladders (diabetic patients) and in patients with gangrenous cholecystitis.

Ultrasound examination of the gallbladder is used as the initial diagnostic procedure for acute cholecystitis since it enables the determination of tenderness over the sonographically identified gallbladder and is able to detect pericholecystic fluid collections and gallbladder wall oedema/thickening (ultrasonographic signs of cholecystitis), in addition to sludge and stones. Nowadays, the sensitivity and specificity of ultrasound in the diagnosis of acute cholecystitis approaches that for gallbladder scintiscanning, which is thus less often used for this purpose.

Gallbladder wall thickening and pericholecystic fluid

Gallbladder wall thickening is defined as a wall diameter greater than 3 mm and is present as a non-specific finding in 50% of patients with acute cholecystitis. Other causes of thickening of the gallbladder wall include adenomyomatosis and cancer of the gallbladder. A thickened gallbladder with a characteristic striated appearance (alternating hyper- and hypoechoic layers) in patients with acute cholecystitis is strongly associated with gangrenous cholecystitis.

Pericholecystic fluid is also a non-specific finding as it can be secondary to localized inflammation from any cause. However, type II pericholecystic collection, which is irregular in shape with thick walls, septations or internal debris, is more likely to be associated with gallbladder perforation and abscess formation.

Benign tumours of the gallbladder

Adenomas appear as well-demarcated, polypoid lesions, and are usually less than 2.0 cm in size and are usually solitary. They are rare compared with cholesterol polyps, the polyps encountered in adenomyomatous hyperplasia, which are usually multiple. On ultrasound, gallbladder adenomas are typically echogenic when small, but become more heterogeneous as they enlarge. The premalignant potential of gallbladder adenomas is believed to be low, although this remains uncertain. On ultrasound imaging, it is impossible to identify coexistent dysplasia or carcinoma *in situ* in an adenoma. The current surgical consensus recommends excision of gallbladder polyps greater than 1 cm in patients older than 50 years or any polyp that is growing on sequential ultrasound scans, even if less than 1 cm.

Malignant neoplasms of the gallbladder

Gallbladder carcinoma accounts for 98% of all gallbladder malignancies; the rest include non-epithelial tumours of muscles and nerves, metastases and lymphomas. The major risk factor is chronic cholecystitis, which leads to dysplasia and carcinoma *in situ*. When gallbladder carcinoma is diagnosed by ultrasound, it is usually advanced. The most common imaging presentation of the gallbladder cancer by ultrasound is that of a mass completely replacing the gallbladder (50%). Less commonly focal or diffuse wall thickening (20–30%) or an intraluminal polypoid mass (15–25%) may be seen. In practice, any solitary mass greater than 1.0 cm with internal vascularity should raise suspicion of gallbladder carcinoma. Marked wall thickening greater than 1.0 cm or loss of the normal mural layers are also indicative of malignancy.

Detection of dilated biliary tract

The ultrasonographic detection of a dilated biliary tract is the first step in the investigation of patients with biochemical evidence of cholestatic jaundice. In icteric patients, its accuracy in the diagnosis of extrahepatic bile duct obstruction exceeds 90% (Figure 25.13).

The internal diameter of the common duct is measured (from inner wall to wall) at the level of the crossing of the right hepatic artery. Normally on ultrasound, at this level the diameter should not exceed 6 mm. The diameter of the common bile duct increases slightly to 7–8 mm distally as it approaches the pancreas. There is still some debate whether the bile duct dilates with age and after cholecystectomy. Most centres consider a common bile duct of less than 6 mm to be normal, and one which is greater than or equal to 8 mm as abnormal. Intrahepatic bile ducts are considered normal if they measure 2 mm or less at the porta. With modern ultrasound scanners and use of harmonic imaging technique, intrahepatic bile ducts can be visualized in normal patients.

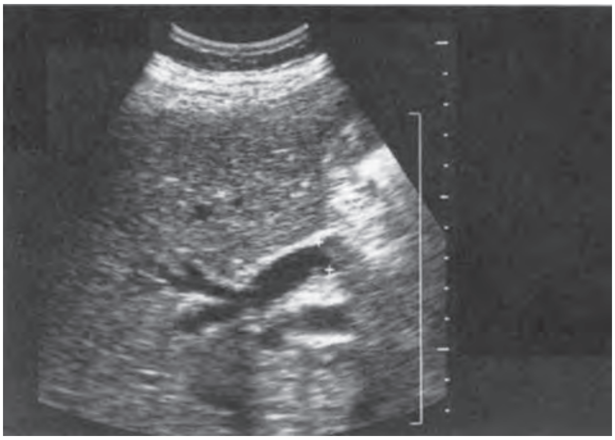

Figure 25.13 Ultrasound examination of the liver showing dilated intrahepatic and common bile ducts in a patient with carcinoma of the pancreas.

Intrahepatic biliary duct dilatation is also accompanied by irregular angular branching, a central stellate configuration, and acoustic enhancement posterior to the ducts. Power Doppler is also extremely valuable in confirming that the dilated intrahepatic tubular structures are indeed bile ducts and not vascular structures. The diagnosis of biliary obstruction by ultrasound requires to be accompanied by clinical signs of obstruction, including elevated bilirubin or elevated alkaline phosphatase. With modern techniques the level of obstruction can be defined in up to 90% of patients and the cause in up to 70%.

Nonetheless, ultrasound examination does not always provide accurate information on the exact site and extent of the lesion causing the extrahepatic obstruction. For this reason, further investigation with CT and MRCP or ERCP is required in most patients. Percutaneous fine-needle cytological aspiration of mass lesions in the liver, extrahepatic bile ducts, gallbladder and pancreas is now routinely performed in many centres under ultrasonographic guidance and may establish the definitive diagnosis regarding the benign or malignant nature of the lesion. There are no known biological hazards of ultrasound investigation (at the energy level used for diagnostic purposes).

Ultrasound examination may prove unsatisfactory for technical reasons in the following:

- in obese patients
- after previous surgery
- in those with ascites
- in those with gaseous distension of the upper abdominal viscera.

In these instances, CT scanning provides more reliable information.

CT scanning

Helical multidetector CT scanning can provide similar information on the biliary tree as ultrasonography, but in view of cost and radiation exposure it is usually held in reserve when ultrasound examination provides insufficient information for any reason. Contrast-enhanced CT provides much better detection of solid lesions of the liver, extrahepatic bile ducts (e.g. CC) and pancreas.

The contraindications to CT include pregnancy (absolute) and history of allergy/hypersensitivity to iodinated intravenous contrast medium (applies only to contrast-enhanced CT).

Two techniques of contrast-enhanced CT are used:

- *Single-phase (portal phase) contrast-enhanced CT* – used in the majority of routine liver CT scanning when the liver is imaged during the peak of parenchymal enhancement (when contrast medium-laden portal venous blood is perfusing the liver). This occurs at about 60–70 seconds after the bolus injection. The slice thickness used depends upon the CT scanner specification and is usually 5 mm or less.
- *Multiphase contrast-enhanced CT* – multiple scanning of the liver after a single bolus injection of contrast. Most liver tumours receive their blood supply from the hepatic artery, in contrast to normal hepatic parenchyma, which receives 80% of its blood supply from the portal vein. Hence hepatic tumours will be strongly enhanced during the arterial phase (at 20–25 seconds after bolus injection) but will have the same density as the normal parenchyma during the portal venous phase. Early and late arterial phase with portal venous phase is used in patients with suspected hepatocellular cancer.

Magnetic resonance imaging

MRI, also known as nuclear magnetic resonance, is being increasingly used for the detection of hepatobiliary and pancreatic disease at the expense of CT, especially with the advent of 3.0T machines, which provide extremely high resolution. The technique is based on the behaviour of protons (e.g. hydrogen) in the nuclei of molecules, which act as spinning magnets and align themselves in a specific direction when exposed to an external electromagnetic field. If radiofrequency (magnetic) pulses corresponding to the spinning frequency of the protons are then applied, the alignment is disturbed with each pulse and then returns or 'relaxes' to the original position. The time taken for the nuclear motion to get out of step is known as T_2 and that required for the return to the original position is known as T_1. Both these time constants vary with the proton density of the tissue and the local atomic and molecular environment of the protons (i.e. chemical state of the tissue). The movement of the nuclei resulting from the externally applied radiofrequency pulses is known as 'resonant absorption' and is accompanied by the re-emission of radiowaves that are picked up by a receiver coil placed round the patient. Different techniques of radiofrequency pulses are used to generate images of different slice thickness and in various planes. The advantages of MRI are:

- excellent soft-tissue definition, particularly of the central nervous system because of the lipid/water content
- it can image in any plane (coronal, sagittal, transverse) without movement of the patient
- it avoids radiation exposure
- it carries no known biological hazard.

It is likely that magnetic resonance spectroscopy will be able to provide the best test of liver function in the near future. Already, it has been used successfully to identify specific inborn errors of metabolism due to specific enzyme deficiencies.

The production of multiplanar images of the pathological anatomy by MRI accounts for its usefulness in the detection of the site and cause of obstruction in patients with cholestatic jaundice. MRI (if available) should be used in preference to CT in patients with suspected hilar CC and primary carcinoma of the gallbladder, where it is superior to CT in assessing the presence and extent of extramural invasion.

Magnetic resonance cholangiopancreatography

The principle of MRCP is based on heavily weighted T_2 pulse sequences (obtained by fast spin echo sequences) since these ensure a very high signal from stationary liquids such as bile and pancreatic juice because of their long T_2 relaxation time, in marked contrast to the surrounding vascular liver parenchyma with its high blood flow that generates virtually no signal because of its much shorter T_2. Hence the bile column stands out as a hyperintense signal against the background hypointense liver tissue. As a result, detailed imaging of the entire biliary tree (intra- and extrahepatic) and pancreatic ductal system is possible without the administration of contrast in the vast majority (>90%) of patients.

Studies have shown that MRCP provides useful clinical information that influences management in the following:

- *Biliary calculi* – MRCP detects stones as small as 2 mm in the bile duct even when this is not dilated. With the right sequences it has a sensitivity of 90–95% and specificity of 90–100% (overall diagnostic accuracy of 95%) for the detection of choledocholithiasis. This has been shown to approximate to the diagnostic accuracy of ERCP (Figure 25.14). Pitfalls for stone detection by MRCP include surgical clips, pneumobilia, haemobilia/clots and flow artefacts. In particular, surgical clips used to secure the medial end of the cystic duct after cholecystectomy create signal void artefacts that obscure the related segment of the common bile duct. MRCP should displace ERCP for the detection of ductal calculi in patients with gallstone-associated acute pancreatitis, and hence the need when these are obstructing the papilla for endoscopic sphincterotomy. MRCP is the best technique for demonstrating the presence and exact location of intrahepatic stones. MRCP is also very useful in differentiating common hepatic duct obstruction by Mirizzi syndrome from obstruction by gallbladder cancer or enlarged lymph nodes.
- *Choledochal cysts* – MRCP displays all types of choledochal cysts.
- *Bile duct injury* – MRCP outlines both the ducts and the perihepatic bile collection but is unable to establish whether the bile leak is active or not. Thus in this situation both MRCP and ERCP are needed.
- *Bile duct tumours* – MRCP has distinct advantages over ERCP and transhepatic cholangiography in the diagnosis of high bile duct tumours because it provides anatomical information of the entire biliary tract on both sides of the stricture. In addition it detects extension of tumour along intrahepatic ducts and enables complete tumour staging of the disease, i.e. assesses involvement of liver, portal nodes and portal vein (with additional MR pulse sequences, e.g. contrast-enhanced T_1 weighted spin echo). MRCP is also valuable in assessing the patency of hepaticojejunostomy following surgery for high bile duct strictures or hilar cholangiocarcionoma (Figure 25.15).

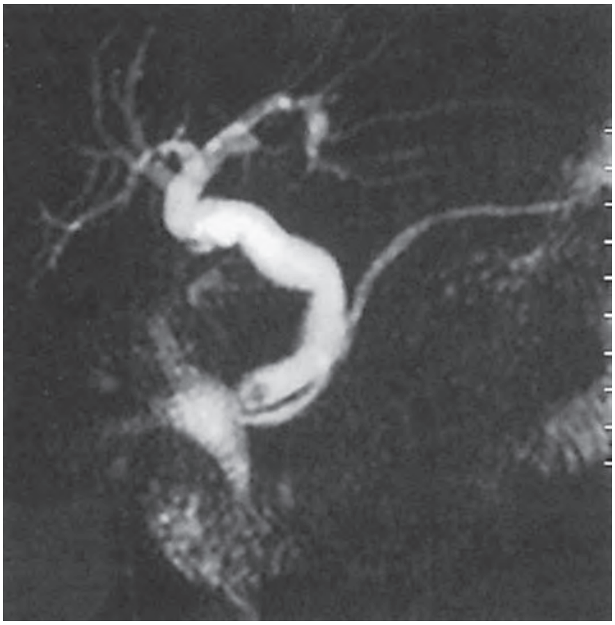

Figure 25.14 Magnetic resonance cholangiopancreatography outlining the entire biliary tree and demonstrating a stone at the lower end of the bile duct. Note also that the pelvicalyceal system of the right kidney is visualized and this obscures the duodenum in this patient who was admitted with acute pancreatitis. The entire pancreatic duct is clearly visible.

- *Pancreatic disease* – the main pancreatic duct is visualized in over 95% of cases. It is highly accurate in the diagnosis of pancreas divisum. In established chronic pancreatitis, MRCP has the same diagnostic accuracy as ERCP but not in early disease with minimal changes in the side branches. MRCP is very useful for ampullary tumours – it detects a dilated bile duct abutting on an irregular ampullary mass indenting the duodenum. Although it can detect proximal and body cancer of the pancreas, it offers no advantages over CT/ultrasound in this respect, except in cystic tumours in view of its ability to detect static fluid collections.

MRCP vs ERCP

MRCP gives the same diagnostic information as ERCP except for the detection of minimal disease chronic pancreatitis. Its distinct advantage is its entirely non-invasive nature. In comparative studies, the failure rate of MRCP (contraindications to MRI, claustrophobia and inadequate examination) is lower than ERCP. MRCP is applicable irrespective of altered or pathological anatomy that precludes ERCP, e.g. duodenal stenosis, hepaticojejunostomy. Thus the trend is to replace diagnostic ERCP with MRCP and restrict ERCP to those patients who require endoscopic intervention, i.e. endoscopic sphincterotomy and stone extraction, stenting, etc.

Percutaneous transhepatic cholangiography

Nowadays, this is a less commonly used technique for the visualization of the biliary tract in the jaundiced patient but it

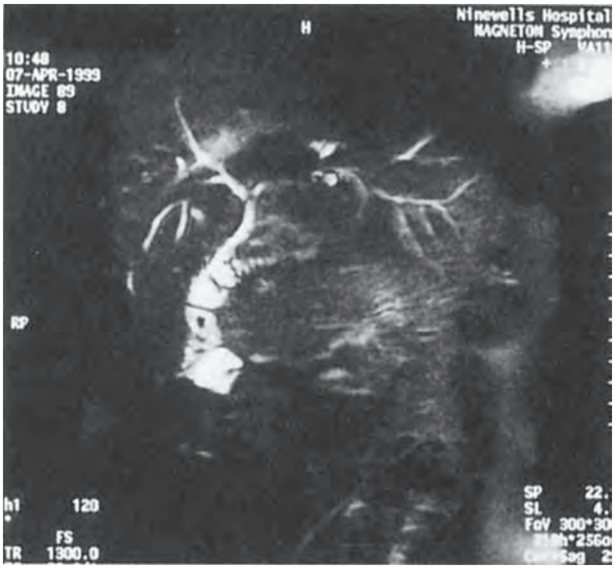

Figure 25.15 Magnetic resonance cholangiopancreatography outlining a hepaticojejunostomy after repair of an iatrogenic high bile duct stricture.

can be modified to allow percutaneous transhepatic drainage and insertion of endoprostheses. In experienced hands, the success rate with percutaneous transhepatic cholangiography (PTC) approximates to 100% in patients with dilated biliary tracts and exceeds 70% in the absence of bile duct dilatation. The reported accuracy of PTC in detecting the level and cause of the biliary obstruction averages 90% (Figure 25.16). Nowadays, the procedure is carried out under sedation using the Chiba (also known as 'skinny') 22-gauge needle, which has an external diameter of 0.7 mm. The use of the Chiba needle has largely replaced the thicker long-dwell trocar cannulas because of the higher success rate and a lower incidence of complications. The procedure must be covered with systemic antibiotic therapy (usually an amino glycoside or cephalosporin or pipericillin) and any clotting abnormality must be corrected with vitamin K and/or the administration of fresh frozen plasma prior to its performance.

In practice, PTC is used when ERCP fails or does not provide sufficient information on the proximal intrahepatic biliary tree because of an obstructing lesion of the extrahepatic bile ducts. However, MRCP can provide this information, and if available should be used in preference to PTC.

Preoperative percutaneous external transhepatic biliary drainage (Figure 25.17) is seldom performed nowadays since

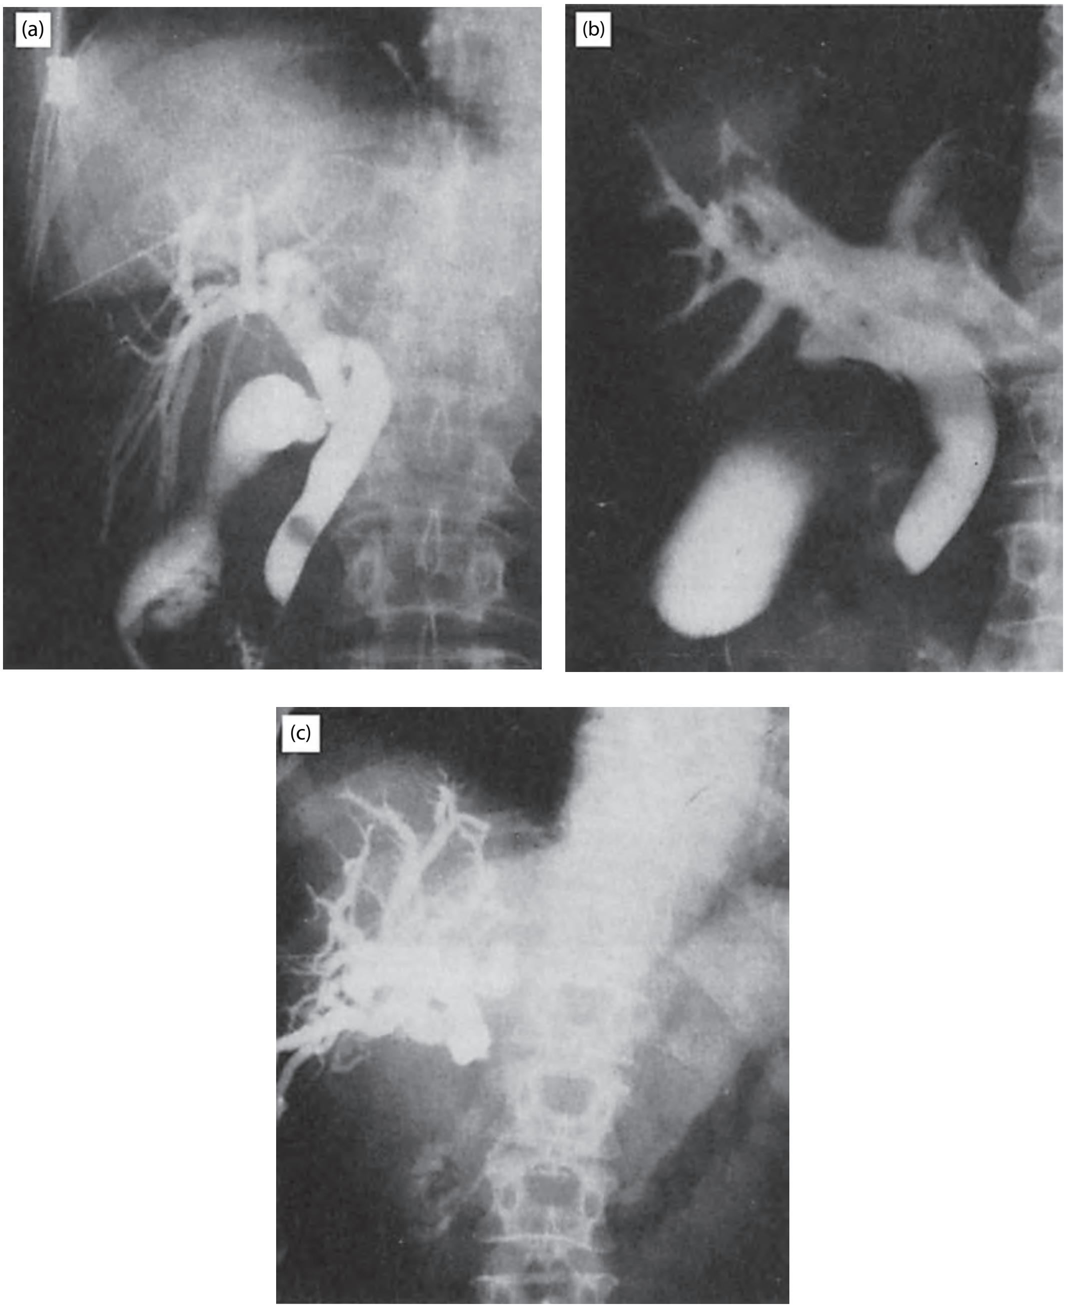

Figure 25.16 Percutaneous transhepatic cholangiograms: (a) ductal calculus proximal to a benign stricture; (b) carcinoma of the pancreas; (c) cholangiocarcinoma.

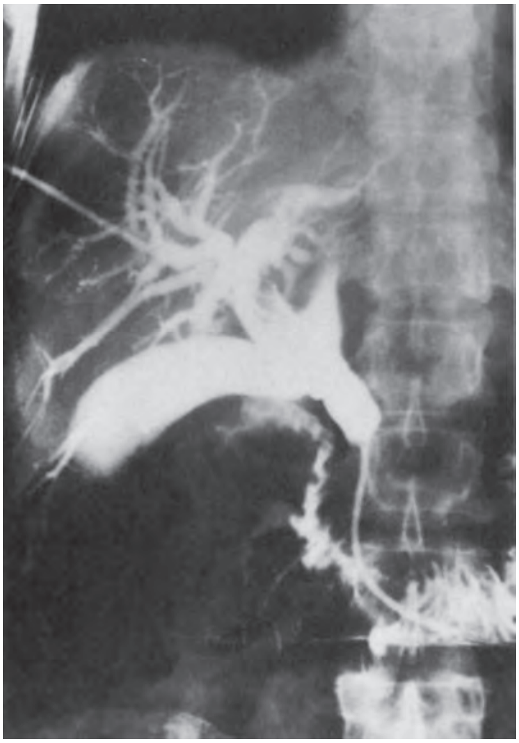

Figure 25.17 Preoperative external biliary decompression for complete obstruction due to carcinoma of the pancreas. This technique is seldom used nowadays except as a prelude to insertion of an endoprosthesis for palliation of complete obstruction caused by inoperable pancreaticobiliary malignancy.

several clinical trials have shown no benefit from the procedure in terms of reduced operative morbidity and mortality in severely jaundiced patients, and the technique predisposes to infection of the obstructed biliary tract, unless a closed collecting system which incorporates bacterial filters is used. However, the percutaneous or endoscopic insertion of endoprostheses (indwelling stents introduced over guide wires and positioned through the obstruction by means of pusher tubes) is a valuable method of palliation of patients with large bile duct obstruction due to inoperable/incurable malignancy (Figure 25.18).

The complications of PTC include:

- bacteraemia
- bile leakage
- haemorrhage: free bleeding into the peritoneal cavity and haemobilia
- bile embolization
- intrahepatic arterioportal fistula
- pneumothorax
- contrast reactions.

The reported incidence of major complications with the Chiba needle varies from 3% to 10% with a mortality of 0.1–0.3%.

Endoscopy and endoscopic retrograde cholangiopancreatography

Upper gastrointestinal endoscopy with a forward- or oblique-viewing panendoscope should be performed in jaundiced patients as significant gastrointestinal pathology is encountered in 25% of jaundiced patients. ERCP, which is performed through a side-viewing endoscope, provides useful information in patients with cholestatic jaundice irrespective of whether the ductal system is dilated or not. In experienced hands, successful cholangiography is achieved by ERCP in over 90% of cases. ERCP permits concomitant endoscopic examination and biopsy of lesions encountered during the endoscopic examination, although the examination of the stomach and duodenum is more difficult and less optimal than with a forward- or oblique-viewing endoscope. A pancreatogram can be obtained during the same investigation. Certain lesions can be treated or palliated during the procedure,

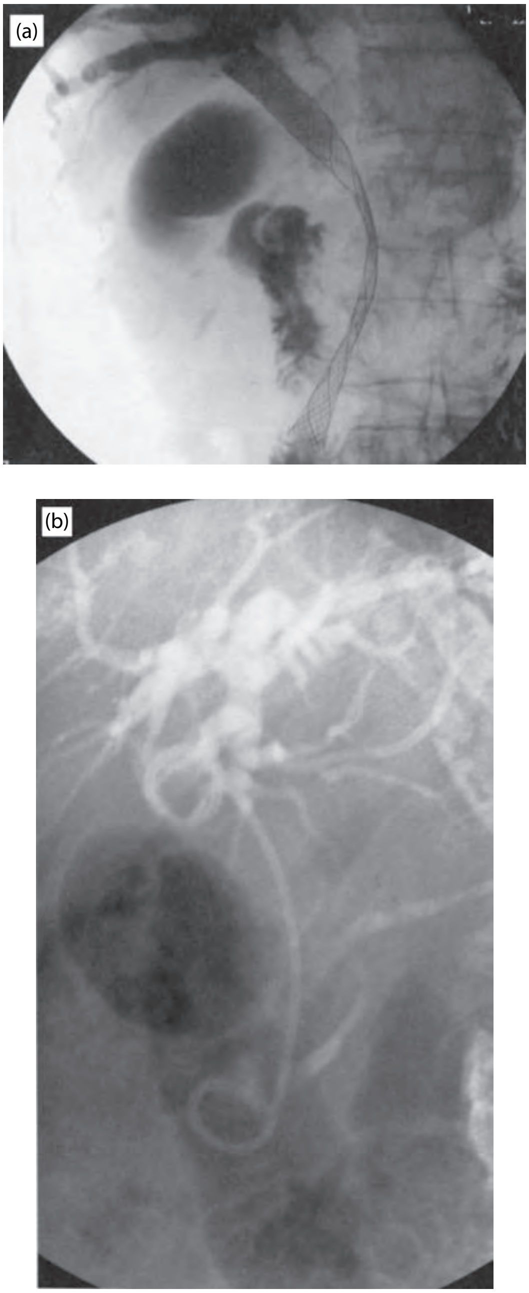

Figure 25.18 Stenting for inoperable disease: (a) expandable metallic endoprosthesis inserted transhepatically under radiological control for palliation of an inoperable hilar cholangiocarcinoma; (b) endoscopic plastic stent for palliation of inoperable carcinoma of the head of the pancreas.

e.g. endoscopic stone removal, endoscopic nasobiliary drainage and stent insertion for inoperable malignant large bile duct obstruction.

Diagnostic ERCP has a very low morbidity, largely due to pancreatitis (1.0%) and mortality (0.1%). The morbidity of interventional (therapeutic) ERCP, especially sphincterotomy, is, however, higher (6–10%). The immediate mortality of endoscopic sphincterotomy averages 1.0%, although the 30 day mortality is 3%. The complications which may follow endoscopic sphincterotomy are:

- haemorrhage
- acute pancreatitis
- cholangitis
- retroperitoneal duodenal perforation
- impacted Dormia basket
- acute cholecystitis
- gallstone ileus – following extraction of large stones.

ERCP is very accurate in the diagnosis of ductal calculi (Figure 25.19), tumours of the bile ducts (Figure 25.20) and pancreas (Figures 25.21 and 25.22) and sclerosing cholangitis. In patients with complete biliary obstructive lesions, the proximal biliary tree is not visualized. These patients require further investigation with MRCP or PTC. ERCP is less accurate than ultrasound and oral cholecystography in the diagnosis of gallbladder disease and gallstones.

Technical failure of an attempted ERCP examination may be due to:

- duodenal or pyloric stenosis
- previous Billroth II gastrectomy
- duodenal diverticulum
- uncooperative patient
- inexperience with the procedure.

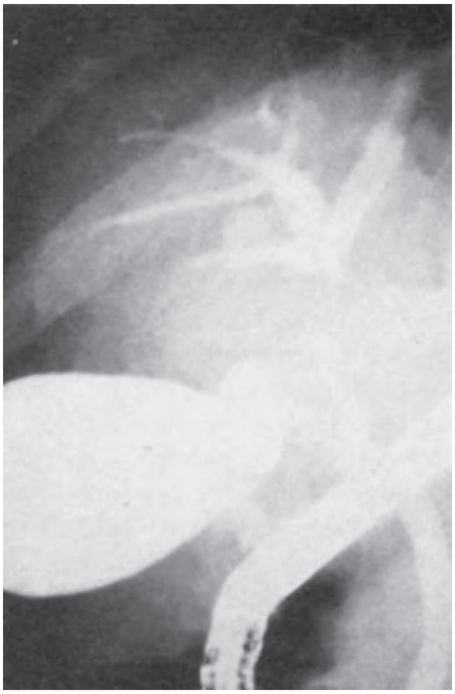

Figure 25.20 Endoscopic retrograde cholangiopancreatography showing a hilar cholangiocarcinoma.

Biliary scintiscanning

The most widely used radiopharmaceutical compounds are ^{99m}Tc-labelled compounds of IDA (iminodiacetic acid), EHIDA (diethylacetanilido-iminodiacetic acid) and more recently ^{99m}Tc-trimethylbromo-iminodiacetic acid (TBIDA). These ^{99m}Tc-labelled IDA derivatives are rapidly cleared from the circulation by hepatocytes and secreted into bile in a similar way to bilirubin; hence their use for the assessment of biliary drainage and gallbladder function. Because TBIDA has high hepatic uptake and low urinary excretion, it gives better visualization of the biliary tract at high bilirubin levels. These agents, which are powerful gamma emitters, are administered intravenously, whereupon they are selectively taken up by the hepatocytes and secreted into the bile. They are therefore ideal for the imaging of the biliary tree by a gamma camera, especially since their uptake by the liver and excretion into the biliary tract is not influenced by the presence of cholestasis.

Biliary scintiscanning is used clinically for the following conditions:

- suspected acute cholecystitis
- assessment of gallbladder, common bile duct and sphincter of Oddi function
- assessment of neonatal jaundice where biliary atresia (BA) is considered
- suspected bile leaks after trauma or surgery
- investigation of biliary drainage.

Biliary cholescintiscanning is the most accurate test of acute cholecystitis irrespective of its nature (acute calculus

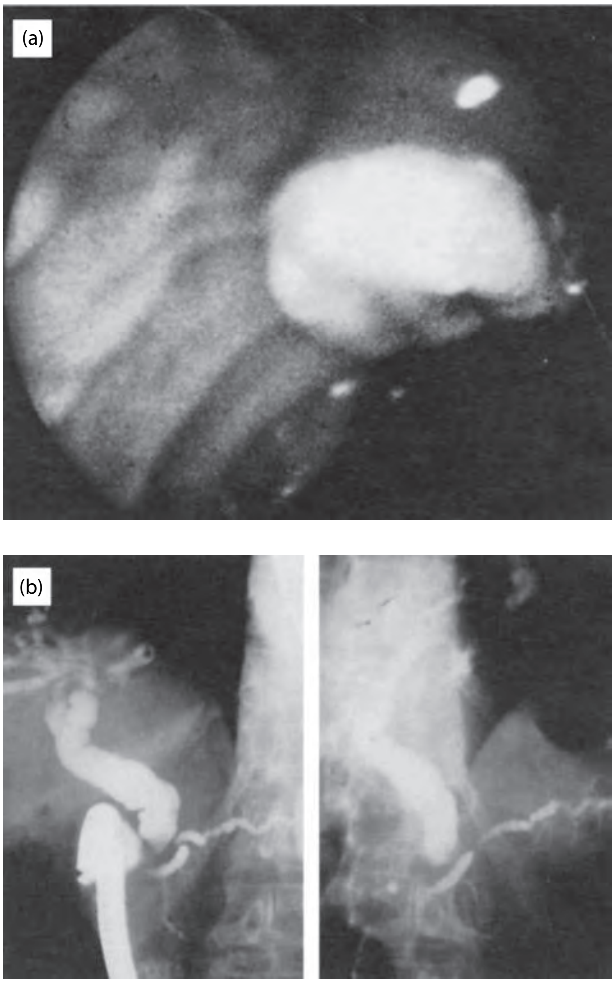

Figure 25.21 (a) Endoscopic view of a periampullary lesion of the pancreas; (b) cholangiopancreatogram of the same patient.

obstructive, acalculous cholecystitis) and establishes the diagnosis within 1 hour of the intravenous administration of the radiopharmaceutical agent. A diagnosis of acute cholecystitis can be confidently made if the scintigram shows prompt excretion and a normal common bile duct with entry of isotope into the duodenum, but the gallbladder is not imaged (Figure 25.23).

The information is stored on magnetic tape/disk for more detailed computer analysis at a later stage. Cholescintiscanning has a sensitivity of 91–97% and a specificity of 87% for the diagnosis of acute cholecystitis. A normal gallbladder scintiscan is virtually 100% accurate in excluding cholecystitis. False positives may be encountered in:

- chronic cholecystitis
- gallstone pancreatitis
- patients with alcoholic liver disease
- patients receiving parenteral nutrition.

The number of false-positive results obtained by cholescintigraphy in the diagnosis of acute cholecystitis can be drastically reduced by the administration of intravenous morphine before the procedure. This opiate causes spasm of the sphincter of Oddi, and thereby induces reflux of bile (and radionuclide) in the gallbladder if the cystic duct is patent. The morphine radionuclide test appears to be very useful in the evaluation of critically ill patients with suspected acute acalculous cholecystitis, in patients who are fasting or receiving parenteral nutrition and as a repeat procedure in those patients in whom the gallbladder was not visualized.

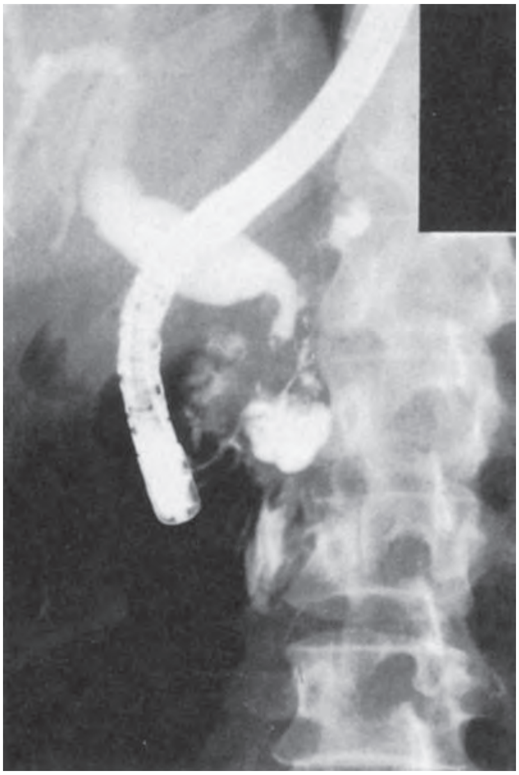

Figure 25.22 Endoscopic retrograde cholangiopancreatography showing a carcinoma of the head of the pancreas.

Biliary scintiscanning has also been used to evaluate the jaundiced patient with a bilirubin greater than 50 μmol/L. Hepatocellular disease is diagnosed when poor liver excretion and intestinal activity are demonstrated after 18 hours of injection. Complete biliary obstruction is denoted by the absence of any intestinal activity after 18 hours, and partial obstruction by normal liver excretion, dilated ducts and delayed intestinal activity. However, biliary scintigraphy is not used routinely for the investigation of the jaundiced patient since other techniques (e.g. ultrasound and cholangiography) give more precise information of the underlying pathology. The exception to the above is provided by jaundice in the neonate where biliary scintigraphy and estimation of faecal radioactivity following the intravenous injection of the isotope is one of the routine tests used for the diagnosis of BA.

Biliary scintigraphy is also very useful for the functional evaluation of surgically constructed bilioenteric anastomoses (Figure 25.24). Biliary scintiscanning after gallbladder contraction induced by a milk meal or intravenous CCK is used to quantify enterogastric reflux. Normal individuals reflux less than 5–10% of the administered dose of the radionuclide. Biliary scintigraphy is also useful in documenting the presence and location of biliary leaks after cholecystectomy. Qualitative analyses based on calculated liver function parameters from scintigraphy dynamic

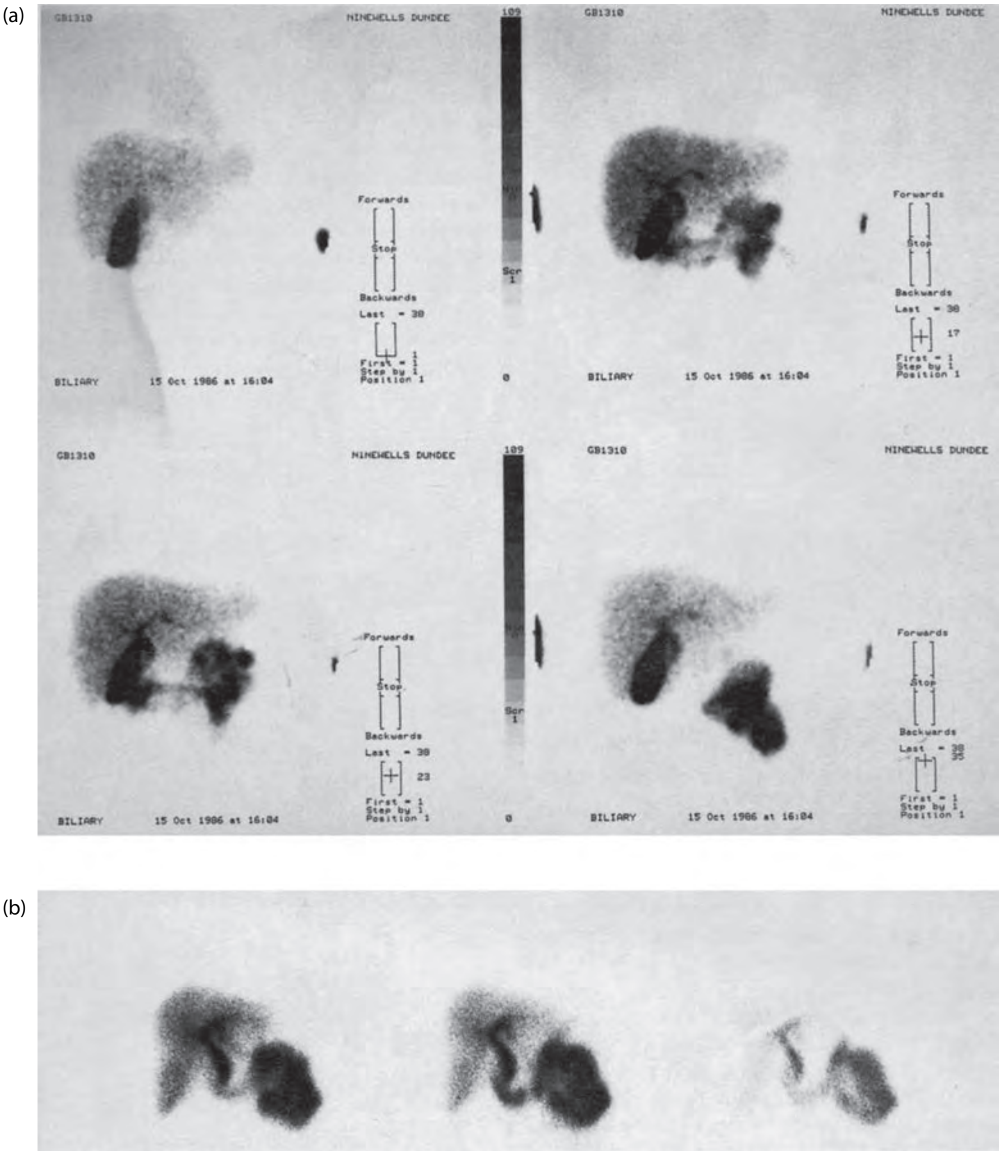

Figure 25.23 Biliary scintigraphy with EHIDA: (a) normal cholescintigram – both the gallbladder and the bile duct are imaged; (b) acute cholecystitis – a normal bile duct with prompt excretion into the duodenum is observed but the gallbladder is not outlined.

studies are used in some centres in the attempt to differentiate between transplant rejection and hepatocyte dysfunction. There are no definite contraindications to biliary scintigraphy.

Cholecystokinin and morphine provocation tests

These involve the use of CCK and/or morphine in combination with TBIDA scanning to improve diagnosis of diseases affecting the gallbladder, common bile duct or sphincter of Oddi. In the CCK test an intravenous infusion of CCK (which contracts the gallbladder) is given over 2–3 minutes and the gallbladder is scanned 30–45 minutes after TBIDA administration. The dynamic imaging is then continued for a further 30 minutes. The tests enable quantitative measurement of the gallbladder ejection fraction and emptying rate. The morphine test is indicated when despite clinical signs of cholecystitis the initial scintiscan is negative or equivocal. Morphine, which contracts the sphincter of Oddi, is administered intravenously (0.04 mg/kg over 1 minute) with scanning for a further 30–40 minutes. Continued non-visualization of the gallbladder for up to 90 minutes confirms the diagnosis of acute cholecystitis. Morphine provocation is also used in diagnosis of motility disorders of the sphincter of Oddi.

Intraoperative fluorocholangiography

Intraoperative fluorocholangiography (IOFC) is commonly performed via the cystic duct (transcystic) but other techniques (direct puncture of the common bile duct, cholecystocholangiography, intraoperative transhepatic cholangiography) are available and used in certain situations.

Transcystic duct fluorocholangiography

Although there are many who practice and advocate the selective use of IOFC during cholecystectomy, in the best

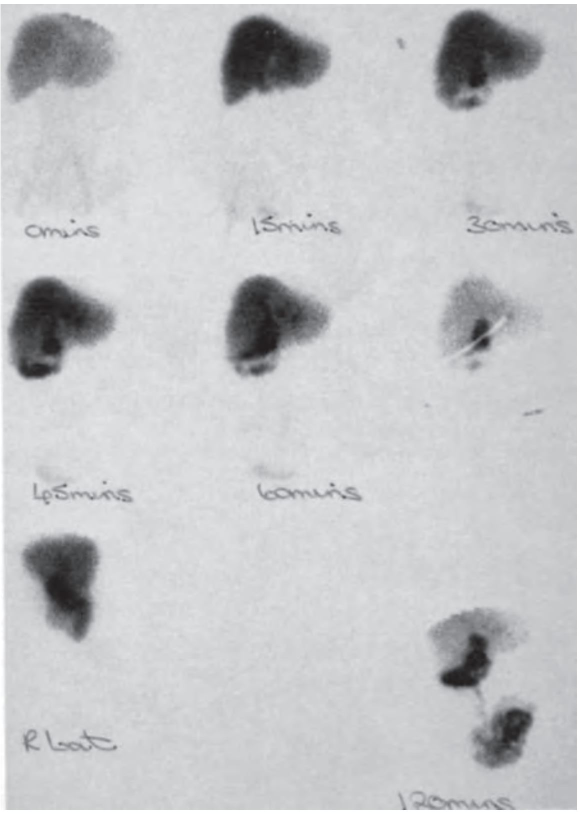

Figure 25.24 EHIDA scintigram showing a functioning hepaticojejunostomy performed for a high bile duct stricture.

interest of the patient this investigation must be regarded as an integral part of cholecystectomy whether this is performed by the open or laparoscopic approach. It provides the best road map of the biliary tree and indicates the need, or otherwise, for exploration of the common bile duct. Although it may not reduce the incidence of bile duct injury during LC, there is good evidence that routine IOFC results in the detection of bile duct damage during the operation. This is important, as the majority of reported bile duct injuries (60%) are missed and discovered in the postoperative period or subsequent to discharge. The arguments for a selective policy for IOFC include increased operating time, unsatisfactory exposures and the safe prediction of a ‘normal’ common bile duct in the absence of a history of jaundice, normal preoperative liver function tests (LFTs) and a normal-sized duct at operation. Intraoperative cholangiography incurs considerable delays and is often unsatisfactory only when performed by a mobile X-ray machine with three blind static films after the sequential injections of contrast medium. The modern procedure entails the employment of portable high-definition C-arm image intensifiers (Figure 25.25).

These have digital facilities and expanded software that enables image storage and advanced image processing: zoom facility, real-time subtraction, road mapping, etc. The entire biliary tree is visualized by screening (fluoroscopy) during injection of contrast medium in all patients inside 5 minutes. Desired images are selected as they appear on the screen and stored on hard disk from which permanent copies can be obtained on X-ray film cassettes.

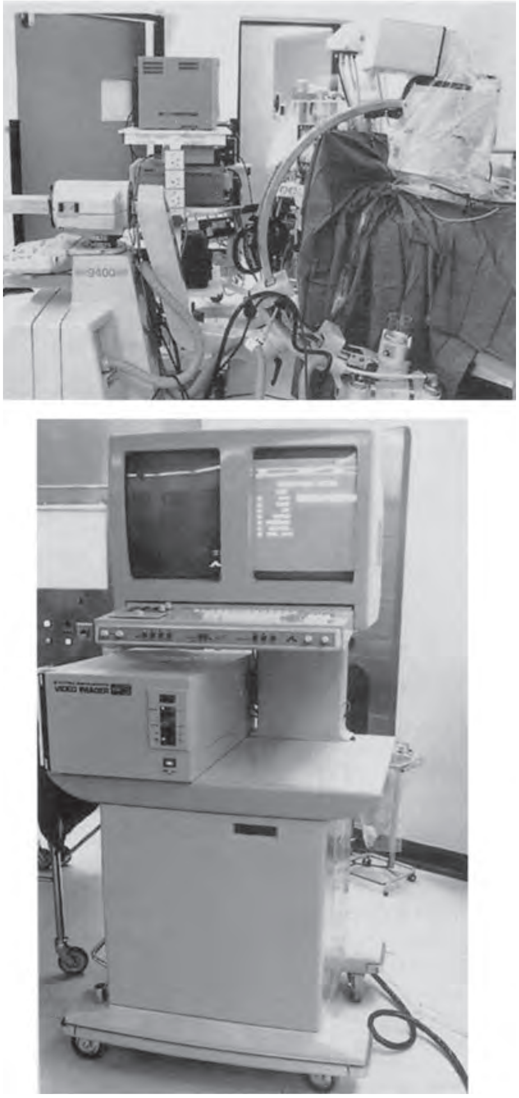

Figure 25.25 Modern C-arm fluoroscopy unit for intraoperative cholangiography.

Unsuspected stones (in patients with normal LFTs and ultrasound examination) are found by digitized fluorocholangiography in normal-sized ducts in 4–7% of patients undergoing cholecystectomy. These stones would all be missed if a selective policy for IOFC were adopted, and although some may pass spontaneously without any adverse effects others will cause acute pancreatitis or cholangitis. Thus the contention that missed stones during cholecystectomy do not matter as they can be treated by endoscopic sphincterotomy when they become symptomatic or cause complications incurs a small but definite morbidity. Anomalies of the biliary tract are encountered in some 19% of patients undergoing routine IOFC during cholecystectomy. Perhaps the most important of these is an abnormal short cystic duct which terminates in either the common hepatic or the right hepatic duct. This anomaly if detected will reduce the risk of bile duct damage, especially during LC where tenting of the extrahepatic conduit is produced as a result of the lateral and upward displacement of the gallbladder. If unrecognized, this will result in partial or total compromise of the common hepatic or common duct by the clip used to secure the medial end of the cystic duct. Finally, a selective policy for IOFC will not impart the experience needed to carry out the investigation expeditiously and the familiarity to interpret accurately the cholangiography findings.

During LC, the most commonly used technique involves cannulation of the cystic duct after this is opened by fine-curved microscissors. Although a variety of disposable purpose-designed catheter systems are available, the best and most cost-effective is the Cook ureter catheter (5 Fr) inserted inside a cholangiograsper (Figure 25.26). This instrument not only guides the catheter to the cystic duct lumen but its jaws allow the cystic duct walls to be grasped on the catheter once this is safely in the lumen of the cystic duct.

Before screening is commenced, the operating table should be tilted 15° to the right (to obviate an intervening spinal column) and in a slight Trendelenburg position to facilitate proximal filling of the ductal system. Nowadays, water-soluble contrast media, such as sodium diatrizoate (25–50%), are used. The volume required depends on dilatation or otherwise of the biliary tract. If during screening a hold-up is encountered at the lower end of the bile duct which does not appear to be organic, intravenous injection of secretin, ceruletide or glucagon is administered when pharmacological relief of spasm of the choledochal sphincter is followed by entry of dye into the duodenum. Contrast injection should be stopped when pancreatic duct filling is observed because of the risk of pancreatitis.

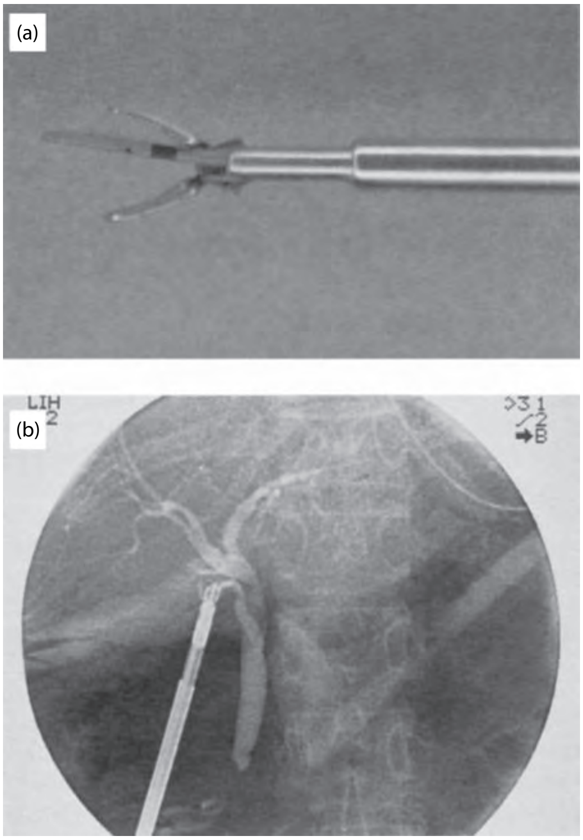

Figure 25.26 Laparoscopic transcystic cholangiography: (a) ureteric catheter inside a cholangiograsper is used for intraoperative transcystic cholangiography during laparoscopic cholecystectomy (LC); (b) intraoperative transcystic cholangiogram during LC using a 4 Fr ureteric catheter and cholangiograsper.

With experience, use of digitized fluoroscopic screening and meticulous technique, both false-negative and false-positive rates of IOFC are very low. Avoidance of metal clips, whenever possible, is desirable as they may obscure small filling defects. The most common artefact leading to unnecessary exploration of the common bile duct remains the air bubble. This can be prevented by ensuring that the delivery system is air free. If 'bubbles' are observed during screening, aspiration should be avoided as this introduces air into the bile duct from the duodenum. In this situation, the syringe should be disconnected from the cannula or catheter, the external end of which is held low, by the side of the drapings, such that the hydrostatic pressure of bile will cause retrograde flow along the cannula and the 'bubble shadow' disappears. Small blood clots, the tips of the transverse processes of the second lumbar vertebra, calcified costal cartilage and a contracted choledochal sphincter with its meniscus effect can also be misinterpreted as ductal calculi when the X-ray machine and static films are used. These sources of error are dismissed easily when fluoroscopic screening is used.

The important rules governing the performance and interpretation of IOFC are listed below.

- Rapid and overfilling of the ductal system must be avoided as, aside from obscuring small ductal calculi, the resulting raised pressure may cause cholangiovenous reflux.
- Unequivocal flow into the duodenum must be demonstrated in all cases.
- Both intra- and extrahepatic bile ducts must be visualized. Non-filling of the intrahepatic biliary tract, or part of it, is always pathological and cannot be ignored. Aside from technical errors, the most common cause for failure of proximal duct filling is a hilar CC. During LC, it may be indicative of common duct injury.
- Contrast injection is stopped with the onset of pancreatic duct filling.
- If doubt exists regarding the interpretation of any abnormalities, expert radiological advice should be sought (Figure 25.27). Ideally, a radiologist should see and comment on the films or the fluoroscopic examination (on hard disk or videotape) routinely.

A completion T-tube cholangiogram is performed after common bile duct exploration, although this is replaced by completion choledochoscopy in some centres. Before injecting contrast, the T-tube and the extrahepatic bile duct is filled with about 60 mL of saline to remove air bubbles. Spasm of the choledochal sphincter is common after biliary manipulations during common bile duct exploration (e.g. passage of balloon catheters). This may result in a hold-up of contrast in the lower end of the bile duct. It is easily differentiated from missed organic obstruction by the intravenous administration of spasmolytic agents such as glucagon or ceruletide (Figure 25.28).

Complications of IOFC are rarely encountered and are usually due to either hypersensitivity to the contrast material or an excessive injection pressure. The latter can result in cholangiovenous reflux and bacteraemia especially in patients with cholangitis.

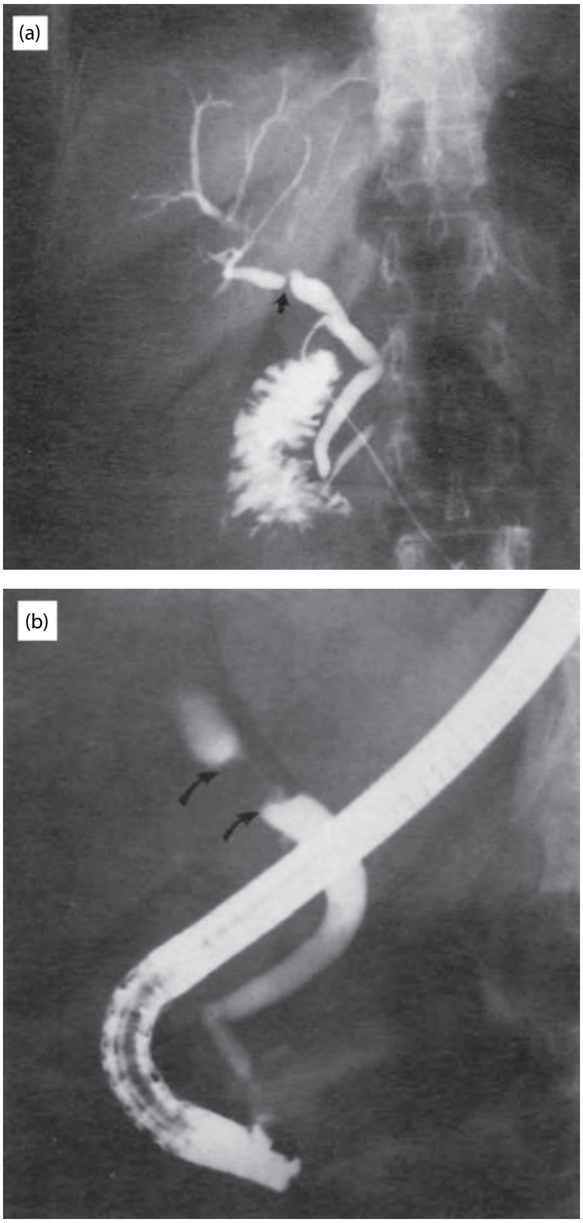

Figure 25.27 (a) Narrowing (arrowed) in the common hepatic duct was thought to be the result of an impression caused by the right hepatic artery. Aside from the obvious stricture, the left intrahepatic ductal system is not visualized. Regrettably, this was overlooked. (b) The patient was referred to the author's unit 3 months later with deep jaundice. The endoscopic retrograde cholangiopancreatography showed an undoubted large carcinoma of the common hepatic duct (outlined between arrows) which proved inoperable.

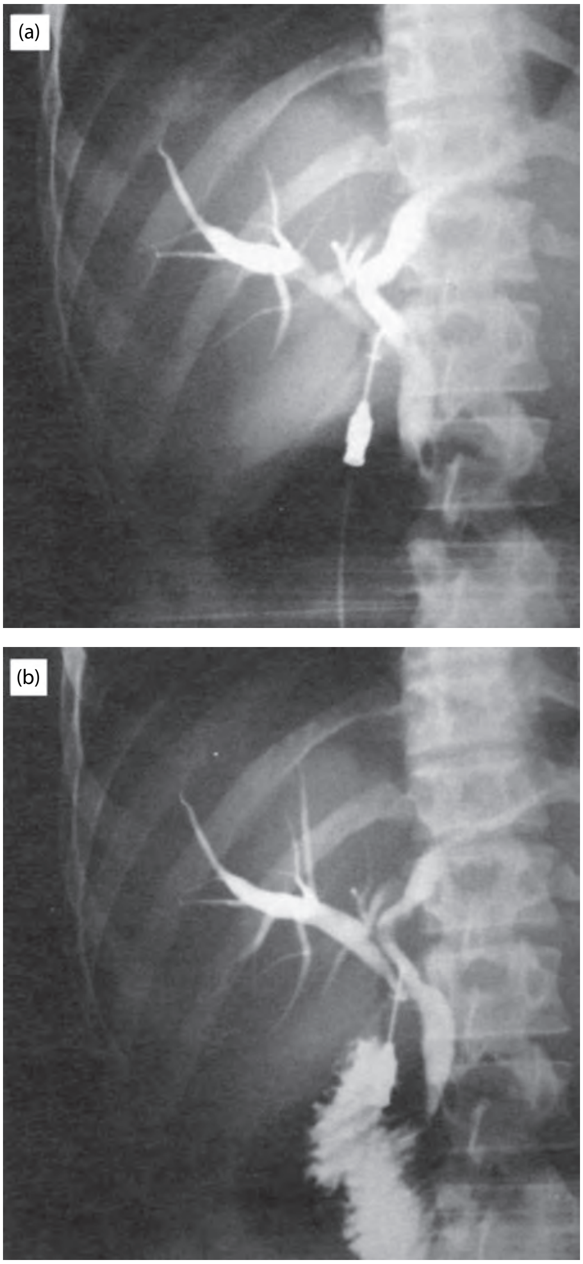

Figure 25.28 (a) Completion intraoperative cholangiogram – there is an apparent hold-up at the lower end which could be due to either spasm or a missed calculus; (b) repeat cholangiogram in the same patient after administration of 1.0 μg of ceruletide as an antispasmodic intravenously. There is now free flow of contrast medium into the duodenum. Alternatively glucagon may be used.

Other methods of intraoperative fluorocholangiograpy

Cholecystocholangiography

This is a simple technique that is primarily indicated when the surgeon is uncertain that the gallbladder needs removal but requires anatomical information of the extrahepatic biliary tract during the operation. Although it has been advocated as an easier alternative to transcystic fluorocholangiography during LC, this practice is ill advised, since forceful injection of large amounts of contrast in the gallbladder may dislodge small stones down a wide cystic duct into the common bile duct. During LC the technique is reserved for when dissection of the triangle of Calot proves difficult.

A cholecystocholangiogram is also indicated if a cholecystojejunostomy is being considered as a palliative procedure in patients with inoperable carcinoma of the pancreas/duodenum with severe obstructive jaundice and itch. The cholecystocholangiogram is performed to determine the patency of the cystic duct and the distance from its entry into the common bile duct and the upper limit of the tumour (Figure 25.29). Only if this distance is greater than 1.5 cm will cholecystojejunostomy suffice as an adequate palliation

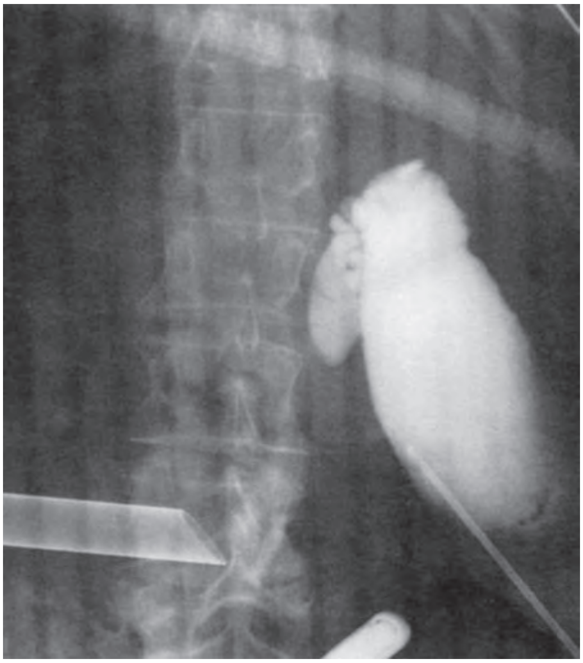

Figure 25.29 Laparoscopic cholecystocholangiogram in a patient with inoperable carcinoma of the pancreas. As the distance between the entry of the cystic duct into the bile duct is more than 1.5 cm from the upper limit of the tumour occlusion, a cholecystojejunostomy will provide adequate palliation of the jaundice and itching during the patient's lifetime.

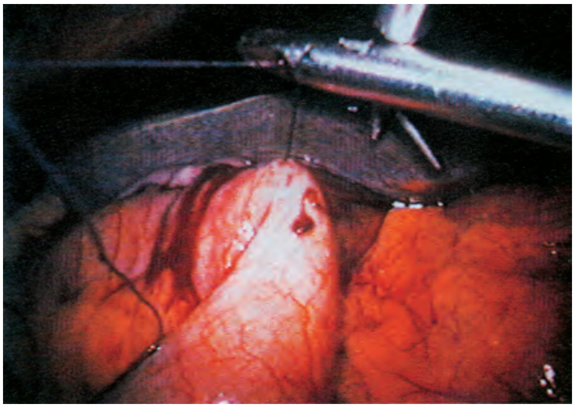

Figure 25.30 Laparoscopic palliative sutured cholecystojejunostomy.

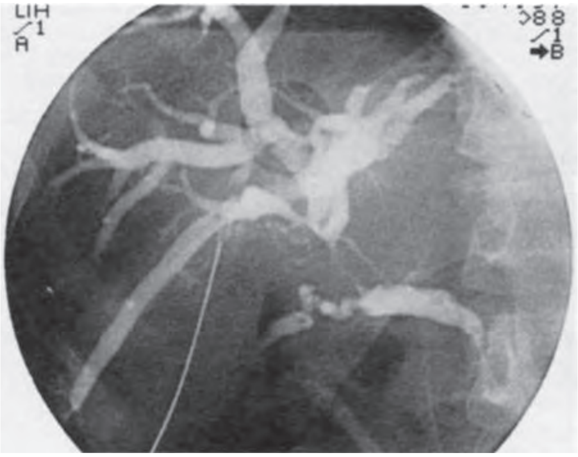

Figure 25.31 Laparoscopic transhepatic cholangiogram showing obstruction of the extrahepatic biliary tract by a large hilar tumour that appeared to originate from the gallbladder.

for jaundice and itching during the patient's lifetime (Figure 25.30). The method involves simple puncture of the gallbladder, using a sharp Veress needle attached by tubing to two 50 mL syringes (saline and diluted contrast). Usually some 40 mL has to be injected before contrast starts exiting the gallbladder into the biliary ducts. At the end of the procedure as much contrast is aspirated as is possible and the puncture site in the gallbladder is sutured with 3/0 absorbable material. However, a choledochoduodenostomy or choledochojejunostomy is preferable as either provide more effective palliative biliary drainage.

Direct puncture

In postcholecystectomy patients, IOFC may be carried out by direct puncture of the common bile duct using a fine intravenous cannula.

Transhepatic operative cholangiography

This is a valuable method that provides very useful information in patients with hilar tumours and during surgery for iatrogenic high bile duct injuries. A Chiba needle is used to puncture an intrahepatic bile duct under contact ultrasound control. When bile is aspirated, contrast is injected into the intrahepatic biliary tree. The technique can also be undertaken laparoscopically (Figure 25.31).

Choledochoscopy (cholangioscopy)

Operative choledochoscopy is well established in biliary tract surgery and is considered an integral part of common bile duct exploration. Two types of choledochoscopes are available: the flexible fibreoptic instrument and the rigid Berci–Shore choledochoscope, which incorporates the Hopkin's rod lens system (Figure 25.32). This is however largely of historical interest as it is more difficult to use and requires a choledochotomy. Furthermore, the rigid choledochoscope can only be used in open surgery. For these reasons it has been replaced by flexible choledochoscopy.

Flexible choledochoscopes

Flexible choledochoscopes do not require preliminary Kocherization of the duodenum for full inspection of the biliary tract and can be passed proximally to visualize the secondary and tertiary intrahepatic ducts. More importantly, they can be used in both open and laparoscopic biliary surgery. The standard choledochoscope has an external diameter of 4.0–4.5 mm and was designed for insertion into the common bile duct through a small choledochotomy (open or laparoscopic). The smaller ones (outer diameter of 2.8–3.0 mm) are referred to as mini-choledochoscopes and are used for transcystic duct extraction of ductal calculi during laparoscopic surgery. Often this entails prior dilatation of the cystic duct with a cylindrical balloon dilator. All mini-choledochoscopes used for laparoscopic extraction of ductal calculi through the cystic duct approach must have an instrument channel of 1.0 mm diameter or larger

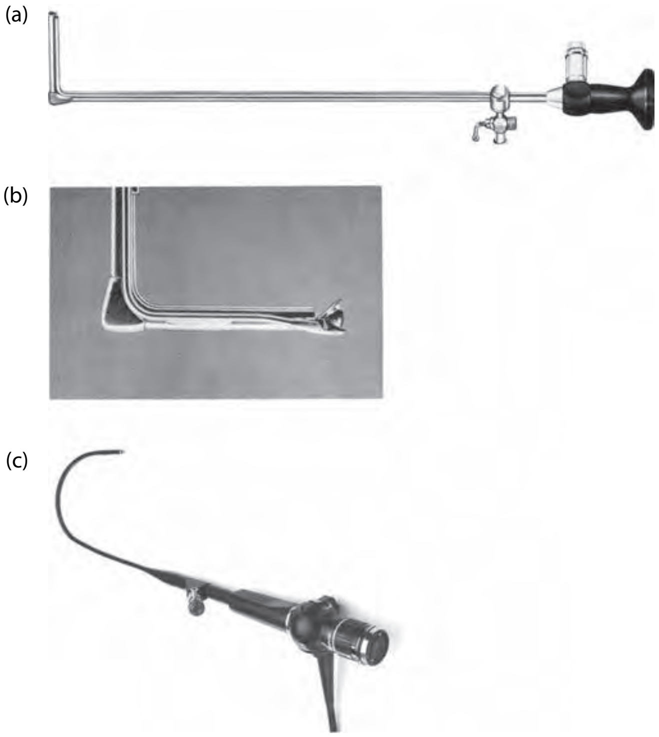

Figure 25.32 (a) The rigid choledochoscope (Berci–Shore). The main disadvantage of this rigid choledochoscope is that it requires a choledochotomy for its insertion and can only be used in open surgery. It has an attachable instrument channel through which biopsy forceps, biliary balloon catheters and Dorian baskets can be passed into the bile duct for visually guided procedures such as stone extraction and biopsy of lesions. (b) It has an attachable strong stone forceps which moves together with the instrument and is extremely useful for dealing with impacted stones at the lower end of the bile duct. The stone can be dislodged and retrieved or crushed under vision. (From Cuschieri and Berci, *Common Bile Duct Exploration*. Dordrecht, The Netherlands: Martinus Nijhoff, 1984, with permission.) (c) The Olympus flexible choledochoscope.

to enable insertion of small wire baskets (3 Fr) and balloon catheters and at the same time leave enough space for effective irrigation. During laparoscopic choledochoscopy, the endoscope is attached to a second charge-coupled device (CCD) camera and with a picture-in-picture display (if available) both the laparoscopic and the endoscopic image are seen on the one monitor. This dual imaging greatly facilitates manipulations, especially extraction of ductal calculi.

The advantages of choledochoscopy are:

- it provides the best evaluation of intracholedochal pathology
- it allows biopsy of suspicious lesions (Figure 25.33)
- it enables visually guided extraction of floating and impacted ductal calculi during both open and laparoscopic surgery
- the routine use of completion choledochoscopy results in an almost negligible incidence of retained ductal calculi
- it reduces the incidence of trauma, especially to the lower end of the bile duct caused by blind instrumentation with metal sounds and forceps
- the flexible endoscope provides an effective method of stone extraction of retained ductal calculi through the T-tube tract.

Biliary manometry

Biliary pressure studies can be undertaken intraoperatively or endoscopically during ERCP using a special perfusion catheter.

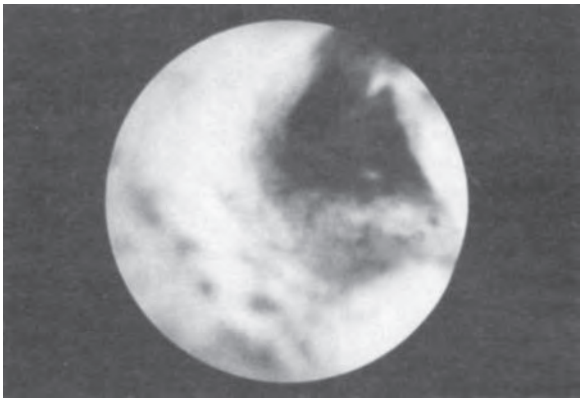

Figure 25.33 Choledochoscopic view of a stenosing lesion of the common hepatic duct. An endoscopic biopsy confirmed the presence of a cholangiocarcinoma.

Intraoperative biliary manometry

This can be performed by the use of a pressure transducer connected to the cannula, which is inserted into the common bile duct via the cystic duct. The transducer is attached to a channel recorder which gives an instant display of the biliary pressure. This technique is known as radiomanometry and permits the measurement of the basal (resting) pressure and the filling pressure during the constant infusion of saline (5.0 mL/min). In addition, it demonstrates the sphincteric contractions and may be used to document the effect of spasmolytic drugs on the choledochal sphincter in patients with biliary dyskinesia (Figure 25.34). Operative biliary manometry is, however, seldom used nowadays except for research purposes.

The other technique used during biliary tract surgery is known as manodebimetry. This measures the passage (yield) pressure at the choledochal sphincter and the flow rate through the common channel into the duodenum. The technique was first described by Caroli (Figure 25.35). The modern modification of the Caroli instrument is known as the Tondelli manodebitometer. After measurement of the passage pressure, the upper limit of which is 25 cm H_2O, the calibrated reservoir (filled with saline or contrast medium) is raised to a standard height of 30 cm above the level of the common bile duct and the flow rate through the common channel measured from the rate of emptying of the reservoir per unit time. The normal flow rate measured in this way should exceed 12.0 mL/mm. A high passage pressure and a diminished flow rate are indicative of obstructive disease.

Endoscopic biliary manometry

Endoscopic biliary manometry is now an established diagnostic procedure in specialized units. It is performed by the use of a special perfusion catheter attached to an external transducer and has been used in the investigation of patients with persistent symptoms and pain after cholecystectomy in an attempt to characterize abnormalities of the sphincter (stenosis, dyskinesia). The procedure measures the basal sphincter pressure, the rate and propagation of sphincteric contractions and the response to pharmacological agents such as morphine and CCK. In patients with dyskinesia, increased basal pressure, altered frequency and amplitude of phasic contractions, and reversal of the normal peristaltic direction (retrograde propulsion) have been reported.

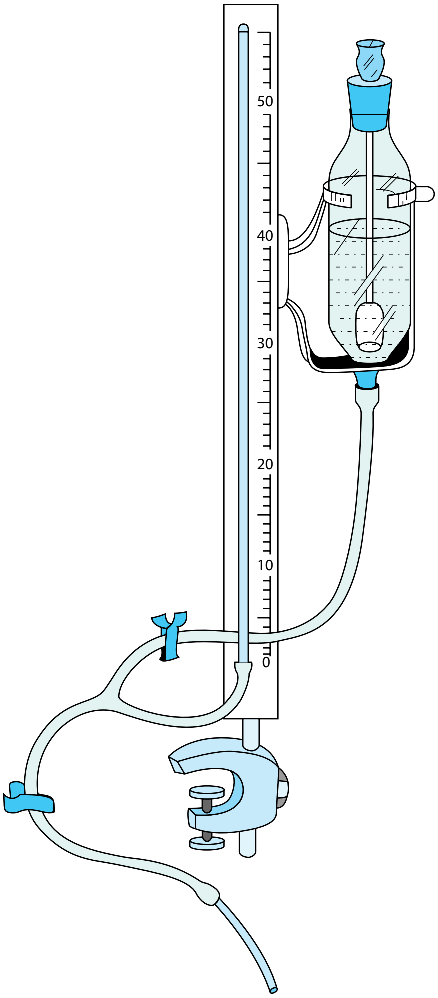

Figure 25.35 The Caroli instrument for manodebimetry. The technique measures the passage (yield) pressure of the choledochal sphincter and the flow rate through the common channel into the duodenum.

Laparoscopy

This procedure should be used routinely by surgeons in all patients with jaundice of malignant origin. It usually provides a direct visualization of the underlying pathology and the exact cause of the jaundice can be determined in all patients if ancillary techniques such as laparoscopic ultrasonography, cholangiography (transhepatic or transcholecystic) and targeted biopsy or cytology are employed. The liver, gallbladder, extrahepatic biliary tract and pancreas are directly visualized, as is the peritoneal lining and most of the intraperitoneal contents. Aside from detecting hepatic disease, primary neoplasms, secondary tumour deposits in the liver and peritoneal dissemination, all of which can be biopsied for histological confirmation, laparoscopy is invaluable in the staging of hepatobiliary and pancreatic tumours. Thus it avoids unnecessary laparotomy in patients with inoperable disease and can now be used to construct laparoscopic bilioenteric and gastrojejunal bypass procedures for advanced inoperable pancreatic cancer. In patients with chronic liver disease and a bleeding tendency, laparoscopic liver biopsy is undertaken in preference to the blind percutaneous procedure as bleeding from the biopsy site can be controlled by electrocoagulation.

Jaundice

Bilirubin is produced in the reticuloendothelial system from the enzymic breakdown of haem, which is derived from effete red blood corpuscles. As it is water insoluble, bilirubin is carried bound to albumin in the plasma and is taken up by the hepatocytes by means of specific membrane carriers. Within the hepatocytes, the bilirubin is stored bound to specific binding proteins (ligandins Y, Z) and then conjugated by a specific enzyme (glucuronyl transferase) to the water-soluble bilirubin glucuronide (conjugated bilirubin) that is then secreted by means of specific carriers into the bile canaliculi, and finally excreted into the biliary tract and intestine. Bacterial degradation of some of the excreted conjugated bilirubin in the distal small bowel results in the formation of urobilinogen, which is reabsorbed and subsequently excreted in the urine and bile. The normal upper limit of serum bilirubin is 17 µmol/L.

Jaundice (hyperbilirubinaemia) is a syndrome of varied aetiology which may be recognized clinically when the serum bilirubin exceeds 40 µmol/L. The hyperbilirubinaemia may be either conjugated or unconjugated and may result from:

- excess bilirubin production
- impaired uptake by the hepatocyte
- failure of conjugation
- impaired secretion of conjugated bilirubin into the bile canaliculi
- impairment of bile flow subsequent to the secretion by the hepatocytes – *cholestatic or obstructive jaundice.*

The defect may be congenital (benign congenital hyperbilirubinaemias) but much more commonly it is acquired as a result of haemolysis, liver disease, adverse drug reaction and biliary tract obstruction which may be intra- or extrahepatic. The early diagnosis and prompt treatment of patients with jaundice reduces both the morbidity and mortality of the underlying disease. In clinical practice, the largest groups by far are those with hepatocellular and cholestatic jaundice.

Hepatocellular jaundice

This is due to parenchymatous liver disease which may be acute (viral hepatitis, liver cell necrosis, acute alcoholic hepatitis, etc.) or chronic (chronic active hepatitis, the various types of cirrhosis, primary biliary, etc.). The principal defect is the failure of secretion of the conjugated bilirubin into the bile canaliculi. The serum transaminases are grossly elevated especially in acute disease. In patients with alcohol-related liver disease, the γ-glutamyl transpeptidase (γ-GT) is elevated as a result of microsomal induction rather than cholestasis. Acute hepatitis due to viral infection or drugs may also cause a cholestatic picture, in which case the alkaline phosphatase and 5-nucleotidase are elevated. The hyperbilirubinaemia is always (predominantly) of the conjugated variety with the presence of bilirubin in the urine even in the absence of a cholestatic component.

Cholestatic jaundice

This is the result of impaired bile flow to the duodenum subsequent to the secretion of conjugated bilirubin into the bile canaliculi. The block may be intrahepatic when it may be functional (e.g. drugs, hepatitis) or organic (obstruction of the intrahepatic biliary tree) or extrahepatic, also known as large bile duct obstruction which constitutes the most important surgical subgroup of cholestatic jaundice as it is always the result of organic disease, e.g. ductal calculi, pancreaticobiliary cancer, etc.

The biochemical features of cholestasis are:

- conjugated hyperbilirubinaemia
- elevation of alkaline phosphatase, 5'-nucleotidase and γ-GT; the enzyme 5'-nucleotidase is the most reliable since its level is not influenced by bone disease and the enzyme is not induced by alcohol
- minimal or no elevation of the serum transaminases
- presence of bilirubin in the urine as the conjugated bilirubin is water soluble and is therefore filtered in the glomerulus
- elevation in the serum cholesterol and bile acid levels although these are not routinely measured in patients with cholestatic jaundice.

It is important to stress that the above biochemical markers of cholestasis do not distinguish between intra- and extrahepatic obstruction.

Haemolytic jaundice

The unconjugated hyperbilirubinaemia results from excess haemolysis. Bilirubin is not present in the urine as the unconjugated pigment is water insoluble and is carried in the plasma bound to albumin. The excess bilirubin production is accompanied by an increased secretion of the conjugated pigment in the bile and therefore increased production of urobilinogen by bacterial decomposition in the distal small intestine. The urine, therefore, contains an excess amount of urobilinogen and urobilin. A cholestatic component may develop in patients with prolonged and recurrent haemolysis (e.g. congenital haemolytic anaemias).

In some patients excess bilirubin production is present in the absence of overt haemolysis. The excess unconjugated bilirubin is thought to result from breakdown of precursor/immature red cells in the bone marrow. This form of benign non-familial congenital hyperbilirubinaemia is referred to as *shunt hyperbilirubinaemia.*

Benign familial congenital hyperbilirubinaemias

This group includes Gilbert disease, Dubin–Johnson syndrome and the Rotor syndrome. All three conditions are congenital and familial. Gilbert disease is due to a defect in the uptake of bilirubin by the hepatocytes and results in mild unconjugated hyperbilirubinaemia. Both the Dubin–Johnson and Rotor syndromes are caused by a secretory defect of conjugated bilirubin by the hepatocytes into the bile canaliculi and therefore lead to a conjugated hyperbilirubinaemia. In addition, patients with the Dubin–Johnson syndrome are unable to excrete contrast medium into the biliary tree and, for this reason, the gallbladder is not visualized by oral cholecystography and intravenous cholangiography. Despite the accumulation of conjugated bilirubin in the blood and its appearance in the urine, there are no other biochemical markers of cholestasis in both conditions.

Management of patients with large bile duct obstruction

It is important to reiterate that a properly taken history and physical examination will allow a correct diagnosis to be made in some 80% of patients. Surgical obstructive jaundice (or large bile duct obstruction) is always accompanied by dilatation of the biliary tract. In essence, the management entails establishing the cause, the general condition of the patient and, in the case of tumours, the stage of the disease. Malignant large bile duct obstruction may be inoperable either because the lesion is not resectable or because the patient's ASA grade or POSSUM risk assessment score precludes major surgical intervention. In this situation management is directed towards palliation by endoscopic/radiological stenting or laparoscopic bypass procedures.

Dilatation of the biliary tract

The common bile duct dilates more rapidly than the intrahepatic biliary tree. Thus, instant passive dilatation of the common bile duct demonstrated fluoroscopically can be produced by excessive filling of the biliary tract by contrast medium. Dilatation of the intrahepatic biliary tree always signifies prolonged obstruction and, experimentally, it requires a minimum of 3 weeks of obstruction for the production of demonstrable intrahepatic duct dilatation. By convention, during surgery (as opposed to ultrasound examination; see section External abdominal ultrasonography) the diameter of the common bile duct is measured just above the junction of the cystic duct. A common bile duct whose diameter exceeds 10 mm after contrast injection (during cholangiography) is considered dilated. In the absence of contrast injection, e.g. ultrasound or MRCP, a diameter above 8 mm indicates dilatation.

Dilatation of the common bile duct signifies existing or recently relieved obstruction, the most common cause of which is calculous disease. There is an established positive correlation between the duct diameter and the incidence of ductal stones. On the other hand, stones may be present in a normal-sized common bile duct and in several reported series a 5–10% incidence of ductal stones has been reported in patients with common bile ducts of 5 mm. Other causes of duct dilatation include pancreaticobiliary cancer, chronic pancreatitis, congenital cystic disease and parasitic infestation. Controversy persists regarding dilatation of the bile duct after truncal vagotomy. Some studies have demonstrated abnormal gallbladder emptying after this procedure but not following highly selective vagotomy. The same controversy surrounds the view that the diameter of the common bile duct increases with age.

Although there are no intrahepatic communications between the right and the left intrahepatic ductal trees in the normal state, communications between the two systems develop following the onset of extrahepatic large bile duct obstruction.

Preoperative management of the patient with obstructive jaundice

Adequate timing of the surgical intervention and preparation of the patient for surgery are essential in the management of patients with obstructive lesions of the biliary tract. Undue delays exceeding 3–4 weeks increase both the morbidity and mortality rates following surgical intervention. Adequate preparation entails the correction of metabolic abnormalities, improvement of the general condition and the institution of specific measures designed to minimize the incidence of complications associated with prolonged or severe cholestasis. These include:

- infections: cholangitis, septicaemia, wound infections
- disorders of the clotting mechanism
- renal failure
- liver failure
- fluid and electrolyte abnormalities.

Furthermore, the conjugation and metabolism of drugs and anaesthetic agents is impaired because of the hepatocyte malfunction. Contrary to popular belief, there is no evidence to support the view that wound healing is impaired in the presence of jaundice. Wound-healing problems are largely confined to patients with malignant obstruction and are the result of the underlying disease and its association with a poor nutritional state. The nutritional deficits of these patients vary with the underlying pathology, age and social class of the patient. In general, parenteral nutrition should be used selectively, and only in those patients who are grossly malnourished, because of infective risks. A high intake of carbohydrates is essential and amino acid solutions containing aromatic amino acids (phenylalanine, tyrosine and tryptophan) should be used sparingly as these may precipitate encephalopathy in susceptible patients. An oral diet is the safest and should be used whenever possible. It may be supplemented by elemental diets in nutritionally compromised patients. Enteral nutrition is considered essential for the maintenance of the mucosal integrity of the gut against bacterial translocation. Some advocate the oral administration of bile salts or lactulose to reduce the intestinal absorption of endotoxin from the intestinal microflora and thus minimize the incidence of renal failure following surgical intervention.

Hypokalaemia is frequently present and should be corrected. In general, intravenous isotonic saline administration should be restricted in the jaundiced patients and those with liver disease as the total exchangeable body sodium is elevated. The low normal values of the concentration of the serum sodium frequently encountered in these patients are due to expansion of the intra- and extravascular fluid compartments consequent on the excessive retention of water (dilutional hyponatraemia). A viral screen is necessary in these patients and, when the serology is positive, special precautions must be taken both in the ward and in the operating theatre to avoid spread of the infection to the attending medical staff.

Prevention of infective complications

Whereas the normal biliary tract and bile in humans is sterile, bacteria are frequently present in biliary tract disorders and may lead to septic complications, particularly cholangitis and septicaemia. Infection of the biliary tract is much more commonly present in ductal calculous disease than in patients with malignant obstructive jaundice. Anaerobes are less frequently found in the biliary tract and duodenum than aerobic bacteria even in the presence of pathological states. Thus, in the absence of stenting, the majority of infections associated with biliary tract disorders are aerobic in origin and most commonly due to Gram-negative bacilli. Endoscopic stenting of patients with malignant large bile duct obstruction results in infection of the biliary tract and is unwise if the patient is deemed operable.

A number of clinical trials have shown that the postoperative sepsis in patients having biliary tract surgery is generally due to bacteria in the bile and the use of short-term prophylactic antibiotics (three-dose regimen perioperatively: immediately before surgery to 24 hours later) significantly lowers the incidence of sepsis only in patients who have bacteria in the bile at the time of surgery. Prophylactic antibiotics are therefore not advised in all patients undergoing surgery on the biliary tract but should be administered to those patients who are likely to have bacteria in the bile. The higher risk groups have been identified and include:

- all jaundiced patients
- patients with rigors and pyrexia
- patients undergoing emergency biliary procedures/operations
- elderly patients
- patients with common duct stones even if not jaundiced
- patients undergoing secondary biliary intervention.

Some advocate the use of Gram's staining of the bile at the time of surgery to determine both the presence and the Gram-staining characteristics of the organisms in deciding on the appropriate antibiotic. The use of prophylactic antibiotic therapy with a cephalosporin, or aminoglycoside or pipericillin (three doses) in the high-risk groups outlined above has been shown to reduce the incidence of postoperative wound infection, cholangitis and septicaemia.

Bacterial proliferation in the bile following exploration of the common bile duct and insertion of a T-tube is extremely common and may become a source of infection or lead to the formation of calcium bilirubinate stones as a result of the deconjugation of the bilirubin glucuronide by glucuronidase-producing bacteria, particularly *Escherichia coli*. Thus, a closed system of T-tube drainage should always be used and a bile culture performed a few days before the removal of the T-tube. A course of the appropriate antibiotic should be administered if the culture is positive.

Correction of disorders of coagulation

The most common disorder of coagulation encountered in patients with large bile duct obstruction is a prolonged prothrombin time resulting from a deficiency of vitamin K-dependent factors consequent on the malabsorption of this vitamin which occurs in cholestatic jaundice. The intramuscular injection of phytomenadione (10–20 mg) will reverse the multifactorial clotting deficiency within 1–3 days. Severe hepatic disease, usually with a poor prognosis, is present if the prothrombin time remains abnormally prolonged despite this treatment. If these patients require surgical intervention, administration of fresh frozen plasma is necessary to cover the perioperative period.

A more serious bleeding disorder may arise usually in the severely jaundiced patient who may develop a consumptive coagulopathy from a disseminated intravascular coagulation due to the presence of circulating endotoxin. This serious haematological complication requires careful monitoring of fibrinogen levels, fibrinogen degradation products and platelet counts. It may improve with control of the infection but often requires specific treatment with fresh frozen plasma alone or in combination with heparin.

Prevention of renal failure

The association between postoperative renal failure and severe conjugated hyperbilirubinaemia is well known but the underlying mechanism of the renal impairment is inadequately understood, although a reduced glomerular filtration is usually present. Even in the absence of infection, endotoxinaemia is frequently present in jaundiced patients when it results from absorption of endotoxin produced by the intestinal microflora. There appears to be a relationship between impaired renal function and the presence of circulating endotoxin in jaundiced patients. Irrespective of the exact cause of the renal damage, there is now good evidence that adequate hydration and preoperative induction of a natriuresis/diuresis reduces the incidence of renal failure after surgical intervention in jaundiced patients. It is current routine practice to administer intravenous fluids (5% dextrose saline) for 12–24 hours before surgery. This is followed by an osmotic diuretic (mannitol) or a loop diuretic (frusemide) administered intravenously at the time of induction of anaesthesia. All patients undergoing surgery should be catheterized and the urine output measured hourly. Further administration of diuretics (mannitol or frusemide) is indicated if the urine output falls consistently below 40 mL/h (despite adequate hydration and normovolaemia) during operation and subsequently thereafter.

Preoperative administration of oral chenodeoxycholate commencing a few days before surgery is practised in some centres and one clinical trial has shown a reduction in the incidence of renal failure, although a second trial with the epimer ursodeoxycholate did not report any benefit.

Also, the administration of oral lactulose has been shown to reduce the incidence of renal failure in jaundiced patients undergoing surgical treatment but this requires confirmation.

Prevention of hepatic encephalopathy

Liver failure is usually encountered in patients with prolonged complete large bile duct obstruction or those patients with pre-existing chronic hepatocellular disease, such as cirrhosis, chronic active hepatitis, etc., who undergo surgery. If the jaundice is severe (above 150 μmol/L) or the patient shows signs of impending liver failure, a period of decompression is indicated. This is nowadays achieved by insertion of a plastic endoprosthesis for patients with malignant obstruction. Alternatively an endoscopic sphincterotomy is performed in patients with periampullary cancer. External percutaneous decompression via a transhepatic tube draining into an external collecting system is no longer advocated since it predisposes to infection and leads to a loss of bile acids unless the bile is returned to the gastrointestinal tube via a nasogastric tube. The correction of hypokalaemia, the restricted use of sedatives, hypnotics and potent analgesics, and the prompt treatment of infection cannot be overemphasized. If sedation is required, small doses of promethazine or chlorpromazine can be administered.

Postoperative jaundice

Jaundice occurring for the first time in the postoperative period may be due to a variety of causes:

- benign reactive hepatitis – self-limiting
- sepsis – leaking anastomosis, abscess formation, septicaemia, pneumonia, etc.
- pre-existing primary disease – known or suspected liver disease
- major hepatic resections
- drug-induced liver disease
- biliary pathology – residual stones, bile duct trauma and missed tumours/ pathology of the biliary tract
- massive blood transfusion – each unit of blood provides a bilirubin load transfusion of 250 mg/100 mL when fresh
- haemolysis – unconjugated hyperbilirubinaemia, positive Coombs' test
- residual haematomas – unconjugated hyperbilirubinaemia.

It always requires detailed investigation to establish the cause and outline the necessary course of action. Mild self-limiting conjugated hyperbilirubinaemia, sometimes referred to as benign postoperative cholestasis, may follow prolonged operations and fever caused by chest infections. It is caused by a reactive hepatitis, which is probably multifactorial in origin, resulting from a combination of reduced liver blood flow, hypoxia, hypercarbia, breakdown of transfused cells and temporary hepatocellular dysfunction. Initially, it warrants observation with repeated assessment of the patient's condition and sequential biochemical profiles, as the majority of cases with this syndrome subside within 3–4 weeks.

Marked cholestatic jaundice develops after extensive hepatic resection, especially right hepatectomy and extended right hepatectomy. The serum bilirubin rises over a period of several days to reach a plateau at 7–10 days, after which it should start to decline. In view of the extensive hepatic resection (low residual liver parenchyma), the rise in the serum alkaline phosphatase is small.

Severe or progressive jaundice in the postoperative period is always sinister and usually indicates a primary biliary tract problem, or significant liver disease or severe sepsis such as that resulting from an anastomotic dehiscence. Aside from the usual liver function tests, the following may be required:

- blood culture
- ultrasound/CT scanning for the detection of collections/bilomas/ abscesses
- biliary scintiscanning
- MRCP
- contrast radiological examination of recently constructed gastro-intestinal anastomoses
- liver biopsy if the above are negative or if hepatocellular disease or drug-induced jaundice is suspected.

Hepatitis B is rare nowadays because of better screening for the viral antigens and improved blood donor selection. Most instances of infection caused by blood and blood products are due to hepatitis C virus and other non-A, non-B viruses. Drug-induced jaundice is common in hospital practice. Some of the important drugs which may give rise to this adverse reaction are listed in Table 25.1.

Severe hepatotoxicity can follow halothane anaesthesia. In the majority of patients (over 80%), this follows repeated exposure usually within 28 days (75%). The disease is usually severe and is accompanied by an overall mortality of 40%. The following recommendations have been issued by the Committee on the Safety of Medicines.

- A careful history to determine previous exposure and reactions to halothane should be obtained from every patient.
- Repeated exposure to halothane within a period of at least 3 months should be avoided if at all possible.
- A history of unexplained jaundice or pyrexia following exposure to halothane is an absolute contraindication to further use of halothane in that individual patient.

Clinical management of postoperative jaundice

In the first instance, a full examination of the patient and a careful reappraisal of the preoperative liver function tests are carried out. If liver function was normal prior to operation, the following are performed in a sequential order.

- *Determination of the nature of the jaundice by the liver function tests and urine testing for bilirubin* – postoperative unconjugated hyperbilirubinaemia is commonly due to large/massive transfusion. Each unit of blood provides a bilirubin load of 250 mg/100 mL of fresh blood. Unconjugated hyperbilirubinaemia may also result from resorption of residual haematoma/haemoperitoneum or haemolysis. Haemolytic reactions resulting from minor/major incompatibilities are accompanied by systemic signs. When suspected, screening tests for haemolysis should be performed.

Table 25.1 Drug-induced liver damage

Category	Example	Hepatic lesion
Antibiotics	Tetracyclines, especially i.v. – dose related Penicillins – hypersensitivity Chloramphenicol Sulphonamides – hypersensitivity	Fatty infiltration Hepatitis Hepatitis Granulomas, focal hepatocellular necrosis
Analgesics and anti-inflammatory drugs	Paracetamol – dose dependent Phenylbutazone – hypersensitivity Carbamazepine Salicylates – dose related	Centrilobular necrosis, massive liver necrosis Hepatitis with granuloma may progress to cirrhosis Cholestasis Focal hepatic necrosis
Psychotropic drugs	Monoamine oxidase inhibitors Phenothiazines – hypersensitivity Tricyclic antidepressants	Hepatitis, may progress to massive hepatic necrosis Hepatitis and cholestasis Cholestatic hepatitis, more usually mild elevation of transaminases
Steroids	Testosterone and anabolic steroids Oestrogens	Cholestasis, peliosis hepatis, hepatic tumours Cholestasis, gallstones, hepatic tumours
Anaesthetic agents	Halothane	Hepatitis which may progress to massive liver necrosis
Antituberculous drugs	PAS – hypersensitivity INAH – related to acetylator status Rifampicin – dose related	Hepatitis Focal to severe hepatic necrosis Defective bilirubin transport, mild hepatitis
Cytotoxic and immunosuppressive drugs	Azathioprine 6-Mercaptopurine – dose related Methotrexate – long-term therapy	Cholestasis and peliosis hepatis Hepatitis Fatty change, fibrosis of the portal tracts and cirrhosis
Others	Benzothiazine diuretics Phenindione Chlorpropamide Phenytoin	Cholestatic hepatitis Cholestatic hepatitis Cholestatic hepatitis Hepatocellular necrosis

i.v., intravenous; INAH; isoniazid; PAS, 4-aminosalicylic acid.

- *If the jaundice is cholestatic*, an assessment of all the drugs and anaesthetic agents used is followed by the withdrawal of any drug known to cause hepatotoxicity. A thorough search for sepsis by the appropriate tests (including blood cultures) is made and an ultrasound/CT examination carried out. External leakage of bile or evidence of anastomotic dehiscence in a jaundiced patient is always serious and establishes the cause. Cholestatic jaundice accompanied by sepsis and abdominal signs is always indicative of a major surgical complication, e.g. bile duct injury, cholangitis or anastomotic dehiscence, and requires urgent radiological investigation. In the absence of sepsis and if the MRCP confirms integrity of the biliary tract, the liver function tests are repeated daily to determine the course of the biochemical profile. If the cholestasis is seen to be resolving, an expectant policy is adopted, otherwise a liver biopsy is undertaken.

Jaundice in infancy and childhood

Apart from the physiological jaundice, the aetiology of hyperbilirubinaemia in infancy may be due to haematological disorders, enzymatic defects, inborn errors of metabolism, infections and obstructive disease. The causes of jaundice in infancy and childhood are:

- physiological jaundice
- haematological disorders – inspissated bile plug
- enzymatic defects
- inborn errors of metabolism
- hepatitis and other infections
- BA
- biliary hypoplasia
- cystic disease of the bile ducts
- congenital perforation of the common bile duct.

Whereas unconjugated hyperbilirubinaemia may be physiological, all causes of conjugated hyperbilirubinaemia are abnormal. Inflammatory disease of the gallbladder and cholelithiasis are rare but do occur, including acalculous cholecystitis. A higher percentage of gallstones in the paediatric age group are associated with haemolytic disorders than in the adult population. An increased incidence of gallstones is also found in patients with cystic fibrosis. Children with gallstones present with an atypical history of vague abdominal pain and distress. Classical biliary colic is rare. An ultrasound examination of the gallbladder should be performed in all children undergoing splenectomy for haemolytic anaemia.

Biliary atresia

BA (also known as progressive obliterative cholangiopathy) is a disease of neonates/infants which is characterized by obliteration of the extrahepatic biliary system, resulting in large bile duct obstruction. It is the most common surgically treatable cause of cholestasis in the newborn. Untreated, BA leads invariably to secondary biliary cirrhosis within 2–3 months of onset, which indicates the importance of early diagnosis and decompression of the obstructed biliary tract.

Patients with BA fall into two groups: (1) those with isolated BA (postnatal form accounting for 65–90% of cases) and

(2) infants with associated situs inversus or polysplenia/asplenia with or without other congenital anomalies (fetal/embryonic form) comprising the rest (10–35%). In terms of the pathological anatomy three types are distinguished:

- type I in which the common bile duct is obliterated but the proximal ducts are patent
- type II in which the atresia affects the hepatic duct with cystic structures being found in the porta hepatis
- type III (the commonest, 90% of patients) in which there is atresia of the right and left hepatic ducts up to the level of the porta hepatis.

Pathology

The pathogenesis of BA remains unknown. There is no evidence to support the view that BA is a congenital malformation of the biliary ductal system. The current opinion on its aetiology favours an acquired origin although no single factor has been identified. Infectious agents are regarded as the most plausible candidates and some studies have identified elevated antibody titres to reovirus type 3 in patients with BA when compared with controls. Other viruses have been implicated including rotavirus and cytomegalovirus. Although BA was initially considered as a cholangiopathy induced by disordered bile acid metabolism, there is no evidence for this, but retained bile acids are thought to be important in the progressive damage to the intrahepatic ducts.

In type III atresia (the most prevalent), a fibrous remnant indicates complete obliteration of a segment of the extrahepatic biliary system. The intrahepatic ducts extending to the porta hepatis are initially patent during the first few weeks, but are progressively destroyed presumably by the same agent acting together with retained toxins in bile and other contributing factors. The destruction is thought to result from the release by the biliary epithelial cells of various cytokines, e.g. CCL-2, MPC-1, tumour necrosis factor, interleukin-6, transforming growth factor-β, endothelin and nitric oxide. This cytokine cascade is held to be the ultimate cause of the progressive fibrosis leading to secondary biliary cirrhosis with the development of portal hypertension, oesophageal varices (which may bleed) and hypersplenism.

Clinical features

Although BA occurs in the West with an overall incidence in the USA of 1 per 10 000–15 000 live births, the incidence of the disease is highest in Asian populations, especially Chinese and to a lesser extent Japanese infants. Additionally the disorder is twice as common in black than white infants. BA is also commoner in female infants. The fetal/perinatal form is evident within the first 2 weeks of life, whereas the postnatal type presents in infants aged 2–8 weeks.

A high index of suspicion is key to making an early diagnosis which is essential for the prevention of irreversible biliary cirrhosis. The diagnostic protocol carried out in these infants is designed to differentiate, in the first instance, neonatal hepatitis from BA and the standard work-up, apart from liver function tests, includes screening for infectious, genetic and enzymatic disorders. Studies required include the biliary scintiscanning (no bile passage into the duodenum over 3–4 days in BA as assessed by faecal radioactivity), liver biopsy and serial total and conjugated bilirubin levels. A rising or flat bilirubin curve over several weeks is found in atresia, whereas in neonatal hepatitis there is a gradual fall in the serum bilirubin after an initial peak.

The clinical features include variable degrees of jaundice, dark urine and pale stools. Most affected infants are full term. This is important as it is in contrast to infants with idiopathic neonatal hepatitis, who are often premature or small for gestational age or both, although a higher incidence of low birthweight has been reported in some BA neonates. Appetite, growth and weight gain may be initially normal during the first few weeks of life. Hepatomegaly may be present early, and the liver is firm on palpation. Splenomegaly is common, and an enlarging spleen suggests progressive cirrhosis with portal hypertension. In infants with the fetal/neonatal form, the liver is palpated in the epigastrium and cardiac murmurs indicative of associated cardiac anomalies may be present. BA is characterized by conjugated hyperbilirubinaemia (defined as any level exceeding either 2 mg/dL or 20% of total bilirubin). Infants with BA typically show only moderate elevations in total bilirubin (commonly 6–12 mg/dL), with the conjugated fraction accounting for 50–60% of total serum bilirubin. Alkaline phosphatase, 5'-nucleotidase, γ-GT and serum bile acids are elevated. Aminotransferase levels are not particularly helpful in establishing a diagnosis, although a markedly elevated alanine aminotransferase level (>800 IU/L) indicates significant hepatocellular injury and is more consistent with the neonatal hepatitis.

Ultrasonography is used to exclude specific anomalies of the extrahepatic biliary system, e.g. choledochal cysts. Although, in BA, ultrasonography may demonstrate absence of the gallbladder and no dilatation of the biliary tree, its sensitivity and specificity for the diagnosis of BA is low and thus this imaging is not very useful. In contrast, hepatobiliary scintiscanning is very useful in evaluating infants with suspected BA as it provides unequivocal evidence of either patency with intestinal excretion of radiolabel (excluding BA) or obstruction of the extrahepatic biliary system, confirming the diagnosis. However, the reliability of the scintiscan is diminished in patients with very high conjugated bilirubin levels (>20 mg/dL). Additionally, the test has a 10% false-positive or false-negative rate. Percutaneous liver biopsy provides valuable information. When examined by an experienced specialist pathologist, it can differentiate between obstructive and hepatocellular causes of cholestasis, with 90% sensitivity and specificity for BA.

The important differential diagnosis is between BA and neonatal hepatitis and *Alagille syndrome*. The latter is an autosomal dominant disorder (OMIM 118450) associated with abnormalities of the liver, heart, skeleton, eye and kidneys and a characteristic facial appearance. The abnormality of the liver consists of hypoplasia of the hepatic ducts which is not surgically correctable.

Treatment

The treatment of BA is surgical and must be carried out within 60 days of birth, otherwise the prognosis is poor from irreversible cirrhosis. At operation a cholecystocholangiogram (if the gallbladder is present) and a wedge liver biopsy are performed.

If an extrahepatic stump of the common hepatic duct is present, a Roux-en-Y jejunal anastomosis is carried out. Hepatic portoenterostomy (the Kasai procedure) is performed if no extrahepatic ducts are discernible. The procedure consists of the progressive excision of fibrosed remnants of the ducts anterior to the portal vein at the porta hepatis together with a 1 cm ring of adjacent liver substance, advancing to some 2–3 cm in depth using the operating microscope until biliary structures are identified: bile ducts, collecting tubules of biliary glands or biliary glands. The excised scar tissue is subjected to histological examination to identify these structures. A modified Roux-en-Y anastomosis (Suruga II procedure) is then performed at the periphery of the saucerized area surrounding the bile ductules (Figure 25.36). This has an access jejunostomy placed subcutaneously which allows irrigation, evaluation of postoperative bile flow and, if necessary, introduction of a paediatric flexible endoscope to inspect the porta hepatis.

In an effort at reducing postoperative cholangitis due to reflux of intestinal contents, various valve constructions have been advocated between the portoenterostomy and the enteroenteric anastomosis. Some favour an isoperistaltic jejunal loop with a nipple valve interposed between the porta hepatis and the duodenum instead of the Roux-en-Y reconstruction. An 80% successful outcome is obtained in infants in whom bile ducts communicating with the intrahepatic system have been identified at operation provided this is performed within 60 days of birth. These infants require vitamin E supplements to minimize the development of neurological sequelae. Overall, some 25% of these children develop cirrhosis and portal hypertension. Hepatic transplantation is now accepted as the treatment of choice in infants and children with BA in whom a portoenterostomy has failed and who develop cirrhosis. Recently the argument has been made for proceeding to primary liver transplantation instead of a portoenterostomy on the grounds that the majority of infants treated by the latter procedure develop biliary cirrhosis and portal hypertension with bleeding particularly when a cutaneous stoma leading from the portoenterostomy loop is employed. While primary hepatic transplantation may be appropriate in a small subset with adverse scoring system based on multiple liver function tests, for the majority of infants this policy is generally considered to be inappropriate. The Kasai operation works best at an age less than 6–8 weeks (when the results of hepatic transplantation are not optimal) and imparts long-term control in 30% of patients. Transplantation success improves considerably when the operation is performed after the age of 12 months. Thus a portoenterostomy buys time, allows patient growth, enhances the donor pool available to the patient and increases the chance of successful transplantation. In a large reported experience based on this policy, the 1 year transplant survival rate was 87%. Poor results were encountered only in patients in whom a portoenterostomy had been revised prior to transplantation. Thus a non-functioning portoenterostomy is an indication for hepatic transplantation and attempts at revision are unwarranted. The problem with transplantation in children relates to the scarcity of appropriate-size livers (which can be housed in the small subdiaphragmatic space), since the vast majority of donors are adults. The size disparity has however been largely resolved by recourse to split liver or segmental hepatic transplantation from either brain-dead donors or living related donors. Corticosteroid treatment after a Kasai operation, with or without choleretics and antibiotics, has a beneficial effect on the postoperative bile flow and can clear the jaundice; but there is some debate on dosing and duration of the ideal steroid therapy (high-dose vs low-dose therapy). Prior to hepatic transplantation the only surgical therapeutic option was portoenterostomy when the long-term survival rate for infants with BA was 47–60% at 5 years and 25–35% at 10 years with inevitable death from end-stage biliary cirrhosis and its complications. Hepatic transplantation is the only option for long-term survival in most patients.

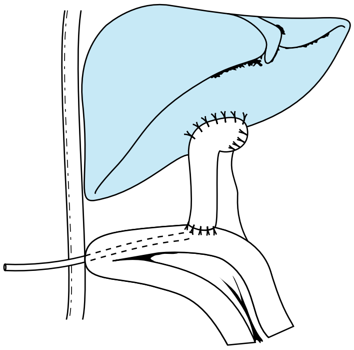

Figure 25.36 The Suruga II procedure of intubated access jejunostomy in patients with biliary atresia.

Biliary hypoplasia

Biliary hypoplasia is not a distinct entity but includes various neonatal disorders which simulate atresia but in whom the expected course of progressive jaundice with the development of biliary cirrhosis does not occur. Indeed in some infants, the jaundice subsides. The conditions include the inspissated bile plug syndrome, partial atresia and infants with small intra- and extrahepatic ducts (true biliary hypoplasia). Some are secondary to another primary disorder, e.g. choledochal cyst, neonatal hepatitis and α_1-antitrypsin deficiency. Early surgical treatment, when indicated, is designed to correct the primary abnormality. The inspissated bile plug syndrome is usually secondary to haemolytic disorders. The diagnosis is made by operative cholangiography and treatment, which is curative, consists of irrigation of the extrahepatic ducts.

Spontaneous perforation of the bile duct

The perforation which occurs at the junction of the cystic with the common duct leads to the formation of a pseudocyst. Surgical treatment consists of transperitoneal drainage, which is usually followed by spontaneous closure of the perforation. Spontaneous perforation of the bile duct (SPBD) is a rare condition affecting infants and children. Most perforations occur close to the junction of the cystic duct and in some patients it leads to the formation of a pseudocyst, whereas in others it causes biliary ascites. SPBD is not considered to have a viral origin but its aetiology is otherwise unknown, although several theories have been proposed:

- congenital mural weakness of the common bile duct
- ischaemia
- distal biliary obstruction
- pancreaticobiliary malunion (PBM).

In some infants there is some evidence to suggest that SPBD and choledochal cysts are related entities with a common pathogenesis to PBM, as intrinsic bile duct weakness and distal bile duct obstruction may be implicated in both conditions. Obstruction distal to the perforation may occur in cases with ductal stones and actual stenosis. However, distal obstruction is commonly secondary to the perforation from stasis and usually resolves with adequate drainage.

Clinical features

SPBD presents during the first to the third month of life. The most common presentation is with abdominal distension due to 'ascites' (60%) and/or jaundice (60%). Other symptoms include fever, vomiting, abdominal mass and pale stools. Less commonly a hernia or a hydrocele may be present, presumably secondary to the increased intra-abdominal pressure. The general condition is relatively good at presentation in most infants. Less commonly SPBD presents acutely with poor general condition requiring resuscitation. The serum bilirubin and liver enzymes are either normal or only mildly elevated. A mild leucocytosis is present and an ascitic tap reveals bile-stained fluid with a bilirubin concentration higher than that in the serum.

Treatment

The treatment is surgical and should be covered by broad-spectrum antibiotic therapy which is continued for a few days postoperatively unless the patient develops cholangitis which necessitates a full course of antibiotic based on culture and sensitivity tests. Intraoperative cholangiography is performed in all of the cases if possible. This is necessary to outline the biliary tract, and document any calculi and distal obstruction. Repair of the perforation is unnecessary, may be hazardous and carries a definite risk of postoperative stricture. Exploration of the porta hepatis is avoided in view of the inflammatory state. The standard treatment consists of insertion of a T-tube through the perforation, lavage and suction of peritoneal contents and insertion of a peritoneal drain with or without cholecystectomy. The distal obstruction resolves after T-tube drainage in the majority of cases. A choledochojejunostomy is indicated at a subsequent stage only in cases where the obstruction persists (on repeat T-tube cholangiography) as it indicates the distal stenosis.

Cystic disease of the biliary tract

Cystic disease of the biliary tract is rare and in the USA accounts for 1 in 13 000 hospital admissions. The aetiology remains unknown. Most instances are thought to represent congenital weakness of the common bile duct with distal obstruction caused by an anomalous acute or right-angle junction between the pancreatic duct and the common bile duct resulting in an abnormally long common channel (>0.6 cm). Another theory postulates an unequal proliferation of the duct epithelium. Several types are recognized (Figure 25.37):

- type I diffuse choledochal cystic dilatation, commonest; B type II localized dilatation of the supraduodenal bile duct
- type III supraduodenal diverticulum
- type IV intraduodenal diverticulum or choledochocele
- type V solitary intrahepatic cyst
- type VI multiple intrahepatic cysts (Caroli disease)
- type VII multiple intra- and extrahepatic cysts.

Type VI (Figure 25.38), which is a hereditary disorder (autosomal recessive), is known as Caroli disease and carries a poor prognosis from recurrent cholangitis and the development of intrahepatic stones, liver abscess formation and, eventually, cirrhosis. In some patients, multiple intrahepatic cystic disease is accompanied by congenital hepatic fibrosis. This condition is known as Grumbach disease.

Clinical features

There appears to be a high incidence of cystic disease in the Japanese. There is a strong female predominance worldwide (70% of reported cases in the West) and 25% of the reported

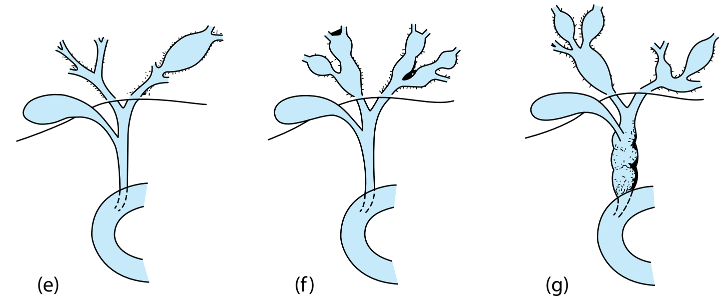

Figure 25.37 Diagrammatic representation of the types of cystic disease of the biliary tract: (a) type I, diffuse choledochal dilatation; (b) type II, localized choledochal dilatation; (c) type III, supraduodenal diverticulum; (d) type IV, intraduodenal diverticulum (choledochocele); (e) type V, solitary intrahepatic cyst; (f) type VI, multiple intrahepatic cysts (Caroli disease); (g) type VII, multiple intra- and extrahepatic cysts.

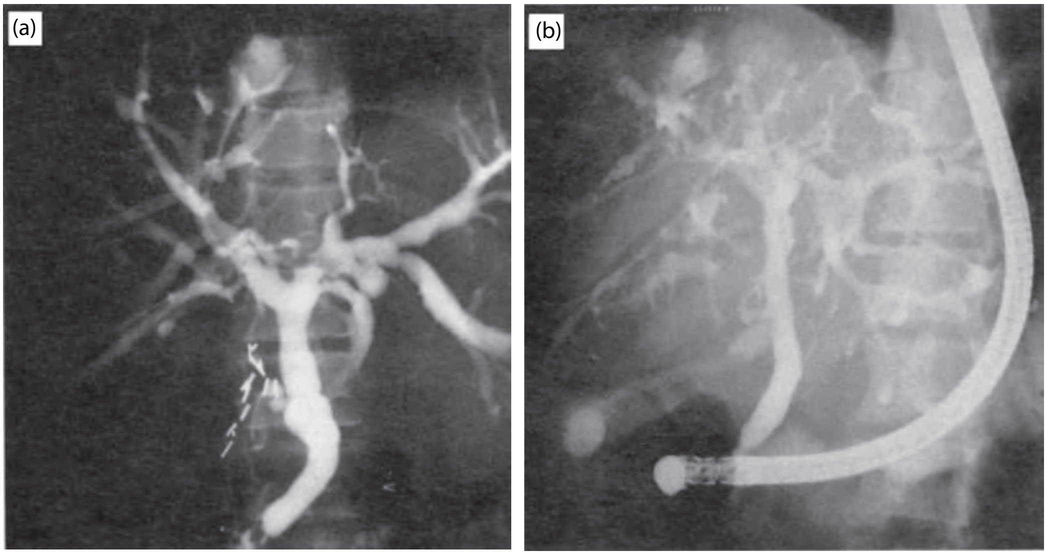

Figure 25.38 Caroli disease. (a) Percutaneous transhepatic cholangiography showing multiple intrahepatic cysts; (b) endoscopic retrograde cholangiopancreatography showing multiple intrahepatic cysts. The patient presented with bleeding from oesophageal varices. Liver biopsy showed hepatic fibrosis. The combination of diffuse intrahepatic cystic disease and hepatic fibrosis is known as Grumbach disease.

cases have been diagnosed during the first year of life. Another 35% become clinically manifest over the next 10 years. The symptoms include cholestatic jaundice, abdominal mass and pain. Complications of the disease include recurrent cholangitis and pancreatitis, hepatic abscess formation, calculous disease, biliary cirrhosis, rupture of the cyst with biliary peritonitis (rare) and portal vein thrombosis. There is also an increased risk of CC, which usually develops in the posteromedial wall of the cyst.

The diagnosis can be established non-invasively with ultrasound and CT scanning. Better definition of the pathological anatomy is, however, obtained with MRCP or ERCP, which also demonstrates the anomalous junction of the bile and pancreatic ducts and its angle (Figures 25.39 and 25.40). Type IV (intraduodenal diverticulum, choledochocele) can be recognized endoscopically as a smooth compressible elevation associated with an enlarged papilla which protrudes into the duodenum.

Treatment

The treatment of choice is surgical excision with a Roux-en-Y anastomosis. This gives much better results than drainage procedures and avoids or minimizes the risk of carcinoma. The excision is, however, difficult as the cyst is often adherent to the other structures of the porta hepatis and is best performed in centres with biliary surgical expertise. The treatment of patients with intrahepatic cystic disease is difficult. When localized, partial liver resection is advisable. It is doubtful whether distal drainage, such as choledochoduodenostomy or transduodenal/endoscopic sphincterotomy, materially influences the course of the disease of the widespread intrahepatic variety and may indeed enhance the risk of cholangitis.

Gallstones

There has been a marked rise in the incidence of gallstones in the West during the past century. The current mean prevalence in Europe obtained from autopsy studies is 18.5% with the lowest prevalence being reported in Ireland (5%) and the highest in Sweden (38%). In the UK, USA and Australia, the prevalence rates vary from 15% to 25%. In every Western country, the prevalence of gallstones in females is approximately twice that of the male population. The highest prevalence is found in the Pima Indian tribe of Arizona with total and female prevalence of 49% and 73%, respectively. A high prevalence rate is also found in South American countries. Gallstones are rare

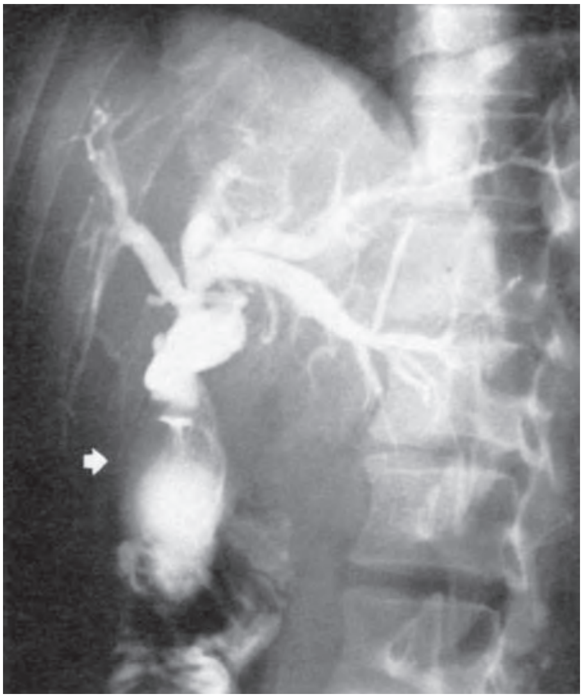

Figure 25.39 Endoscopic retrograde cholangiopancreatography outlining diffuse choledochal dilatation (type I). This is the commonest variety and accounts for 80% of cases.

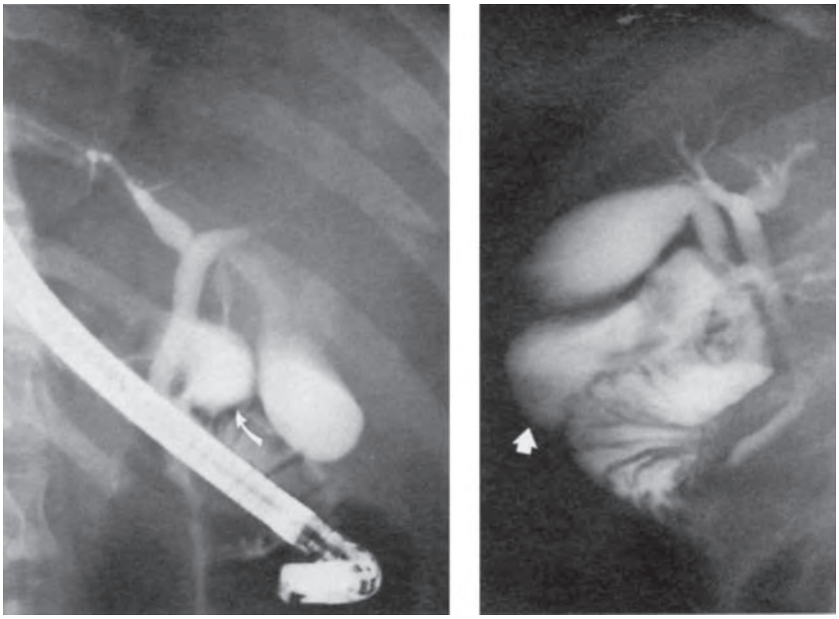

Figure 25.40 Endoscopic retrograde cholangiopancreatography demonstrating a supraduodenal diverticulum (type III) beneath the gallbladder. The arrows point to the diverticulum.

in Africa and most recorded rates in this continent are below 1%. The prevalence of gallstones in Japan has also risen since the early twentieth century from 2% to 7%. In addition, the composition of stones in Japan has changed during the same period such that cholesterol stones now predominate over pigment stones.

Classification

The old classification of Aschoff into inflammatory, metabolic, static and mixed does not correlate with the present pathophysiological information relating to the formation of gallstones and is not currently used. Likewise, the classification into 'pure' and 'mixed' stones is inaccurate as the overwhelming majority of stones are composed of more than one component. The accepted current classification recognizes three main types of gallstones: cholesterol, black pigment and brown pigment stones.

Cholesterol stones

These form in the gallbladder and are preceded by the formation of biliary sludge (see below). They account for the vast majority (75%) of gallstones encountered in the West. They have a protein matrix, and although they are composed predominantly of cholesterol they contain bile pigments and varying amounts of calcium carbonate and palmitate. These calcium salts are deposited on the periphery of the stones and their amounts determine the radiodensity of these yellow gallstones. Cholesterol gallstones do not commonly harbour bacteria (10%) and are not usually associated with infected bile. They are often radiolucent and cast strong acoustic shadows on ultrasonography. Cholesterol stones are often multiple and medium sized, but when solitary they attain a large size and have a radiating crystalline cross-sectional appearance.

Black pigment stones

Black pigment stones form in the gallbladder and account for 25% of stones in the West although their prevalence is higher in Asian countries. They are composed of bilirubin polymers without calcium palmitate, varying amounts of cholesterol (3–25%) and a matrix of organic material. Associated infection is present in less than 20% of patients. Black pigment stones are usually multiple, small, irregular and dark green to black in colour. Although haemolytic states predispose to the formation of black pigment stones, the vast majority occur in patients without detectable chronic haemolysis. Their consistency is hard and they have a layered cut surface.

Brown pigment stones

In contradistinction to the above types, brown pigment stones form in the bile ducts (primary ductal calculi) and are associated with infection of the biliary tract. Scanning electron microscopy of fresh specimens demonstrates bacteria inside crevices and pits of these amorphous soft stones in 98%. Brown pigment stones contain calcium bilirubinate, calcium palmitate and only small amounts of cholesterol bound in a matrix of organic material.

Aetiology

There is an increased prevalence of gallstones in females and the frequency of gallstones increases with age in both sexes. Although familial incidence remains unproven, a positive family history of gallstones is more often obtained from patients with symptomatic gallstone disease than in controls. The importance of genetic and ethnic factors is exemplified by the unusually high prevalence of gallstones in the American Indians, particularly the Pima tribe. The genetic disorder in this ethnic group results in the production of a supersaturated bile and a deficient secretion of bile acids by the liver. Certain risk factors are known to increase the prevalence of gallstones; others induce symptomatic disease in patients with silent gallstones without necessarily enhancing the overall frequency (Table 25.2).

Table 25.2 Risk factors for gallstone prevalence and symptomatic gallstone disease

Increased prevalence	**Precipitation of symptomatic disease**
Female sex*	Pregnancy
Obesity*	Clofibrate
Age*	Thiazide diuretics
Genetics and ethnic factors*	?Oral contraception
Highly refined, fibre-depleted, high animal fat diet*	
Diabetes mellitus*	
Ileal disease and resection	
Haemolytic states*	
Infections of the biliary tract†	
Parasitic infestations†	
Cirrhosis†	
Cystic fibrosis	

*Increased prevalence of cholesterol stones.
†Increased prevalence of pigment stones.

Although it is generally stated that the gallstones which form in patients with ileal disease or after ileal resection are of the cholesterol variety, recent studies have demonstrated that a substantial number of these stones are of the pigment variety. The enhanced lithogenicity and increased incidence of gallstones in the obese are the consequence of an increased hepatic synthesis and secretion of cholesterol. The supersaturation of bile with cholesterol is found in maturity-onset diabetes but not in the juvenile type. The exact mechanism responsible for bile lithogenicity in maturity-onset diabetes is not known. The enhanced incidence of gallstones in children with cystic fibrosis has been attributed to the abnormal mucus that impairs bile flow and favours nucleation.

Early reports demonstrated an increased incidence of symptomatic gallstones in females on the oral contraceptive pill, the relative risk being estimated at 2.5. However, more recent studies have been unable to confirm this finding. This discrepancy has been attributed to the lower oestrogen component of the modern 'mini' contraceptive pill. Studies on the prevalence of gallstones in asymptomatic populations with ultrasound scanning have shown no difference between women on the contraceptive pill and those who are not. Some reports have indicated that the modern 'mini' contraceptive pill may be associated with an increased risk of symptomatic disease in young women (aged 29 years or less).

Pathogenesis of gallstones

Our knowledge of the pathogenesis of gallstone formation remains incomplete, although there has been considerable progress on the mechanisms involved during the past two decades. Undoubtedly the pathogenesis of cholesterol stones is different from that of black pigment stones; and brown pigment stone formation differs from both.

Cholesterol stones

The formation of cholesterol stones involves seven processes:

- supersaturation of bile with cholesterol
- incomplete transfer of cholesterol from the biliary vesicles to the bile salt micelles and formation of abnormal high cholesterol-containing biliary vesicles
- aggregation and fusion of unstable vesicles
- cholesterol crystallization: nucleating and antinucleating factors
- biliary sludge formation
- stone growth.

Supersaturation with cholesterol

The outstanding biochemical abnormality associated with the formation of cholesterol gallstones is the secretion of bile that is supersaturated with cholesterol. Under normal physiological conditions, cholesterol is secreted by the hepatocytes into the hepatic bile as cholesterol–phospholipid vesicles. Within the bile a phase change occurs due to the relative high concentrations of bile acids, and micelles form. These are essentially molecular aggregates in which the cholesterol and phospholipid molecules form a central core surrounded by bile salt molecules. This mechanism is invoked to maintain cholesterol (which is water insoluble) in solution. Within the narrow range of water content of bile (80–95%), the solubility relationships of the biliary lipids can be expressed by plotting their relative molar concentrations on triangular coordinates (Figure 25.41). In the micellar zone, which represents the normal, the cholesterol is in solution as micelles and the bile is unsaturated with respect to cholesterol. Thus cholesterol precipitation and stone formation do not occur. Other methods are used to express the solubility of cholesterol in bile. These include the percentage saturation, the lithogenic index and the ratio of the concentrations of bile salts and phospholipids over the concentration of cholesterol.

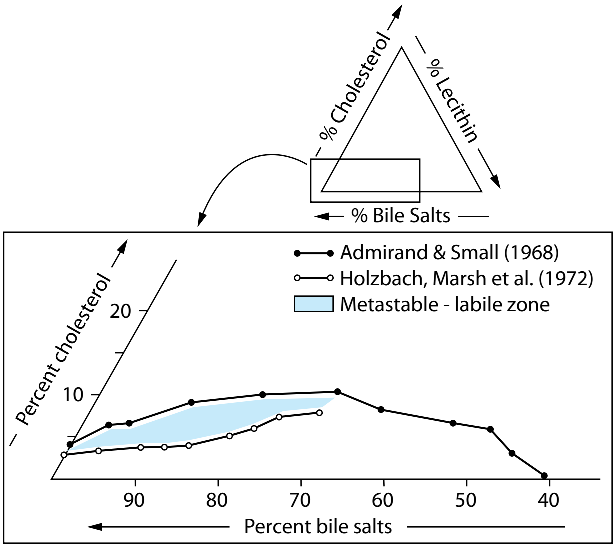

Figure 25.41 Solubility relationships of cholesterol, bile salts and lecithin (phospholipid) expressed by plotting their relative molar concentrations on triangular coordinates. Points below the metastable–labile zone indicate unsaturated bile. (From Popper, Schaffner (eds) *Progress in Liver Disease*, vol. V. New York, NY: Grune and Stratton, 1976.)

The lithogenic index is the ratio of the actual amount of cholesterol that can be dissolved in the bile sample using the triangular coordinate plots. A lithogenic index of unity or greater indicates that the bile is supersaturated with respect to cholesterol. The normal ratio is concentration bile salts + concentration phospholipids/concentration cholesterol = 10:1.

The source of the supersaturated bile is the liver, from either increased synthesis of cholesterol or a decreased synthesis/secretion of bile salts and phospholipids. Excess cholesterol secretion in the bile is well documented in obese patients and is thought to result from the increased activity of the enzyme hydroxymethylglutaryl coenzyme A (HMG CoA) reductase resulting from the chronically elevated levels of insulin found in overweight individuals. Most non-obese patients with cholesterol gallstones have a reduced absorption as the cause of the diminished bile salt pool in these patients. The most likely explanation of the smaller pool (and supersaturated bile) is an exaggeration of the normal feedback mechanism between the bile salt return and the hepatic synthesis of bile acids together with an increased enterohepatic cycling possibly consequent on abnormal excessive gallbladder contractility. Although gallstones develop only in individuals with supersaturated bile, many patients with this abnormality never develop gallstones. Thus other factors are involved. These include the persistence of biliary vesicles and kinetic factors.

Biliary vesicles

Under normal conditions, the cholesterol–phospholipid vesicles are relatively stable and disappear as micelles form and take up their cholesterol and phospholipid constituents. In the pathological state, the phase change to micelles is incomplete and as more phospholipid than cholesterol is extracted into the micellar aggregates with bile salts, biliary vesicles with an abnormally high cholesterol–phospholipid ratio are produced. These abnormal vesicles are unstable and are the source of cholesterol monohydrate crystals in the bile. The crystallization is preceded by aggregation and fusion of the high cholesterol-containing vesicles.

Kinetic balance between nucleating and antinucleating factors

Bile contains substances which either inhibit (apolipoprotein A1) or promote (mucin) the growth of cholesterol crystals. Thus the development of cholesterol gallstones is influenced by the balance between these two kinetic factors. An anionic polypeptide fragment (APF) of high-density lipoprotein occurs in bile and together with immunoglobulin A constitutes the lipoprotein complex of bile. It is thought that an absolute or relative decrease in the amount of APF favours nucleation and growth of cholesterol monohydrate and pigment crystals.

The biliary proteins include enzymes, transport proteins, hormones, plasma proteins and mucin. The evidence for the important role of mucin in the nucleation and growth of cholesterol crystals is overwhelming. Hypersecretion of densely glycosylated mucin is observed in experimental models of gallstone formation; mucin is a major component of biliary sludge and stone formation appears to start in the mucous gel. Thus gallbladder mucus is thought to be involved both as a nucleation-promoting agent and in providing the right milieu which encourages stone growth. Recently a protein with marked nucleation promotion activity for cholesterol crystals that binds to concavalin A has been isolated from the bile of patients with and without gallstones. Its activity was found to be increased in patients harbouring gallstones.

Biliary sludge

Biliary sludge is composed of mucin, calcium, monoconjugated bilirubin and cholesterol and is now thought to be the direct precursor of gallstones. A number of reports have documented symptoms including biliary-type pain in patients who were found to have biliary sludge but no gallstones.

Other factors

There is no doubt that the above account presents an incomplete picture of the pathogenesis of cholesterol stones. The role of calcium is indicated by the presence of calcium salts in the majority of stones, and the experimental demonstration in the prairie dog model that cholesterol vesicle aggregation and the induction of cholesterol gallstones is associated with an increase in the total and free ionized calcium concentrations in the gallbladder bile.

That the gallbladder plays an important role in gallstone formation (both cholesterol and black pigment) is evident by the fact that 85–90% of stones are encountered in this organ rather than in the bile ducts. It has been postulated that the gallbladder may alter the physicochemical composition of bile, favouring nucleation and crystal growth by abnormal absorption/secretion, defective surface pH, stasis resulting from impaired gallbladder emptying and stratification of bile (Figure 25.42) or by providing essential nucleating factors including mucin, desquamated cells, bacteria and refluxed intestinal contents. It is probable that gallstones are formed at different occasions depending on the balance between nucleation inhibition and promoting factors at different time periods (Figure 25.43).

Black pigment stones

Much less is known about the pathophysiology of black pigment stones. In cirrhotic patients who have a high prevalence of these stones, an elevated concentration of monoconjugated bilirubin and a lower bile salt concentration than normal has been documented. The hypothesis that patients with black pigment stones have a bile which is supersaturated with calcium bilirubinate has had some experimental backing in a dietary model of pigment stones by which a significant increase in the gallbladder concentrations of unconjugated bilirubin and calcium were documented. Calcium is a universal component of black pigment stones and both free and total ionized calcium is increased in canine models of pigment gallstone disease. As the hepatic bile concentration is unchanged, the altered chemical composition is thought to be secondary to altered gallbladder function.

Patients with bile acid malabsorption (after ileal resection) have low biliary cholesterol in addition to a reduced bile salt pool. They exhibit an increased risk of gallstone formation, predominantly of the black pigment kind. This observation has led to the hypothesis that biliary cholesterol may exert a protective action on the gallbladder mucosa and, accordingly, low biliary cholesterol renders the mucosa susceptible to direct

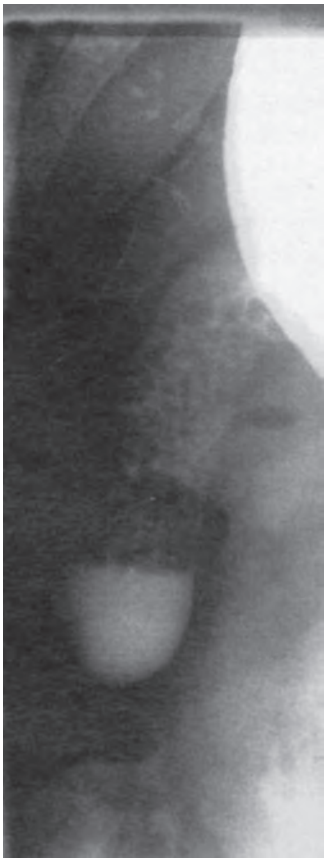

Figure 25.42 Stratification of bile with floating gallstone layer.

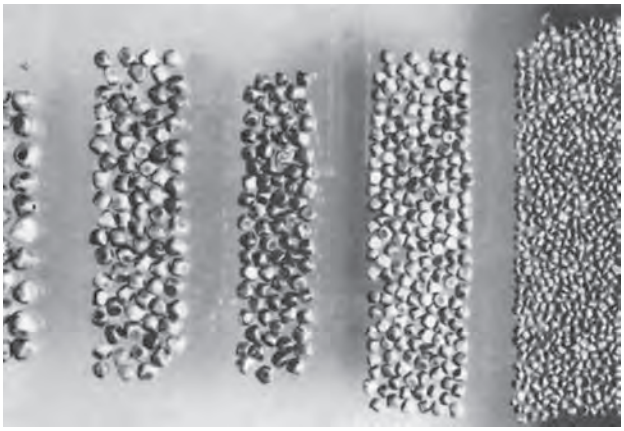

Figure 25.43 Several generations of cholesterol stones removed from a gallbladder after cholecystectomy. The factors within the gallbladder which favour precipitation of cholesterol crystals and the growth of cholesterol microliths into discernible stones are outlined in the text.

injury by bile acids as these are concentrated in the gallbladder. There is no proof for this hypothesis.

There is increasing evidence for the important role of some mucins (especially MUC3 and MUC5B) in the development of pigment stones, especially those forming in the intrahepatic ducts. The peribiliary glands are the source of the mucins. A recent study has demonstrated an increased mRNA expression of MUC3 and MUC5 in the cells of the peribiliary glands of stone-harbouring intrahepatic ducts compared to normal controls.

Brown pigment stones

These ductal calculi are caused by infection by Gram-negative bacteria such as *E. coli* and *Bacteroides fragilis*, which elaborate and release β-glucuronidase in the bile. Recent studies have documented infection in 80–98% of cases. In many Eastern countries where infestation with *Ascaris lumbricoides* is endemic, the eggs of this parasite have been repeatedly identified in the nucleus of brown pigment stones, but the cause is the associated bacterial infection of the biliary tract. Likewise, the formation of both intrahepatic and extrahepatic ductal calculi in recurrent pyogenic cholangitis is due to infection of the biliary tract by Gram-negative bacteria. The bacterial β-glucuronidase is implicated in the hydrolysis of conjugated bilirubin with consequent precipitation of insoluble calcium bilirubinate. Brown pigment stones are encountered in biliary tract conditions associated with stasis and infection such as chronic obstructive disease, indwelling biliary endoprostheses and around non-absorbable suture material or metal clips used in biliary tract surgery.

Clinical syndromes of gallstone disease

The symptomatology of gallstone disease is varied. Often non-specific, the symptoms may be acute, chronic or totally absent when gallstones are diagnosed as an incidental finding during the investigation of patients for unrelated disorders. The differentiation between silent and symptomatic gallstones is important since this affects management in the individual case.

In patients with chronic symptoms, it is important to stress that the demonstration of gallbladder disease by oral cholecystography/ultrasound scanning does not exclude other disorders being responsible for the symptoms, and a careful clinical evaluation, together with the appropriate investigative protocol, is essential in all patients with chronic symptoms and ultrasonically confirmed gallstone disease. This is especially important in the selection of patients for elective cholecystectomy. The common coexisting diseases include:

- colonic motility disorders and diverticular disease
- and peptic ulceration
- reflux oesophagitis and hiatal hernia
- pancreatitis
- colonic cancer
- renal disease
- ischaemic heart disease.

In addition to gallbladder imaging, an upper gastrointestinal endoscopy or barium series and, in certain situations, a barium enema is advisable in all patients undergoing elective cholecystectomy for chronic symptoms.

Symptomless (silent) gallstones

Most surveys have shown that silent gallstones heavily outnumber the symptomatic ones. Silent gallstones are diagnosed as incidental findings most commonly by abdominal radiographs. The previous controversy regarding the management of asymptomatic gallstones has been resolved by prospective studies which have shown that the vast majority of silent gallstones will not cause symptoms or complications during life.

Comparative evaluation of expectant vs surgical management of asymptomatic gallstones has shown that cholecystectomy reduces marginally the life expectancy in addition to being substantially more costly. Another argument for cholecystectomy in the past has been the prevention of gallbladder cancer, the development of which is known to be associated with the presence of gallstones. However, carcinoma of the gallbladder is rare and the overall operative mortality with the widespread adoption of prophylactic cholecystectomy in patients with silent gallstones would certainly exceed that due to cancer of the gallbladder by a significant margin. The evidence linking cholecystectomy with the development of colon cancer remains conflicting and cannot be used as a further argument against prophylactic cholecystectomy. The consensus of current surgical opinion is that there is no indication for cholecystectomy in the management of patients with asymptomatic gallstone disease.

There are four exceptions to this policy. The first relates to patients undergoing surgical intervention for other conditions in which gallstones are found at laparotomy. In one report, 50% of these patients developed complications or symptomatic disease subsequently and 12% required cholecystectomy within 30 days after the operation. On the other hand, concomitant cholecystectomy increases the postoperative morbidity. Thus if incidental gallstones are found at operation, cholecystectomy is indicated if the patient's general condition is good (ASA I, II). The second group which merits cholecystectomy for asymptomatic gallstones is made up of acromegalic patients on long-term treatment with somatostatin analogue, which often produces large gallstones. As somatostatin treatment has to be continued indefinitely, LC is indicated in these patients, once stones are documented by ultrasound. Presently, prophylactic removal of the gallbladder (prior to stone formation) is not practised in these patients. Patients with a calcified gallbladder have a significant risk of developing cancer of the gallbladder and for this reason cholecystectomy is indicated even if the condition is asymptomatic. Diabetic patients with gallstones are more prone to develop symptoms and complications and for this reason some advocate LC in this group although this remains debatable.

Symptomatic gallstone disease

The clinical presentation varies and may be acute or chronic.

The spectrum of symptomatic gallstone disease is:

- chronic cholecystitis
- acute biliary colic/acute cholecystitis
- jaundice due to large bile duct obstruction
- cholangitis/septicaemia
- acute gallstone pancreatitis
- biliary fistulous disease
- gallstone ileus.

Chronic cholecystitis

Chronic inflammation of the gallbladder is most commonly due to stones and the term 'chronic cholecystitis' should be restricted to gallbladders containing gallstones with varying degrees of inflammation, from mild mucosal/submucosal changes to gross transmural fibrosis leading to a contracted fibrous encasement of the biliary calculi.

Symptoms and signs

Most commonly, patients with chronic cholecystitis complain of recurrent attacks of epigastric or right hypochondrial pain, often radiating to the right side of the back and, less commonly, to the shoulder blade. The pain is more often persistent than intermittent. Episodes of biliary colic with severe intermittent peaks of pain lasting a few minutes to several hours may subside spontaneously or progress to cystic duct obstruction and acute cholecystitis. Nausea and vomiting may accompany both episodes of persistent pain and severe attacks of biliary colic. Jaundice and dark urine may follow an attack and indicate common bile duct obstruction by a calculus. The jaundice often subsides after a few days but may persist as a major presenting symptom. It is now established that indigestion, dyspepsia, flatulence, intolerance to fatty foods, abdominal distension and belching occur with the same frequency in the general population as they do in patients with chronic gallstone disease.

The only reliable sign, which is infrequently found on clinical examination, is tenderness in the right upper quadrant. More often than not, the clinical features of chronic cholecystitis are non-specific and confirmation by imaging tests (usually ultrasonography) is essential for diagnosis in the vast majority of cases.

Treatment

Cholecystectomy

The treatment of chronic cholecystitis is surgical – cholecystectomy. There is little doubt that these patients should have their gallbladder removed, as approximately 30% of them will develop complications if surgical treatment is delayed. Furthermore, the morbidity and mortality following surgical intervention are enhanced in those patients who develop complications necessitating surgical intervention. In practice, the problem concerns the selection of patients, which should be based on establishing that the gallstones are the cause of the patient's symptoms since these are by no means specific and can be caused by other common gastrointestinal disorders. Poor case selection accounts for a large cohort of those patients who continue to experience symptoms after cholecystectomy (postcholecystectomy syndrome). Some of these patients are subsequently found to have disease outside the biliary tract.

Peroperative cholangiography should be considered as an integral part of cholecystectomy. The cholangiographic findings, the presence of jaundice together with the operative appearances, dictate the need for exploration of the common bile duct. Exploration of the common bile duct is usually followed by the insertion of a T-tube even in those patients who are found to have a negative exploration, although some surgeons would opt not to insert a tube in patients with a negative exploration and simply close the choledochotomy. Others insert a small cannula through the cystic duct remnant to enable the performance of postoperative cholangiography before discharge from hospital. The T-tube should not be smaller than 14 Fr and its long limb should be brought out by the shortest route laterally in the right subcostal region. These measures facilitate considerably the removal of retained ductal stones through the T-tube tract by means of the flexible choledochoscope (see below). The Whelan–Moss T-tube was specially designed to create a wide tract between the bile duct and the abdominal parietes and thus facilitate percutaneous stone extraction via the T-tube tract. Its long limb is wider than the intracholedochal portion.

Opinion on the need for drainage of the gallbladder fossa remains divided. The argument against drainage has been strengthened by the results of several prospective clinical trials since these have either failed to show a difference between the drained and the undrained groups or indicated that drainage increases the postoperative sepsis and morbidity. It seems likely that the routine uneventful cholecystectomy without exploration of the common bile duct does not require the insertion of a subhepatic drain, but most biliary surgeons would still recommend drainage for the following:

- difficult cholecystectomy
- early cholecystectomy for acute cholecystitis
- in patients who require exploration of the common bile duct.

The mortality of elective open cholecystectomy for chronic cholecystitis is low (0.3–1.0%) but is higher in the elderly (5–6%). LC is now firmly established as the gold standard therapy for symptomatic gallstone disease. With experience and training, it is applicable to over 95% of patients. The procedure reproduces all the steps of the traditional open cholecystectomy, which it has largely replaced because of its well-documented advantages. Conversion to open surgery is indicated if a safe dissection of the structures in the triangle of Calot cannot be performed because of dense fibrosis, severe adhesions from previous surgery, the presence of a Mirizzi syndrome and severe acute disease with gross inflammatory oedema. Conversion to open cholecystectomy may also be necessitated because of the onset of a complication (severe bleeding, bile duct injury, etc.) which cannot be safely dealt with by the laparoscopic approach.

The advantages of LC over the conventional operation include less postoperative pain, virtual absence of ileus, short hospital stay (0–2 days) and accelerated return to full activity or work (within 10–14 days). In addition, there is an overall reduction of the incidence of postoperative wound and chest infections, wound dehiscence, incisional hernia and deep vein thrombosis. The postoperative mortality appears to be lower than that of open cholecystectomy. Other advantages include reduced adhesion formation and wound complications. The downside is an increased incidence of iatrogenic bowel, vascular and biliary injuries. The importance of routine IOFC during LC must be stressed. The overriding reason for routine IOFC is the provision of a road map of the biliary anatomy and the determination of a safe site for medial ligature or clipping of the cystic duct without compromise of the extrahepatic bile conduit. The other reasons for routine IOFC are similar to those for open cholecystectomy: detection of biliary tract anomalies and unsuspected ductal calculi. If the surgeon is experienced, these calculi are best removed during the operation either by extraction through the cystic duct or by direct laparoscopic common bile duct exploration.

Single port laparoscopic cholecystectomy

A recent modification is a single port LC in which a single port (disposable or reusable) is used that enables the insertion of a 5 mm laparoscope and at least two instruments (Figure 25.44).

However some surgeons prefer to use a single incision (subumbilical) and insert the three separate 5.0 mm ports and instrument without use of any special single multi-instrument port (*single incision technique*). Single port or single incision LC has been shown to reduce postoperative pain and improve cosmesis as the scar is 3.0 cm and is located in or just below the umbilicus. It is however more difficult than the conventional multiport LC, although the reported data indicate equivalent safety between the two approaches.

To date, a broad spectrum of operations have been performed by the various specialties by the single port laparoscopic (SPLS) approach: cholecystectomy, colorectal resection, totally extra-peritoneal inguinal hernia repair**,** bariatric surgery including sleeve gastrectomy, gastric banding**,** gastric bypass, fundoplication, splenectomy, laparoscopic urology, e.g. nephrectomy, pyeloplasty, and prostatectomy, laparoscopic gynaecology, e.g. salpingostomy, salpingectomy, cystectomy and hysterectomy. Worldwide SPLS cholecystectomy has been the commonest operation performed in the published literatures with more than 2000 cases reported to date.

The safety and efficacy of the SPLS for LC has been confirmed by randomized and case cohort studies. One prospective randomized controlled trial of traditional multiport LC vs SPLS confirmed equivalent safety of the two approaches. In this trial, the cosmetic score was higher for SPLS than with traditional LC. However, despite the enthusiasm of many surgeons in adopting the technique, others remain unconvinced of the real benefit for the patients, especially with reference to reduction of the postoperative pain and adhesion formation and furthermore have concerns on the increased risk of periumbilical hernia formation with SPLS.

Compared with the traditional multiport laparoscopic surgery, there are a number of major constraints in ergonomics of and technologies for SPLS, which have hindered the wide spread uptake of this approach. Even with the best operating set-up, image display system, port and instrumentation available, the SPLS approach imposes several restrictions: maintenance of sufficient exposure, sustained pneumoperitoneum, adequate retraction, collision between instruments (internal and external), collision between instruments and optics, and limited instrument manipulation and triangulation. For this reason, many surgeons have had to overcome these restrictions by various techniques such as using percutaneous sutures for retraction and employing coaxial, flexible, and articulating instruments to improve triangulation.

Different operating systems, various ports, types of instruments, and endoscopes have been tried and used which have, to some extent, reduced the constraints imposed by the SPLS approach. Undoubtedly further more advanced instrumentation such as hand-held manipulators with 7 degrees of freedom and robotic devices for SPLS are needed to realize the full potential of the SPLS approach.

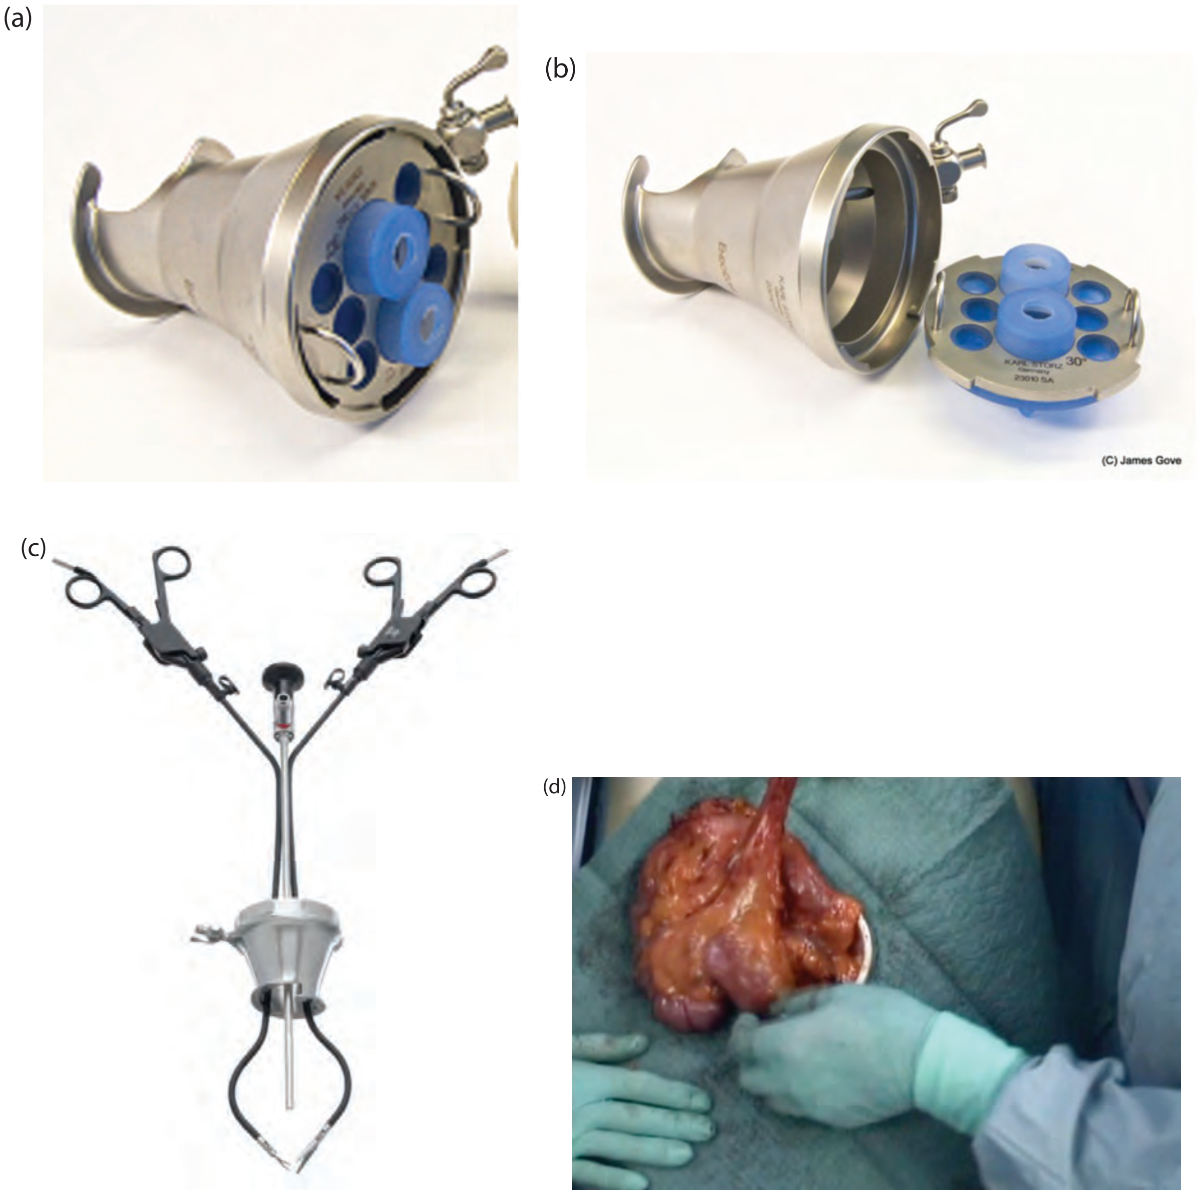

Figure 25.44 Dundee EndoCone for single port laparoscopy (Storz, Tuttlingen). This reusable port is introduced by a screwing movement after creation of a 3.0 cm transumbilical incision and is self-retaining. The detachable bulkhead (cap) has two central large valves (admitting instruments up to 13 mm including staplers) and six 5.5 mm valved ports for 5 mm instruments which are specially designed: they have distal curves to restore triangulation and proximally diverting handles that permit separation of the two hands of the operator, essential for ergonomic manipulations.

Mini-cholecystectomy

This implies performance of cholecystectomy through a small (5 cm wound) that should be placed in the midline and not in the right subcostal region. Proponents recommend this technique for both elective cholecystectomy and patients with acute cholecystitis. The procedure uses standard operating techniques with certain modifications such as the use of a headlight, a ring retractor, clip applicators and long instruments. The need to extend the incision is encountered in 15% of patients. A more recent modification has been described as ‘cylindrical cholecystectomy’. The operation is based on the introduction of a 3.8–5.0 cm diameter cylinder that is 10 cm long which isolates the hepatocystic region from the surrounding structures, and thus facilitates the intervention.

In general, mini-cholecystectomy is associated with a shorter hospital stay (3.5 days vs 8.5–11 days) than patients undergoing cholecystectomy through an unrestricted incision, and some have reported an earlier return to work after the procedure.

The procedure can be technically difficult especially in patients with excessive fat in the triangle of Calot and most surgeons have abandoned it in favour of the laparoscopic approach.

Partial cholecystectomy

This technique was first described by the group at Cape Town for cholecystectomy in patients with cirrhosis. Many variations of this technique have been described involving a subtotal (fundus first) resection of the gallbladder but leaving the posterior wall attached to the hepatic bed. The Cape Town group reported on this technique performed by the laparoscopic approach for patients with complicated acute cholecystitis or fibrosis and encountered one postoperative death (myocardial infarction) and three bile leaks in 29 patients. Thus suction drainage of the gallbladder bed is necessary after subtotal cholecystectomy (open or laparoscopic).

A modification using a 1 cm rim of Hartmann's pouch to buttress and occlude the internal opening of the cystic duct and leaving the structures of Calot's triangle undisturbed was described by Schein, who reported favourably on the technique in 16 elderly/high-risk patients. This author emphasizes its speed (mean operating time of 40 minutes), technical safety in obviating a difficult dissection of the liver bed and the practical advantage compared with other conservative surgical procedures that leave the gallbladder *in situ,* of preventing gallstone formation.

Cholecystolithotomy

Patients with previous vagotomy for ulcer disease frequently develop symptomatic gallstones. Cholecystectomy in vagotomized patients with a functioning gallbladder incurs the risk of severe explosive diarrhoea in a high percentage of cases. For this reason, cholecystectomy is not warranted in this subset of patients and removal of the gallstones (cholecystolithotomy) constitutes the appropriate treatment. This may be followed by maintenance therapy with oral bile salt in an attempt to prevent recurrence if the stones are of the cholesterol variety (see below). The best approach is laparoscopic cholecystolithotomy with closure of the gallbladder with absorbable suture after gallstone clearance has been achieved. Others favour radiological guided stone extraction, fragmentation or dissolution. A cholecystectomy is the right treatment in vagotomized patients if the gallbladder is non-functioning.

Dissolution by MTBE and percutaneous lithotripsy

Methyl tert-butyl ether (MTBE) is a powerful organic solvent which dissolves cholesterol gallstones within hours. It is administered locally via a pigtail or other self-retaining catheter introduced percutaneously (usually through the hepatic substance) into the gallbladder under radiological control. MTBE is then instilled and left in the gallbladder for several hours. When dissolution is achieved, the gallbladder liquid contents are aspirated and the catheter is removed. MTBE is toxic following systemic absorption and can cause local damage if it escapes into the common duct and duodenum (erosions). For this reason, microprocessor-controlled pump delivery systems (pressure and volume controlled) are used to obviate spillage of the solvent into the ductal system. MTBE dissolution is rarely used nowadays and is indicated as one of the alternatives when removal of the gallbladder is contraindicated (poor-risk patients, previous vagotomy) or the patient specifically requests removal of the stones but not the gallbladder.

Alternatively, a rotary mechanical lithotriptor (Kinsey–Nash) can be inserted percutaneously under radiological control into the gallbladder. This device operates by creating a vortex that draws stones to a high-speed rotating impeller that fragments the calculi. Although effective, this technique results in damage to the mucosa by the bombardment with stone fragments and the limited reported literature on its use indicates a high incidence of complications. This method has been abandoned.

Extracorporeal shockwave lithotripsy

With these devices, extracorporeal shockwaves produced by spark-gap (Dornier system), piezoceramic (Wolf system) or electromagnetic (Siemens system) generators are focused by a concave reflector and targeted under ultrasound guidance to the stones, thereby inducing fragmentation. The third-generation machines avoid the need for immersion in a water bath and general anaesthesia. Although extracorporeal shockwave lithotripsy (ESWL) can achieve successful stone fragmentation in 80% of patients with solitary small gallstones at 1 year, it often fails if the stones are large (>3 cm), multiple and calcified. It is thus applicable to only 19% of patients with symptomatic gallstones. Furthermore, repeated treatment is often necessary to achieve complete fragmentation and this has to be followed by maintenance therapy with oral bile salts, despite which stone recurrence occurs in 50% at 5 years. Compared with surgical treatment, ESWL is costly, unreliable and has a limited applicability. Contrary to its established value in the treatment of renal calculi, ESWL is seldom used in the treatment of gallstones and its current role seems restricted to fragmentation of occluding ductal calculi in jaundiced patients. Even this indication is not established and remains to be defined in large patient studies. Currently, fragmentation of ductal calculi by ESWL can be achieved in 70–90% of patients with an average of two lithotripsy sessions. However, some 50% of patients require additional procedures (endoscopic extraction) to achieve stone removal, including operative intervention in 10%. Complications such as haematuria, biliary pain, sepsis and haemobilia are encountered in 15% of patients.

Oral bile salt therapy

Oral dissolution is applicable only to patients with cholesterol stones in a functioning gallbladder. The administration of the primary bile acid chenodeoxycholic acid and its 7-β epimer, ursodeoxycholic acid, reduces the cholesterol saturation of bile and prolongs nucleation time, thereby resulting in stone dissolution after several weeks/months of therapy. Following successful dissolution, maintenance therapy with low-dose ursodeoxycholic acid is required. Despite this, the risk of gallstone recurrence is 12.5% after the first year and 61% by the eleventh year. Oral dissolution fails if the gallstone load is large (larger than 3 cm or multiple) and if the stones are calcified. The disadvantages of this treatment of gallstones include high cost, high recurrence rate and limited applicability. Currently, the place of bile salt therapy is restricted to patients in whom cholecystectomy is contraindicated, either as primary treatment or after gallstone extraction, fragmentation or dissolution by MTBE. Another important indication of oral bile salt therapy is in patients with endoscopic stents as a prophylactic measure to reduce the incidence and severity of stent encrustation with calcium bilirubinate.

Chemical sclerosis

Experimental sclerosis of the gallbladder (chemical cholecystectomy) after occlusion of the cystic duct has been achieved by instillation of various sclerosants in various animal models. However, none of the agents used to date is safe enough to use clinically. The other problems with this approach include regeneration of the gallbladder mucosa from the cystic duct remnant and the possible late risk of malignant change. Physical methods of destruction of the gallbladder mucosa are currently being studied in animal experiments. These include photodynamic laser treatment.

Acute biliary colic and acute cholecystitis

Acute biliary colic results in severe colicky abdominal pain usually accompanied by nausea and vomiting. The duration of the severe pain, which makes the patient restless, varies from 30 minutes to several hours. Biliary colic often merges into acute obstructive cholecystitis. However, resolution of the severe colicky painful episode either spontaneously or as a result of analgesic medication/antispasmodic without the development of acute cholecystitis is common, and many patients give a history of recurrent episodes of biliary colic before the development of acute cholecystitis.

Between 10% and 30% of patients undergoing cholecystectomy present with acute cholecystitis. This is most commonly obstructive in nature (>95%) from impaction of a stone in Hartmann's pouch/cystic duct. Much less commonly, acute cholecystitis is acalculous, although the incidence of this complication in critically ill patients is diagnosed more frequently nowadays. Acute cholecystitis in elderly people may result from cystic duct obstruction due to carcinoma of the gallbladder. Whereas patients harbouring residual infection of the gallbladder with *Salmonella typhi* as typhoid carriers may cause sporadic outbursts of typhoid, acute salmonella cholecystitis is very rarely encountered in the West.

Acute obstructive (calculous) cholecystitis

Pathology

The attack develops when the cystic duct becomes obstructed by a gallstone impacting in Hartmann's pouch. Following obstruction of the cystic duct/Hartmann's pouch, the gallbladder becomes hyperaemic, oedematous, tense and distended. The initial inflammation is chemically induced and is not of bacterial origin although sepsis is an important feature of the established disease and its complications. Cultures of gallbladder bile taken during open cholecystectomy are positive in only 15–30% of cases and in only 3% of patients undergoing LC for the same disease. The predominant micro-organisms isolated from the gallbladder bile in these patients are *E. coli* (60%), *Klebsiella* spp. (22%) and *Streptococcus* spp. (18%). There appears to be no relation between positive gallbladder cultures and postoperative wound infections for both open cholecystectomy and LC but the overall incidence of wound infection is much higher after the open procedure (14% vs 5%) and serious wound infections after LC are very rare. Thus the small incisions used in laparoscopic gallbladder surgery may be less susceptible to infective complications.

These observations indicate that the initial inflammatory process following obstruction of the cystic duct is of a chemical nature with infection supervening in some patients during the later stages of the disease. It is believed that trauma, secondary to gallstone impaction, leads to mucosal damage through the release of phospholipases that convert lecithin (a mucosal protective factor against bile acids) to lysolecithin, a known mucosal toxin. Alternatively, the release of the prostaglandin precursor arachidonic acid by the action of phospholipase A on lecithin may mediate the inflammatory response by producing prostaglandins. In the first few days, the bile appears macroscopically normal and is sterile, but, with the progress of the inflammation, absorption of pigments and bile salts takes place, and the contents then vary from a thin mucoid material to frank pus. The histological changes of the established condition involve the mucosa, fibromuscular wall and serosa and vary from mild acute inflammation with transmural oedema to severe disease with patches of necrosis usually in the fundal region of the gallbladder, which becomes wrapped by the greater omentum.

With conservative treatment, the inflammation resolves in some 80% of patients as the rising tension in the gallbladder lumen from the outpouring of the inflammatory exudate lifts the walls of Hartmann's pouch off the impacting stone. When this disengages and drops into the gallbladder lumen, cystic duct drainage leads to resolution. This fortuitous sequence is not encountered in 20% of patients, usually elderly, in whom patchy gangrene and/or perforation with a large inflammatory phlegmon or peritonitis supervene.

The subsequent sequence of events following the acute inflammatory process may vary:

- resolution (most common) with scarring, abnormal function or non-function of the gallbladder
- persistence of the infection: the gallbladder becomes distended with pus (empyema of the gallbladder)
- resolution of the inflammatory process within the gallbladder with persistence of the cystic duct obstruction – mucocele (hydrops) of the gallbladder
- gangrene and acute perforation leading to localized (pericholecystic) abscess or frank biliary peritonitis
- chronic perforation with the development of bilioenteric and biliobilial fistulas.

Whereas the majority of patients diagnosed as acute cholecystitis have the classic acute cystic duct obstruction and its associated inflammatory condition of the gallbladder, others are instances of chronic cholecystitis presenting with acute pain or biliary colic. Although acute cholecystitis is often suspected on clinical grounds, a definitive diagnosis can only be obtained by specific investigations (EHIDA scintiscanning, ultrasonography). The serum amylase should always be performed in addition to the liver function tests. Scout abdominal plain film and chest radiographs are used to exclude perforation and the presence of gas in the biliary tract.

Symptoms and signs

The clinical picture varies with the severity of the inflammatory process. Known pre-existing gallbladder disease may be present or chronic symptoms over several months to years may precede the acute presentation. Alternatively, acute obstructive cholecystitis may be the first intimation of gallstone disease.

In mild cases, the patient complains of right upper quadrant pain and tenderness. Pyrexia, severe pain and tenderness in the right hypochondrium with rebound reflect more severe degrees of gallbladder inflammation. In these instances, Murphy's sign (inspiratory arrest due to pain on inspiration during gentle palpation of the right subcostal region) is usually present. Nausea, vomiting, ileus, mild abdominal distension and toxicity are encountered in the severe forms of the disease. Jaundice is present in 20–25% of patients with acute obstructive cholecystitis but common duct stones are found in only 12% of these patients. In the absence of ductal calculi, jaundice has been ascribed to reactive hepatitis or oedema of the common bile duct. A tender palpable mass in the right subcostal region is found in 25% of cases and signifies one of the following:

- empyema of the gallbladder
- omental phlegmon
- abscess due to localized perforation
- carcinoma of the gallbladder, especially if the patient is elderly.

Laboratory tests are frequently non-specific, their greatest value being to rule out other important conditions in the differential diagnosis, particularly acute pancreatitis. Most patients will have a neutrophil leucocytosis ($>10 \times 10^9$/L) together with some abnormality of the liver function profile. The levels of serum bilirubin and alkaline phosphatases do not invariably correlate with the presence of ductal calculi but are suggestive and clinical jaundice warrants investigation with endoscopic retrograde cholangiography (ERC) or MRCP. Other laboratory findings include raised transaminases and minor elevations of the serum amylase, below the diagnostic threshold for acute pancreatitis.

Differential diagnosis

Usually the diagnosis of acute cholecystitis is not difficult, but other common intra-abdominal conditions, e.g. perforated peptic ulcer, acute pancreatitis or a retrocaecal appendicitis associated with a high caecum and viral hepatitis, need to be considered in the individual case. Enterally transmitted non-A, non-B viral hepatitis can simulate acute cholecystitis quite closely as may right-sided pyelonephritis, lobar pneumonia and myocardial infarction. Aside from routine chest radiography and plain abdominal films, an electrocardiogram is advisable in elderly patients and in those patients with a known history of ischaemic heart disease.

Imaging tests

The yield from a plain abdominal radiograph, although limited, may be detection of important calcified gallstones in 10–20% of patients. Gas in the gallbladder lumen and biliary tract caused by emphysematous cholecystitis (see below) is encountered infrequently but is obviously very important. Absence of free air under the diaphragm is useful for excluding perforated ulcer.

Real-time ultrasonography and biliary scintiscanning form the mainstays in the confirmatory diagnosis of acute cholecystitis. Greyscale B-mode ultrasound is the most commonly used test since it is readily available, non-invasive, quick and easy to perform. Furthermore, it has the advantage of providing information about the liver, biliary tract and pancreas together with other sources of non-biliary right upper quadrant pain. The sonographic features include a positive Murphy's sign, calculi or sludge, thickened gallbladder wall and pericholecystic oedema. The examination is hampered by obesity and overlying bowel gas and is, of course, observer dependent. There is now good evidence from reported studies that the accuracy of ultrasound for the diagnosis of acute cholecystitis is considerably improved with colour velocity imaging and especially with power Doppler when compared with greyscale imaging (sensitivity 95% vs 86%, accuracy 99% vs 92%). However, the high susceptibility of power Doppler to motion artefacts requires expert adjustments of the technical parameters, and, if anything, increases observer dependency. The resistive index within the intramural vessels of the gallbladder which can now be measured by ultrasound techniques does not differentiate between inflamed and non-inflamed gallbladders.

Gallbladder scintiscanning using iminodiacetic acid derivatives (HIDA, PIPIDA scans) can be used to confirm a non-functioning gallbladder and is regarded as the most accurate test of acute cholecystitis with a sensitivity of 97% and a specificity of 87%. A normal gallbladder scintiscan is virtually 100% accurate in excluding acute cholecystitis. The presence of pericholecystic uptake of the isotope is a valuable secondary sign in the diagnosis of acute cholecystitis and correlates with the presence of gangrenous cholecystitis or gallbladder perforation.

Intravenous cholangiography has been superseded by sonography in the diagnosis of acute cholecystitis. CT scanning is useful in complicated cases but ill advised in the majority in view of the radiation dosage. Good diagnostic accuracy for acute cholecystitis has been reported with MRI.

Acute acalculous cholecystitis

Acute acalculous cholecystitis accounts for up to 5–14% of cases of acute cholecystitis. It is seen most commonly in critically ill patients. The acute inflammation of the gallbladder arises in the absence of gallstones, although biliary sludge is often present. Although most commonly encountered in critically ill elderly patients, acute acalculous cholecystitis has also been reported in children. The disorder usually occurs during the course of a prolonged serious illness, e.g. multiple trauma, following major surgical intervention, in patients with extensive burns, severe sepsis and drug overdosage. The risk factors that predispose to the development of acute acalculous cholecystitis are:

- blood volume depletion
- prolonged ileus
- morphine administration exceeding 6 days
- intravenous hyperalimentation
- multiple blood transfusions
- sepsis
- starvation.

However, acute acalculous cholecystitis does not always arise on a background of a critical illness, and in one report more than 70% of patients suffering from the condition presented *de novo*. Most of these patients were elderly men with atheromatous vascular disease and 15% were diabetic.

Pathology

The exact pathology is not known but the available evidence suggests that the inflammation develops as a consequence of prolonged distension of the gallbladder, bile stasis and inspissation (biliary sludge), which results in mucosal injury and thrombosis of vessels of the seromuscular layer of the gallbladder. These critically ill patients are often medicated with narcotics, placed on ventilators and receive hyperalimentation that contribute to biliary stasis and functional obstruction of the cystic duct obstruction. The thrombosis is thought to be initiated by the activation of factor XII. Some have suggested that the development of acute acalculous cholecystitis may be related to a hypersensitivity reaction to concomitant antibiotic therapy because of the frequent presence of substantial eosinophilic infiltration of the mucosa of the gallbladder. Culture of the aspirated gallbladder bile from these patients is positive in only 38% of cases. Thus the inflammation is predominantly chemical in origin. In the fully developed condition, the gallbladder shows marked oedema of the seromuscular layer, mucosal ulceration, sloughing and focal necrotic areas. Gangrene of the gallbladder develops in approximately 40–60% of patients who have an associated increased risk for perforation. Mortality ranges from 6% to 44% but can be reduced by early diagnosis and therapy.

Clinical features

The diagnosis of acute acalculous cholecystitis is often difficult, especially in critically ill patients receiving narcotics and on artificial ventilation. The early manifestations include fever, leucocytosis and tenderness in the right hypochondrium. However, the diagnosis of acalculous cholecystitis is difficult to make clinically and by ultrasound, because gallstones are absent and the sonographic Murphy's sign may not be detected because of diminished mental status, medication and comorbid illness. In the series reported by Cornwall and colleagues, only 50% of patients who had acalculous cholecystitis had a positive Murphy's sign. The ultrasound diagnosis is, therefore, based on distension of the gall bladder in a suspicious clinical setting, the presence of intraluminal debris, gallbladder tenderness when present (~50%) and gallbladder wall thickness greater than 4 mm, pericholecystic fluid or subserosal oedema without ascites, intramural gas or sloughed mucosal membrane. However, ultrasonography and isotope scintiscanning are less accurate for this condition than their diagnostic yield for acute calculous cholecystitis. CT provides better diagnostic specificity in patients at risk of the condition by confirming the presence of pericholecystic inflammation in patients with a thick gallbladder wall demonstrated by ultrasonography.

Treatment

Emergency surgical therapy is essential for survival. In the absence of significant gangrene, cholecystostomy (performed percutaneously, laparoscopically or by mini-cholecystostomy) is increasingly favoured, particularly in critically ill patients. Follow-up of patients treated with cholecystostomy has confirmed return to normal gallbladder function in the majority of these patients. Established gangrene requires total or subtotal cholecystectomy. Some advocate change of antibiotic regimen in view of the unproven hypersensitivity theory.

Acute emphysematous cholecystitis

This fulminant form of acute cholecystitis is fortunately rare, accounting for less than 1% of all complicated cases of acute cholecystitis. It is caused by a mixed polymicrobial infection which includes gas-forming bacteria (*E. coli, Clostridium welchii*, aerobic and anaerobic streptococci). The gallbladder may or may not contain stones. Thrombosis of the cystic artery has been implicated in the development of acute emphysematous cholecystitis.

Clinical features

Acute emphysematous cholecystitis occurs predominantly in males (70%) and has a special predilection for diabetic individuals up to 40% in reported series. The affected patients do not often have gallstones. The clinical picture is that of severe rapidly oncoming upper abdominal emergency with prostration fever and marked toxicity. The clinical course is rapidly progressive, with a 75% incidence of gallbladder gangrene and a 20% incidence of gallbladder perforation by the time of diagnosis. The presence of air within the gallbladder lumen, its wall or the biliary tree on the plain radiograph is diagnostic. Emphysematous cholecystitis can be recognized on ultrasound examination by the extremely echogenic gas which casts a distal shadow and layers non-dependently within the gallbladder lumen. If the findings of the ultrasound or plain abdominal film are equivocal, CT is used to confirm the diagnosis.

Treatment

The antibiotic regimen of choice in these patients is a combination of penicillin and aminoglycoside. Emergency surgical intervention is imperative and consists of cholecystectomy, which is usually carried out by the laparoscopic approach but in the knowledge that there is approximately a 30% conversion rate to an open procedure in patients with advanced complicated disease: gangrene, perforation and established peritonitis. The reported mortality of emphysematous cholecystitis is 15%.

Complications of acute cholecystitis

The important complications of all forms of acute cholecystitis are empyema, perforation and gangrene. All require urgent surgical intervention.

Empyema (suppurative cholecystitis)

Empyema of the gallbladder is an uncommon complication and has a reported incidence of 2–3% of all patients with gallstone disease. It presents as a tender mass in the right hypochondrium and usually affects elderly patients in whom systemic signs, including pyrexia and leucocytosis, may be minimal. Cultures of the gallbladder contents are positive in 80%. Empyema of the gallbladder doubles the mortality figures of cholecystectomy.

Gangrene

Patchy gangrene of the fundus of the gallbladder is encountered in 5–7% of patients with obstructive cholecystitis. It is more commonly encountered in elderly patients, diabetics and in patients with empyema of the gallbladder, acute acalculous cholecystitis and, especially, emphysematous cholecystitis. It may lead to localized or free perforation of the gallbladder. Gangrenous cholecystitis is defined histologically as coagulative necrosis of the mucosa or the entire gallbladder wall associated with acute or chronic inflammation. It occurs in up to 20% of patients who have acute cholecystitis and has an increased risk for perforation. Unfortunately ultrasound is non-specific for the diagnosis of gangrenous cholecystitis. This is because the sonographic Murphy's sign is absent in up to 75% of patients. A specific finding is the presence of intraluminal membranes or stranding caused by sloughing of the gallbladder mucosa, necrosis of the gallbladder wall or fibrinous exudates. This finding is present on ultrasound examination, however, in only 5% of patients.

Perforation

Perforation of the gallbladder occurs in 5–10% of patients who have acute cholecystitis, most often in association with gangrenous cholecystitis. The fundus is the most common site for perforation, because it has the least blood supply. Acute gallbladder perforation with an intraperitoneal bile leak will result in peritonitis but is much less common than subacute perforation, which typically leads to pericholecystic abscess formation. These abscesses may occur within or adjacent to the gallbladder wall in the gallbladder fossa, within the liver, parenchyma, or along the free margin of the gallbladder within the peritoneal cavity. A localized perforation may involve the duodenum with the development of a cholecystoduodenal fistula and resolution of the inflammatory episode. However, this bilioenteric fistula persists and passage of a large stone through this fistula may eventually cause gallstone ileus.

Free perforation resulting in generalized infected biliary peritonitis carries a high mortality, variously reported as 30–50%.

Treatment of acute cholecystitis

Initial management

This consists of intravenous fluid and electrolyte replacement, nasogastric suction, systemic antibiotics and parenteral analgesia. The patient is kept fasted to reduce the CCK release from the upper small bowel in order to minimize gallbladder stimulation. Although the inflammation is initially chemical, most surgeons will choose to use systemic antibiotics because of the risk of progression to an empyema and septic complications. Also, if surgery is performed, antibiotic prophylaxis will reduce the wound infection rate although this has recently been questioned in patients undergoing LC. As the organisms cultured from gallbladder bile are predominantly Gram-positive aerobes (*E. coli, Klebsiella* spp., *Streptococcus* spp.), a third-generation cephalosporin is the antibiotic of choice. Anaerobes such as *B. fragilis* and *Clostridium perfringens* are associated with more severe, mixed infections particularly in elderly people. These require combination chemotherapy using metronidazole with an aminoglycoside and/or penicillin. The diagnosis of acute cholecystitis should be confirmed during this initial 12–24 hour period of stabilization by ultrasonography or gallbladder scintiscanning.

Opinions still differ regarding the definitive treatment of acute cholecystitis. The management depends on whether the inflammatory condition is progressive and life-threatening or the cholecystitis is mild and resolving.

Severe progressive disease

The timing of surgery is dictated by the severity of the attack. Box 25.1 summarizes the indications for emergency or urgent surgical intervention.

In these patients surgical intervention is carried out under antibiotic cover active against both Gram-negative aerobes and anaerobes (cephalosporin + metronidazole or piperacillin, etc.). Traditionally, such patients have been managed by laparotomy using a midline epigastric incision and the open approach is still favoured by many in critically ill elderly patients. Hitherto, less than 10% of cases fell into this severe category but more recent reports from North America and Europe have highlighted an increasing proportion of acute severe cases requiring urgent surgical intervention (from 6–10% up to 25%). This has been attributed to a decrease in the number of patients undergoing elective cholecystectomy though this has been reversed with the advent of LC, an increasingly aged population, and a rise in the actual incidence of acute complications of gallstone disease.

The exact procedure depends on the operative findings. In patients with a tense empyema, preliminary decompression of the gallbladder contents using a Mayo–Ochsner suction trocar–cannula inserted through a purse-string suture in the fundus should precede the cholecystectomy which, in the acute situation, is best performed by the retrograde technique (starting at the fundus). This allows easier identification of the cystic duct and, thereby, reduces the risk of bile duct damage. At times, the precarious condition of the patient precludes a lengthy operation or the anatomy may be so obscured by the inflammatory mass as to render the cholecystectomy hazardous. In these situations, a cholecystostomy should be performed. The gallbladder contents are evacuated, any gangrenous patches of its walls are excised and a 22–24 Fr Malecot catheter is inserted into the organ, which is closed round it by a purse-string suture. The catheter is then brought out through a separate stab wound. In these patients a cholecystectomy is advisable at a later stage unless the patient is elderly or has severe comorbid cardiorespiratory disease, because of the risk of recurrence of gallstones and symptoms. Moreover, the incidence of carcinoma of the gallbladder in patients who had previously undergone cholecystostomy is appreciable (7%).

Subtotal cholecystectomy is performed as an alternative approach to cholecystostomy in patients in whom formal cholecystectomy is considered hazardous. In this procedure, the posterior wall of the gallbladder is left *in situ,* attached to the liver bed, and the cystic duct is secured from within the gallbladder lumen by a purse-string suture (Figure 25.45).

In all instances specimens of bile and pus are obtained for bacteriological culture. Pus is thoroughly evacuated and peritoneal lavage, preferably with an antibiotic solution, carried out when gross peritoneal sepsis is found. Adequate drainage of the gallbladder bed is still considered advisable but is no substitute for thorough peritoneal toilet. All these patients are at risk from Gram-negative bacteraemia. They require a full course of antibiotic therapy for a minimum of 7 days. The results of the culture of operative specimens of bile and pus may dictate changes in the antibiotic regimen.

BOX 25.1 Indications for emergency surgical intervention in patients with acute cholecystitis

- Progression of the disease despite conservative treatment
- Failure to improve within 24 hours especially in patients >60 years
- Presence of an inflammatory mass in the right hypochondrium
- Detection of gas in the gallbladder/biliary tract
- Established generalized peritonitis
- Development of intestinal obstruction

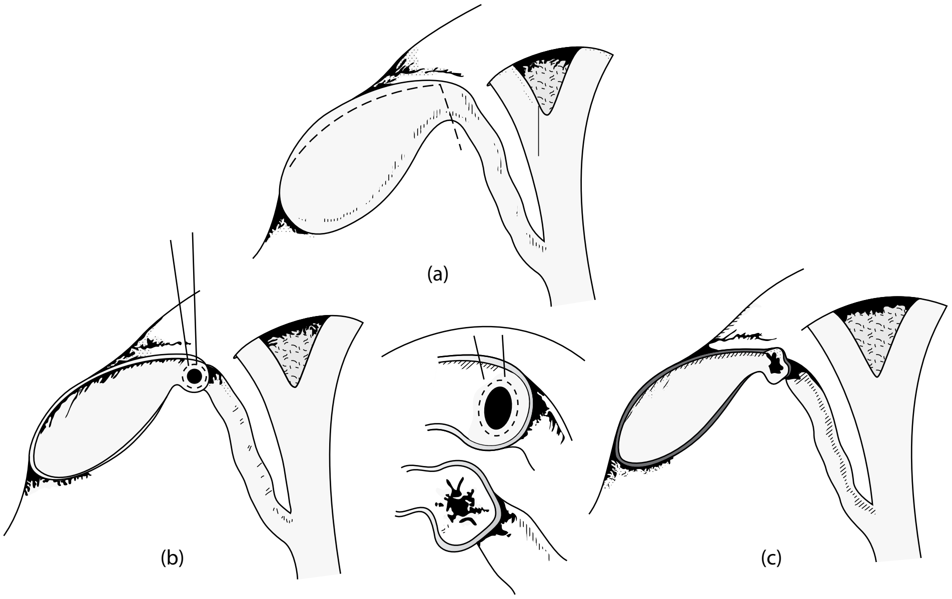

Figure 25.45 Technique of subtotal cholecystectomy described by Bormann and Terblanche: (a) the broken line shows the extent of the cholecystectomy – the posterior wall of the gallbladder is left attached to the liver; (b) a purse-string suture is inserted around the cystic duct orifice; (c) the purse-string suture has been tied with closure of the cystic duct orifice.

Laparoscopic management of severe acute disease

Although the open surgical management outlined above is still considered by many to be the standard surgical management of these severely ill patients, there is a strong case, and indeed an increasing trend, for laparoscopic management. This is intended in the first instance as a diagnostic inspection to assess the severity of the disease. In the presence of established gangrene and perforation, open surgical management as outlined in the preceding section is indicated. Otherwise, a laparoscopic insertion of a self-retaining catheter will effectively drain the inflamed gallbladder and tide the patient over a critical illness. Once this has resolved and if the patient's condition permits, a cholecystectomy (laparoscopic or otherwise) is performed. If the patient's cardiorespiratory status precludes an elective surgical intervention, then gallstone extraction, fragmentation or MTBE dissolution through the established cholecystostomy tract is performed.

Mini-cholecystostomy of Burhenne and Stoller

This is an equally valid approach in poor-risk patients with severe acute disease. After the position of the fundus of the inflamed gallbladder is located by ultrasound, a small incision is made over it. Stay sutures are inserted. The gallbladder contents are aspirated and sent for culture and a Foley catheter is inserted into the gallbladder lumen and held in place by a purse-string suture. This approach, which can be performed under local anaesthesia and sedation, is quick and extremely safe.

Mortality of severe acute cholecystitis

The overall reported mortality of acute cholecystitis is 3%. The mortality in the elderly is higher (10%) and more than half of the deaths in patients over 65 years are secondary to cardiovascular and respiratory complications.

Established non-progressive disease

These form the majority and the acute obstructive cholecystitis usually resolves with conservative treatment. There are two management options:

- delayed (interval, subsequent admission) cholecystectomy
- early (same admission) cholecystectomy.

The interval approach is the traditional one and entails conservative management of the acute episode with discharge of the patient after complete resolution of the attack. Subsequently, the patient is admitted some 2–3 months later for an elective cholecystectomy. The rationale for this treatment is that in most instances the raised pressure within the gallbladder lumen lifts the walls of the organ off the impacted stone which then dislodges and falls into the lumen with resolution of the inflammation, the view being held that it is safer to operate several weeks after the acute inflammatory episode has subsided.

Early cholecystectomy is increasingly favoured in the management of acute cholecystitis. It must be distinguished from emergency cholecystectomy. Following initial conservative management and confirmation of the diagnosis as outlined previously, the patient is operated electively (scheduled urgent) on the next available operating list or within a few days of admission. The results of several prospective clinical trials comparing early vs interval cholecystectomy have shown clear benefits from early cholecystectomy performed during the same hospital admission in fit patients (ASA I and II). These include less time spent in hospital and lower cost of treatment. Fears that an early cholecystectomy is a more hazardous procedure have proved groundless, in particular the incidence of complications including missed common duct stones and mortality rates reported in these prospective trials have been similar. On the other hand, the delayed management has several disadvantages which include:

- failure of conservative treatment in 13%
- premature readmission with a further attack while waiting for elective cholecystectomy (13%)
- patient defaulting after discharge (10%).

More recently, a randomized trial of early vs interval LC for acute cholecystitis has demonstrated similar results. In particular there was no significant difference in the conversion rates (early 21% vs interval 24%), similar morbidity but a significantly ($p < 0.001$) shorter hospital stay, 7.6 vs 11.6 days, although the operating time was longer for the early group, i.e. 122 vs 106 minutes. Similar benefits have been reported by another randomized trial comparing early vs interval LC for acute cholecystitis. Thus early LC carries both medical and socioeconomic benefits over interval LC for acute cholecystitis.

An aggressive policy of early cholecystectomy is indicated in elderly and diabetic patients unless they have comorbid significant heart disease as these patients often have gangrenous disease.

Laparoscopic vs open cholecystectomy

As with the elective situation, LC offers significant advantages over open cholecystectomy for acute cholecystitis, and early LC has rapidly become the treatment of choice for this condition. Aside from several retrospective reports indicative of reduced morbidity and hospital stay, the benefit of LC vs open cholecystectomy for acute cholecystitis has been confirmed by a prospective randomized clinical trial. This study showed a significant reduction in the postoperative morbidity in the LC arm (only 3% minor complications vs 23% major complications and 19% minor complications in the open cholecystectomy group). In adopting LC as the routine option, it must be stressed that the need for conversion is encountered in 5–15% of all cases and is higher in LC for acute cholecystitis. An early decision should be made to convert electively in the presence of obscured anatomy. This is far better than persistence with a difficult operation with enforced conversion because of the onset of an intraoperative complication. These patients are at risk of severe postoperative complications.

Thus the valid approach is a flexible one. The procedure starts with an exploratory laparoscopy to assess technical difficulty of the operation with particular reference to the structures in the triangle of Calot. A large distended gallbladder should be aspirated and lifted by a retractor rather than grasped. Large stones impacted in Hartmann's pouch that cannot be dislodged may prove problematic. The practical axiom is a simple one, i.e. if adequate exposure for a safe dissection cannot be obtained, the case should be converted. In some cases, a fundus first dissection of the gallbladder may be required.

The case for routine fluorocholangiography is much stronger when cholecystectomy is performed for acute cholecystitis as these patients are much more commonly jaundiced (the inflammatory oedema or by concomitant ductal calculi). The cholangiogram should outline the entire biliary tract (intra- and extrahepatic). It ensures safe occlusion of the cystic duct stump without compromise of the common hepatic or common duct and differentiates stones from distortion caused by the inflammatory oedema.

Mucocele of the gallbladder

Mucocele of the gallbladder is usually encountered in elderly patients and presents with a painless mass in the right hypochondrium. Reported data indicate that about 3% of all pathological gallbladders in adults are mucoceles, although the true prevalence may be higher because of the varying criteria used to define the condition. Most commonly mucoceles are associated with solitary gallstones impacted in Hartmann's pouch.

Pathology

The usual underlying pathology is due to longstanding obstruction to the gallbladder which becomes distended with mucus such that the organ may enlarge considerably. The obstruction to the outflow from the gallbladder results in the slow reabsorption of bile and bile pigment but the gallbladder mucosa continues to secrete clear and watery or mucoid fluid (white bile) in copious amounts. Although the gallbladder wall may be of normal thickness, in longstanding cases there is atrophy of the mucosa such that the wall becomes thin and semitransparent. However, wall thickening can develop with recurrent attacks of infection (cholecystitis). The contents of mucocele of the gallbladder are usually sterile, although infection may supervene leading to empyema of the gallbladder. Progressive overdistension may result in gangrene and/or perforation of the gallbladder, with ensuing pericholecystic collection or peritonitis. Other causes of mucocele include:

- resolved acute cholecystitis
- polyps or malignancy of the gallbladder
- compression of the neck or cystic duct by lymph nodes or inflammatory fibrosis
- congenital narrowing of the cystic duct
- obstruction by parasites, e.g. *A. lumbricoides*.

Clinical features

There may or may not be a history of acute pain indicative of biliary colic or mild acute cholecystitis. The clinical features of gallbladder mucocele include right upper quadrant or epigastric pain and discomfort, nausea and vomiting. Fever and rigors indicate the onset of infection with the development of empyema of the gallbladder. Jaundice is unusual except in patients with coexisting bile duct obstruction either by stones or by extrinsic compression (Mirizzi syndrome). On palpation, the distended gallbladder is usually palpable and tender. In uncomplicated cases the laboratory test results are normal or just within the upper limit of the normal range for the laboratory. Plain radiograph of the abdomen shows a soft-tissue density, globular shadow in the subhepatic region and ultrasonography is usually diagnostic: thin distended gallbladder with minimal wall thickening, and impacted stone in the neck/Hartmann's pouch.

Treatment

The treatment is cholecystectomy which can be performed safely by the laparoscopic approach. It is important that the thin-walled distended gallbladder is decompressed by aspiration before it is grasped by any laparoscopic forceps to prevent rupture and escape of contents into the peritoneal cavity.

Acalculous chronic gallbladder disease: hyperplastic cholecystoses

Chronic inflammation of the gallbladder in the absence of gallstones is due to adenomyomatosis or cholesterolosis of the gallbladder and these may be conveniently grouped as acalculous chronic gallbladder disease, sometimes also referred to as hyperplastic cholecystoses. Both conditions are common and involve various layers of the gallbladder wall, but are usually asymptomatic. However, they can give rise to vague symptoms not dissimilar to those of chronic cholecystitis. Oral cholecystography shows no abnormality of the gallbladder in 50% of these patients, or is reported as demonstrating poor function or unusual appearances. Thickening and 'polypoid' lesions/diverticula may be documented by high-resolution ultrasound. In many instances, the diagnosis is made on pathological examination of the excised gallbladder. In general, the results of cholecystectomy for these conditions have been difficult to evaluate but, in the presence of persisting symptoms, most surgeons would advise operation.

Adenomyomatosis of the gallbladder

Adenomyomatosis (diffuse, focal or polypoid) is found in 8.7% of surgical gallbladder specimens. This is variously named as adenomatous hyperplasia, diverticulosis of the gallbladder and cholecystitis glandularis proliferans. It is thought to represent a developmental defect that results in hyperplasia of the smooth muscle bundles with sacculation or diverticulum formation of the epithelial lining (Rokitansky–Aschoff sinuses). The cholecystogram (rarely performed nowadays) may be normal or the late film taken after a fatty meal may demonstrate either the mural diverticula (Figure 25.46) or a concentric narrowing of the fundus.

Adenomyomatosis involves the mucosa and the muscular and connective tissue layers of the gallbladder wall. The epithelium and muscular layers proliferate, and the subsequent invagination of the mucosa into the gallbladder wall produces intramural diverticula (med Rokitansky–Aschoff). These diverticula may accumulate bile, cholesterol crystals, or even stones. On ultrasound examination they may be anechoic if large enough and contain bile but more frequently the diveticula are small and contain cholesterol, biliary sludge or small gallstones that create echogenic foci, often with ring-down or comet tail reverberation artefacts.

There are three distinct forms of adenomyomatosis. The most common form of adenomyomatosis is a focal polypoid lesion, also known as an adenomyoma, typically located at the tip of the gallbladder fundus. The segmental form consists of localized gallbladder wall thickening that typically narrows the gallbladder body in an hourglass configuration. Diffuse adenomyomatosis involving the entire gallbladder wall is less common than focal or segmental diseases.

Treatment

This is needed only in symptomatic patients in whom other pathologies have been excluded by appropriate investigations, and consists of LC, which may or may not relieve their symptoms.

Cholesterolosis of the gallbladder

In this condition, the epithelial cells and macrophages within the gallbladder mucosa become laden with cholesterol and lead to the formation of numerous lipid deposits. Chronic inflammation of the adjacent mucosa then leads to a striking appearance of the interior of the gallbladder, which has been aptly described as the 'strawberry gallbladder'.

Cholesterolosis, which may be diffuse or polypoid, has been reported in up to 25% of surgical specimens. The condition is caused by deposition of lipid-laden macrophages in the lamina propria of the normal mucosal epithelium of the gallbladder wall. The diffuse form, which is more common, is more likely to cause symptoms. Cholesterol polyps account for 20% of cholesterolosis but constitute approximately one-half of all gallbladder polyps. They are usually less than 1.0 cm in size, often multiple, and have no malignant potential. On ultrasound they appear as brightly echogenic, round or lobulated, immobile, non-shadowing masses abutting the gallbladder wall. The condition is very rarely symptomatic.

Ductal calculi and cholangitis

The majority of ductal calculi are found in the common bile duct and, in the West, only an estimated 5% of ductal calculi are located

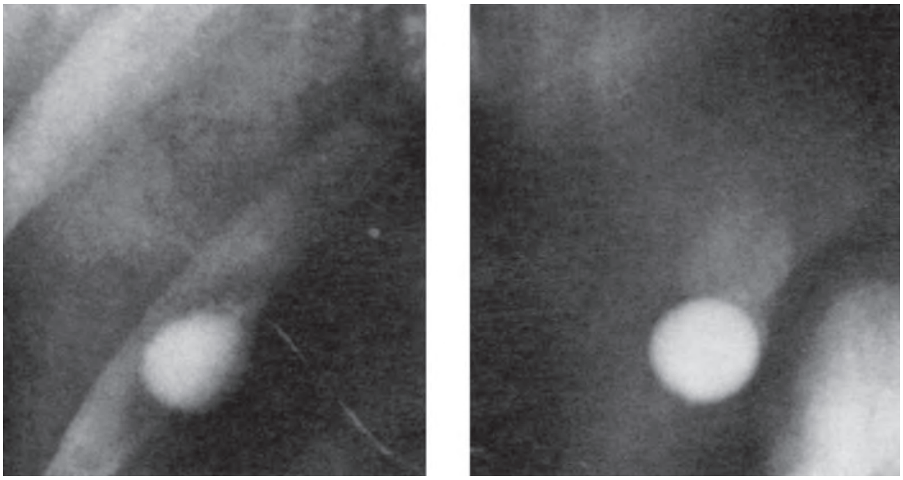

Figure 25.46 Oral cholecystogram: a concentric narrowing of the fundus is the striking feature but on closer inspection, intramural diverticula are discernible. When encountered, these are pathognomonic of adenomyomatosis of the gallbladder. Often, however, the oral cholecystogram is normal.

in the intrahepatic ducts (more commonly the left), although multiple intrahepatic calculi are common in Eastern countries, especially where parasitic infestations and recurrent pyogenic cholangitis are endemic. Ductal calculi may arise as follows:

- as secondary calculi from migration of gallstones
- as primary calculi arising *de novo* within the bile ducts.

Primary ductal calculi are brown pigment stones. Their composition and infective aetiology are discussed earlier in this chapter. In surgical practice, brown pigment stones are often encountered in the following conditions:

- stasis in the biliary tract caused by strictures, tumours and sclerosing cholangitis
- parasitic infestations
- recurrent pyogenic cholangitis (Asia)
- indwelling endoprostheses/internalized clips and non-absorbable sutures.

Less commonly, pigment stones form around metal clips and non-absorbable sutures when these become incorporated inside the bile duct. The important predisposing condition to infection and brown pigment stone formation is stasis and this requires correction in addition to removal of the calculi and eradication of any infection.

Clinical manifestations of ductal calculi

Although 15–20% of patients with stones in the common bile duct are asymptomatic, the majority present sooner or later with severe symptoms, and by and large incur a significant morbidity as the pathological potential of ductal calculi is high and may contribute to the death of the patient. Ductal calculi may present with:

- recurrent bouts of biliary colic accompanied by intermittent jaundice
- episodic upper abdominal pain and dyspepsia (Figure 25.47)
- stone impaction with progressive jaundice
- cholangitis
- gallstone pancreatitis
- secondary biliary cirrhosis and portal hypertension.

Management of ductal calculi

Role of endoscopic sphincterotomy and stone extraction

The current orthodox treatment for ductal calculi is by endoscopic sphincterotomy and stone extraction; in patients requiring cholecystectomy for symptomatic gallstone disease, endoscopic stone extraction is performed before the operation preferably during the same hospital admission. However, the increasing efficacy and usage of laparoscopic stone clearance for patients harbouring ductal calculi is challenging the role of preoperative endoscopic stone extraction in centres with the necessary expertise. In addition, there is increasing concern regarding sphincterotomy in patients below the age of 50 years. The short-term morbidity of endoscopic stone extraction ranges from 5% to 10%. It has a median failure rate of 10% and a mortality of 0.5–1.0%. In addition, endoscopic sphincterotomy carries a long-term morbidity that includes recurrence of common duct stones (average of 11%), and stenosis (3% in the absence of papillitis and 30% if papillitis is present). Further, the sphincterotomy results in bacterial colonization of the extrahepatic biliary tract.

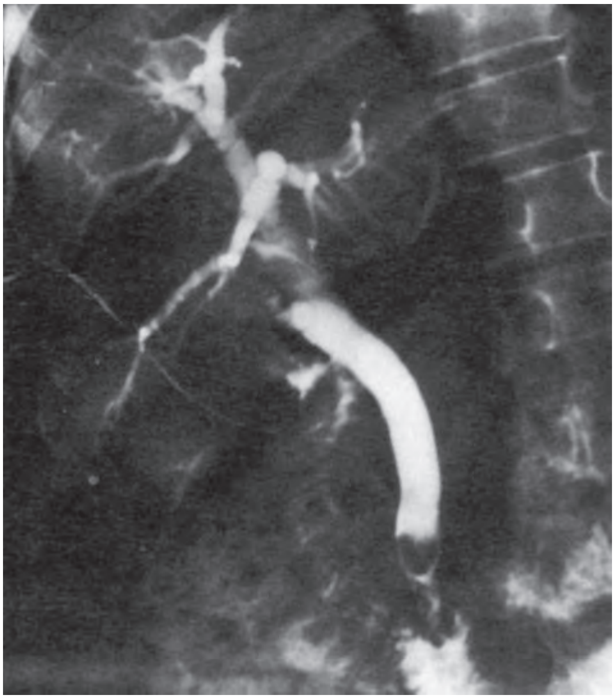

Figure 25.47 Primary ductal calculi situated at the lower end of the bile duct 13 years after a cholecystectomy. The patient complained of dyspepsia and episodic abdominal pain. Although the patient was not jaundiced, the liver function tests showed a mild elevation of the serum bilirubin and raised alkaline phosphatase.

There is agreement that the two-stage approach is indicated in poor-risk patients including those with established cholangitis or severe pancreatitis, but these constitute only 30% of patients with ductal calculi. In fit patients with ductal stones, single-stage laparoscopic surgical treatment (laparoscopic stone extraction and cholecystectomy) is gaining favour among laparoscopic surgeons, especially as the evidence from four randomized clinical trials is that the two-stage sequential management of patients with ductal stones is inferior (increased overall morbidity) to single-stage surgical treatment. A large clinical trial involving 300 randomized patients showed the same efficacy, morbidity and mortality but a significant reduction in the hospital stay in the single-stage laparoscopic arm. Undoubtedly, the single-stage laparoscopic approach requires a lesser resource and should replace the two-stage approach on the grounds of equal efficacy and safety but diminished costs. On average in 50% of patients undergoing ERCP for suspected ductal calculi, the ERCP is normal. The persistence of the two-stage approach is attributed to reluctance of gastroenterologists to relinquish this treatment and the limited number of centres undertaking laparoscopic ductal stone extraction routinely – regrettably the two are interlinked. If evidence-based treatment is to be followed, then endoscopic stone extraction should reserved for:

- poor-risk patients
- patients with cholangitis
- patients with severe pancreatitis

- some patients with failed laparoscopic stone extraction as an alternative to conversion
- retained or recurrent stones after cholecystectomy.

In elderly or poor-risk patients, endoscopic sphincterotomy alone leaving the gallbladder *in situ* has been recommended in the past. However, subsequent clinical trials comparing this approach with definitive single-stage treatment (open or laparoscopic) have shown similar morbidity and mortality rates and a high incidence (30%) in patients with *in situ* gallbladder of biliary symptoms/cholecystitis requiting subsequent cholecystectomy. Thus endoscopic sphincterotomy alone is no longer favoured unless the patient is totally unfit for surgery (Figure 25.48).

Laparoscopic extraction of ductal calculi

The techniques of laparoscopic ductal stone clearance include:

- transcystic duct extraction
- direct supraduodenal common bile duct exploration
- rendezvous laparoendoscopic approach.

Transcystic duct extraction

This is the least invasive technique and has the undoubted merit of leaving the extrahepatic biliary tract including the choledochal sphincter intact. Thus its morbidity is low and the average postoperative hospital stay is short (3 days). It is indicated for small floating stones up to 5 mm diameter, where its reported efficacy in achieving ductal stone clearance ranges from 80% to 95%. There are two commonly used techniques:

- the choledochoscopic visually guided method
- the radiologically guided wire basket trawling technique.

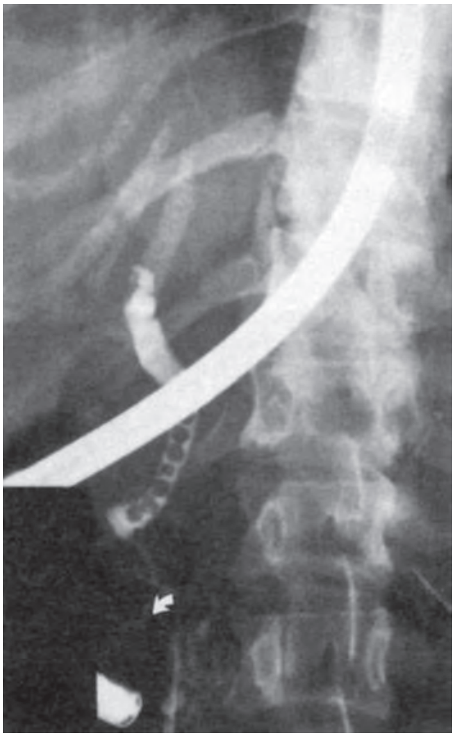

Figure 25.48 Endoscopic papillotomy for multiple ductal calculi in an elderly patient. The wire of the sphincterotome is visible above the tip of the endoscope.

The choledochoscopic technique requires dilatation of the cystic duct before insertion of the mini-choledochoscope through the cystic duct into the common bile duct. The stones are visualized and trapped using a wire basket introduced through the instrument channel of the endoscope and extracted through the cystic duct. Some advocate delivering the trapped stones through the sphincter of Oddi into the duodenum where they are released. This is, however, not generally recommended because of the risk of pancreatitis. A completion cystic duct cholangiogram is performed, and if this is normal the cystic duct is ligated and the gallbladder removed. If there is any doubt about residual fragments, a cystic duct drainage cannula (Cook) is inserted into the common bile duct and tied to the cystic duct with two Roeder catgut extracorporeal slip knots. A postoperative cholangiogram is performed 24 hours later. If this is normal, the cystic duct drainage cannula is capped with a Luer lock and covered with an occlusive dressing before the patient is discharged usually on the third postoperative day. The cannula is removed as an outpatient 10–14 days later.

The radiologically guided trawling technique is quicker and simpler than the above. Furthermore, it has the added advantage of obviating the need for dilatation of the cystic duct. It consists of the insertion of a soft pleated four-wire basket in the closed position through the cystic duct into the lower end of the common bile duct. Once in position with the tip among the stones, the basket is fully opened and then withdrawn slowly. No attempt is made to close the basket as the wires of this are folded over the stones by the narrow cystic duct during the trawling process (Figure 25.49a–d). With experience, the radiological exposure is minimal. The trawling process is repeated until complete stone clearance is achieved.

Laparoendoscopic approach

This combined approach entails insertion of a guide wire by the laparoscopic surgeon through the cystic duct down the common bile duct into the duodenum. The endoscopist then performs a sphincterotomy and stone extraction with the patient in the supine position. The reported experience with the laparoendoscopic technique although limited has been entirely favourable, but the technique requires additional resource and the availability of an experienced flexible endoscopist. The perceived risk of acute postoperative pancreatitis with this technique has not materialized in any of the reported series.

Direct supraduodenal common bile duct exploration

This is indicated for large or occluding stones. The technique is similar to open exploration of the common bile duct. The dissection is minimal and consists of exposure of the anterior wall of the common bile duct after downward displacement of the duodenum. No stay sutures are inserted. A choledochotomy is made in the supraduodenal segment. The size of the choledochotomy should be approximately half to three-quarters the maximum diameter of the largest stone. Avoidance of a large choledochotomy reduces the amount of intracorporeal suturing needed, and, in view of the elasticity of the common bile duct, the opening can be stretched to accommodate large stones. The extraction manoeuvres include milking the duct from below upwards with an instrument on side, balloon dislodgement and direct visual wire basket extraction after the insertion of a 4 mm flexible choledochoscope. The stones delivered through the choledochotomy are removed by the Semm's spoon forceps. Following ductal clearance, biliary drainage is advisable. This can be performed by the orthodox T-tube (Figure 25.50), or preferably through a cystic duct drainage cannula (Figure 25.51). This is inserted until the S-shaped perforated terminal segment is well inside the common bile duct, after which it is secured to the cystic duct by two Roeder catgut sutures. Primary closure of the choledochotomy is carried out, during which the common bile duct is constantly irrigated with saline via the cystic duct drainage cannula.

In either case, a completion cholangiogram is essential to ensure ductal clearance and a subhepatic drain is necessary. The cystic duct drainage cannula or the T-tube is firmly anchored to the abdominal wall and connected to a biliary drainage bag. When a cystic duct drainage cannula is used, the postoperative cholangiogram is carried out on the second day; if this is normal, the cannula is sealed with a Luer lock and covered with an occlusive dressing. In the absence of any bile leakage from the subhepatic drain over the next 24 hours, the drain is removed and the patient discharged the next day with the cystic duct drainage cannula *in situ*. This is removed 7 days later as an outpatient. If a T-tube has been inserted, the postoperative cholangiogram is carried out on the seventh postoperative day, and, if normal, the tube is clamped and provided there is no leakage from the subhepatic drain and the patient has no symptoms or fever over the next 24 hours the T-tube is removed. The subhepatic drain is removed a day later. In the elderly, diabetics and patients on immunosuppressive drugs, the T-tube is kept in place for at least 2 weeks as the maturation of the T-tube tract is impaired in these patients. Thus early removal may lead to biliary peritonitis.

Patients with ductal calculi discovered during elective cholecystectomy (unsuspected ductal calculi)

These account for 4–10% of cases and are discovered by routine IOFC. They are usually small floating calculi without dilatation of the common bile duct. As these patients have no obstruction and normal liver function tests, some surgeons have advocated no intervention other than the cholecystectomy on the grounds that some of these calculi will pass spontaneously and if and when

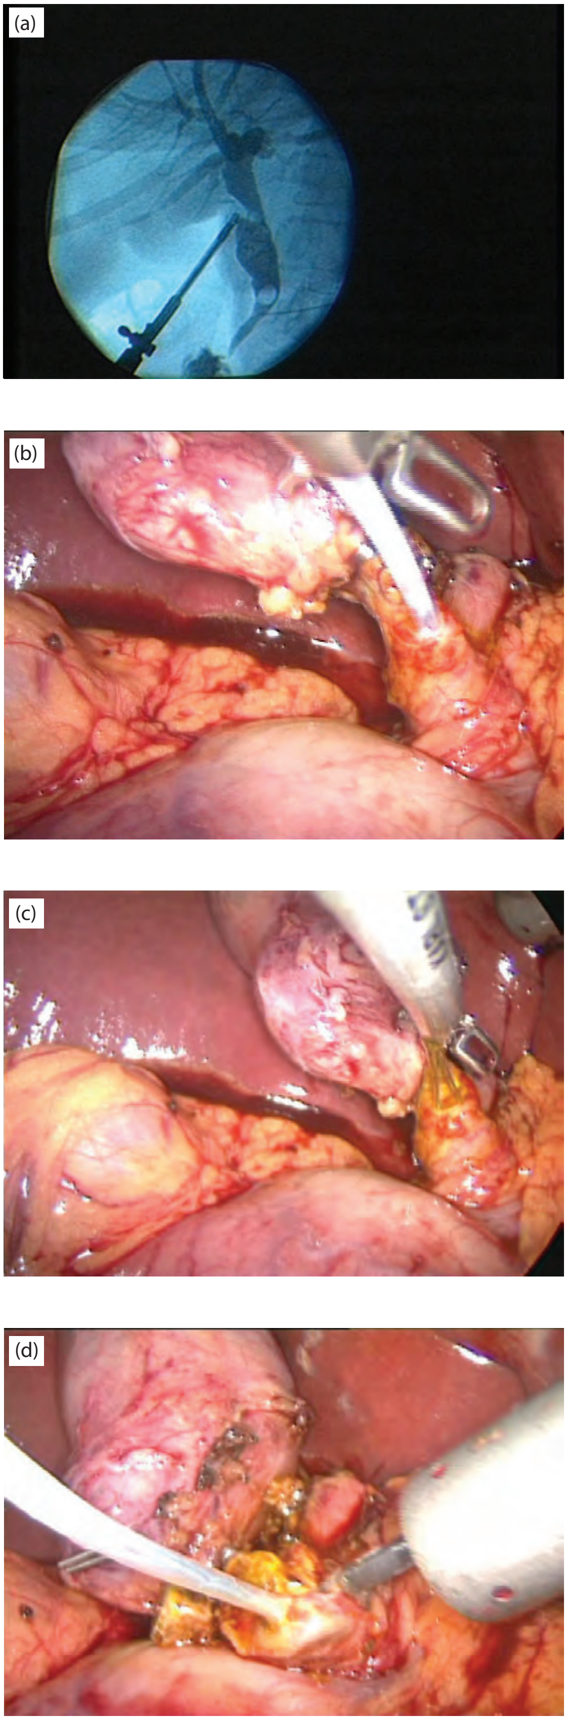

Figure 25.49 (a) Ductal calculi on the intraoperative cholangiography. (b,c) Transcystic duct clearance with a pleated soft wire basket.

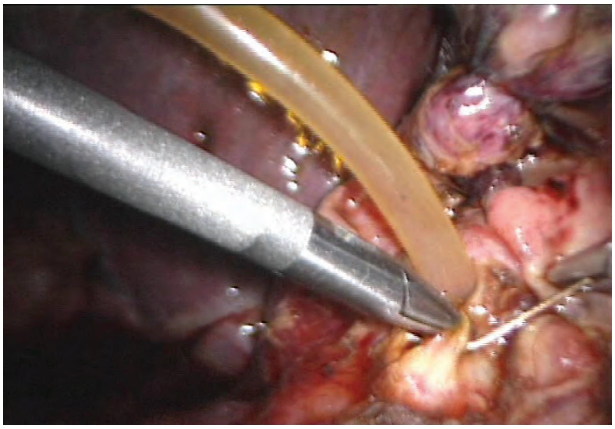

Figure 25.50 Laparoscopic common bile duct exploration with closure of the common bile duct around a T-tube.

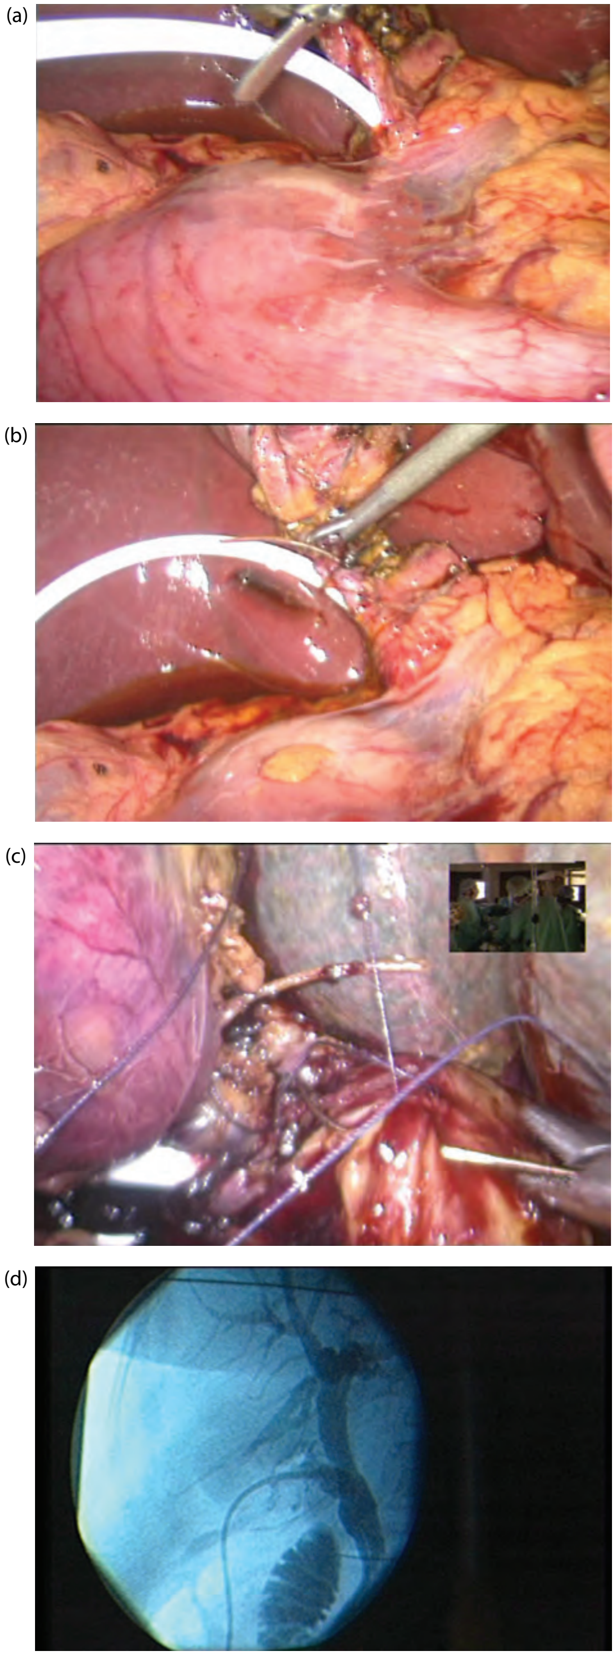

Figure 25.51 Decompression of the extrahepatic biliary tract by the Cuschieri cystic duct drainage cannula with primary closure of the choledochotomy: (a) a drainage cannula is inserted and fixed to the cystic duct stump; (b) primary closure of the choledochotomy; (c) completion cholangiogram through the cystic duct drainage cannula.

they become symptomatic or complications arise after surgery, endoscopic sphincterotomy can be performed. This policy is ill founded for several reasons. In the first instance, there are no hard data as to the frequency of spontaneous passage without complications. Furthermore, it is impossible to predict uncomplicated stone passage in the individual patient. This expectant policy will incur a definite morbidity from jaundice, cholangitis or pancreatitis and some (albeit few) patients will die as a result of one of these complications. The appropriate management of these patients, based on the known pathogenic potential of ductal calculi, is removal either at the time of LC (transcystic duct extraction) or by postoperative endoscopic sphincterotomy.

Ductal calculi discovered soon after cholecystectomy and exploration of the common bile duct

These are referred to as missed, retained or residual stones. The incidence varies from 2% to 15% and averages 8%. Routine completion choledochoscopy/cholangiography virtually abolishes this complication. Retained ductal calculi following biliary tract surgery are either diagnosed in the immediate postoperative period by the postoperative T-tube cholangiogram or present with recurrent symptoms usually within 2 years of cholecystectomy without exploration of the common bile duct. Ductal stones presenting beyond this interval are generally considered to be of the primary variety.

Certain general considerations apply with regard to the management of patients with residual calculi following biliary tract surgery. Urgent intervention is not indicated if the liver biochemistry is normal, the patient is asymptomatic, and the T-tube cholangiogram shows no organic disease or significant dilatation. Spontaneous passage is likely if the calculi are small (less than 3 mm) and may be aided by simple measures such as T-tube clamping. If the patient tolerates clamping and providing no untoward symptoms or complications develop, such a conservative approach can be continued for a few weeks, at the end of which time the situation is reviewed radiologically.

The various methods available for the non-surgical management of retained stones are:

- flushing
- dissolution
- percutaneous stone extraction via the T-tube tract
- endoscopic sphincterotomy and stone extraction.

The first three options are applicable only to patients with an indwelling T-tube whereas endoscopic stone extraction can be used in all patients. All the above methods are performed under antibiotic cover because of the risk of cholangitis and septicaemia.

Flushing is usually carried out with saline, heparinized saline or lidocaine–saline solution. The technique, which is simple and effective if the stones are small (<0.3 mm), is performed by infusing the solution through the T-tube under manometric control to ensure that the pressure does not exceed 30 cmH_2O, as this can lead to cholangiovenous reflux and septicaemia. The efficacy of this simple method of treatment, which does not require any special expertise, can be enhanced when it is accompanied by pharmacologically induced relaxation of the sphincter of Oddi.

Cholate infusion can dissolve cholesterol stones but its efficacy is low and it has been replaced by mono-octanoin, which acts more rapidly and achieves complete stone clearance in 40%. The most effective agent for the dissolution of ductal calculi is MTBE, which is capable of achieving gallstone dissolution within hours of instillation.

Percutaneous stone extraction via the T-tube tract was initially performed by the Burhenne technique using a Dormia basket introduced via a specially designed steerable catheter to capture and extract the stone under fluoroscopic control. It has largely been replaced by the flexible choledochoscopic technique which is successful in 90–95% of cases. A 4–6 week period of maturation of the T-tube tract is required before the procedure can be performed safely. A guide wire is introduced into the common bile duct and the T-tube removed. Thereafter, the T-tube tract is dilated to allow the introduction of the narrow flexible choledochoscope. The retained stones are removed by means of a Dormia basket under visual control.

Endoscopic sphincterotomy with stone extraction is the most effective method of dealing with the problem of retained stones and can be performed in patients with and without T-tubes. Surgical management of missed stones is reserved for those patients in whom the above methods have failed or complications have developed during or after attempted endoscopic or percutaneous stone extraction.

Recurrent ductal calculi

Ductal calculi presenting 2 years or more after an operation are generally regarded as primary. One study has identified suture material in 30% of cases. This finding stresses the importance of avoiding non-absorbable material during operations on the biliary tract. Internalization of metal clips used to secure the medial end of the cystic duct during LC is now a well-recognized complication of this procedure. The exact pathology remains unclear, but it seems likely that the clip is placed too close to the common bile duct resulting in localized pressure necrosis. The internalized clip becomes covered with calcium bilirubinate to form a brown pigment stone. The patients who develop this condition present between 6 and 12 months after the procedure with jaundice and/or cholangitis. The condition is easily diagnosed on the ERCP films as the stone has a characteristic 'cat's eye' appearance.

The management of patients with recurrent ductal calculi depends on their age and general condition. Endoscopic sphincterotomy and stone extraction is the first-line treatment and surgery (open or laparoscopic) reserved if this approach fails. During surgery, the stones are removed atraumatically by means of biliary balloon catheters, stone-grasping forceps or Dormia baskets as described previously. A completion check by means of a choledochoscopic inspection or cholangiography abolishes or reduces the incidence of residual stones. Temporary biliary drainage is advisable and provides a means of decompression.

In other situations, recurrent ductal calculi are often multiple and associated with gross dilatation of the bile duct and in some cases obvious distal ductal stenosis. This may be primary (papillary stenosis) or be secondary to trauma inflicted by metal bougies introduced through the sphincter region at the time of exploration of the common bile duct. In patients with multiple ductal calculi, grossly dilated bile duct (>2 cm) or papillary stenosis, a drainage operation is indicated: choledochoduodenostomy or transduodenal sphincteroplasty. Opinions are divided as to the relative merits of these two procedures. However, sphincteroplasty carries a significant risk of pancreatitis and involves a sizeable duodenotomy. A transection choledochoduodenostomy (Figure 25.52) is preferable to the side-to-side anastomosis as it provides dependent drainage and avoids the complication of the inspissated sump syndrome. Transection choledochoduodenostomy can be performed laparoscopically and is a relatively straightforward procedure as the bile duct is grossly dilated in these patients (Figure 25.53).

Intrahepatic calculi (hepatolithiasis)

Intrahepatic stones (hepatolithiasis) are prevalent in Southeast Asia but rare in Western countries. They are defined as stones located in the biliary tract proximal to the confluence of

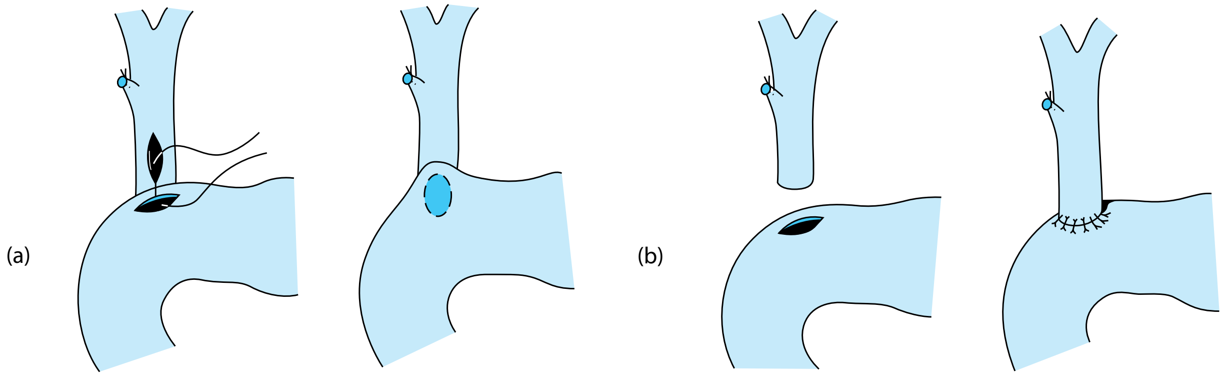

Figure 25.52 Choledochoduodenostomy: (a) lateral or side-to-side choledochoduodenostomy – this may result in the passage of food debris from the duodenum through the stoma into the lower end of the bile duct (distal to the anastomosis with the development of the inspissated sump syndrome which presents with cholangitis). (b) Diagrammatic technique of the procedure of transection choledochoduodenostomy. The bile duct is mobilized from the portal vein and hepatic artery. It is then transected as it enters the pancreas. The distal end is closed with a running suture and the proximal end is anastomosed in an end-to-side fashion to the duodenum at the junction of the first with the second part.

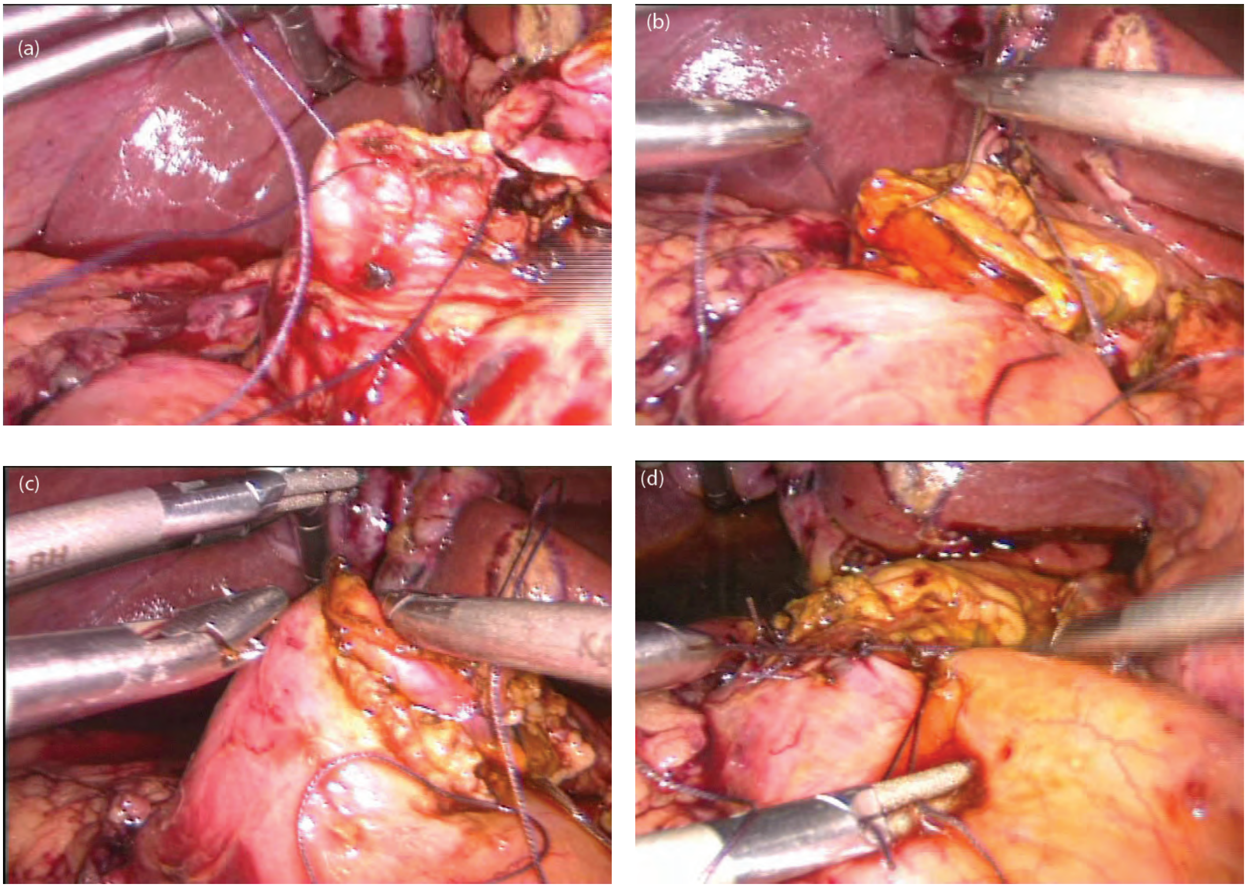

Figure 25.53 Laparoscopic transection choledochoduodenostomy for multiple ductal calculi and grossly dilated duct: (a) closure of the distal pancreatic end of the transected dilated common bile duct (CBD); (b) proximal end of the CBD approximated to the superior border of the duodenum; (c) completed running posterior anastomotic line; (d) interrupted anterior suture line using inverting deep seromuscular sutures.

the right and left hepatic ducts. Intrahepatic stones are categorized as:

- primary intrahepatic stones, which form within the intrahepatic ducts and are associated with intrahepatic duct strictures
- secondary, which form within the extrahepatic ducts but migrate subsequently to the intrahepatic ducts.

Primary intrahepatic duct stones are usually multiple and occur in association with pathological changes in the intrahepatic biliary tree: strictures, dilatations or angulation. The condition is also known as recurrent oriental cholangitis and has been recently reviewed.

Epidemiology

Primary intrahepatic stones are prevalent in East Asian countries (Taiwan, China, Japan and Korea) and rare in Western countries, the Middle East and Africa. In Taiwan, primary ductal calculi account for more than 50% of all cases of cholelithiasis and in Japan, 34%.

In countries of high prevalence, primary intrahepatic stones occur more frequently in rural areas, and this has been attributed to a low-protein, high-carbohydrate diet, although the reason for this dietary factor is not known. Some have suggested that a low-protein diet decreases glucuronolactone in bile, which is an inhibitor of β-glucuronidase. Glucuronolactone deficiency may thus lead to increased deconjugation of bilirubin diglucuronide with formation of calcium bilirubinate stones.

Pathology

The exact aetiology of primary intrahepatic calculi is not known, but several risk factors have been identified:

- infection by β-glucuronidase-producing bacteria
- parasitic infestations
- bile stasis and bile duct strictures
- congenital anomaly of bile ducts
- low-protein, high-carbohydrate diet
- low hygiene standards.

Bacterial infection of the biliary tree and bile stasis appear to be the most important as the prevalence of bacteria in the bile of patients with hepatolithiasis exceeds 90%. Furthermore, bile infection precedes formation of intrahepatic stones. Several bacterial species are responsible for the infection including *E. coli*, *Clostridium* spp. and *Bacteroides* spp. All exhibit β-glucuronidase enzyme activity, which is thought to be responsible for the hydrolysis of the soluble bilirubin glucuronide to the water-insoluble unconjugated bilirubin which then combines with ionized calcium and precipitates, forming calcium bilirubinate stones. Intrahepatic stones are usually associated with strictures and dilatations of the intrahepatic ducts.

Parasitic infestation, e.g. *A. lumbricoides* or *Clonorchis sinensis*, has also been implicated as a risk factor but this is unlikely for several reasons. In Taiwan, which has a very high incidence of intrahepatic lithiasis, infestation with *C. sinensis* is rare and in Japan, which has the second highest incidence, the prevalence of intrahepatic brown pigment stones has remained high despite the eradication of these parasites. Furthermore, the prevalence of gallstones in individuals of Chinese and Japanese descent born and living in the USA is no different from that of the general population.

Clinical features

Many patients with intrahepatic stones may remain asymptomatic for many years and often the condition is only discovered during routine investigation. Symptomatic patients can present with upper abdominal pain, occasional fever, rigors and, less frequently, jaundice. These symptoms are largely due to recurrent episodes of cholangitis. The laboratory findings include abnormal elevations of serum alkaline phosphatase, 5-nucleotidase and γ-GT. In addition, these patients have moderate elevations of serum transaminases and mild to moderate iron-deficiency anaemia. Untreated patients with longstanding disease with recurrent attacks of bacterial cholangitis can develop biliary cirrhosis with coagulation defects, low serum albumin and the development of ascites.

The important imaging modalities to establish the diagnosis include CT, MRCP and PTC. Ultrasound scanning is used for screening only as its diagnostic accuracy for documenting the full extent of hepatolithiasis is limited. In contrast, CT scanning provides detailed objective information on the number and location of the intrahepatic stones and the deformity/dilatation of intrahepatic ducts. MRCP is also useful in this respect. ERCP should be used with caution as, despite its established ability to accurately delineate the extrahepatic and intrahepatic ducts and detect intrahepatic stones, it can be complicated by severe cholangitis. PTC is very useful especially in the presence of strictures and has several advantages:

- It can be converted to percutaneous transhepatic biliary drainage (PTBD) in patients with obstruction and cholangitis.
- When established and mature, the PTBD tract can be dilated for the introduction of a flexible cholangioscope providing a percutaneous method of non-surgical treatment.

Treatment

Currently, two major treatment modalities are used with specific indications:

- surgical operative management
- percutaneous treatment.

Surgical management is still the mainstay of therapy. However, percutaneous transhepatic cholangioscopy removal gives good results and is emerging as the initial treatment in patients with bilateral disease.

Surgical treatment

This aims at both complete removal of stones and dilation of bile duct strictures to ensure adequate drainage with no bile stasis, essential for the prevention of recurrence and bacterial infections. When stones are located only in the left intrahepatic ducts and the affected left hepatic lobe is fibrotic and atrophic, left lateral hepatic segmentectomy or left hepatic lobectomy is the appropriate treatment. Likewise for disease located exclusively in the right intrahepatic ducts, right anterior or posterior segmentectomy may be necessary. Right hepatic lobectomy is however inadvisable because of surgical risks especially because the percutaneous cholangioscopic approach provides a much safer and effective treatment. In the past, an extended hepaticojejunostomy (Roux-en-Y) with a permanent cutaneous access was used for the removal of stones from the right hepatic ductal system. However, this has been largely replaced by the percutaneous transhepatic treatment.

When hepatolithiasis involves both intrahepatic ducts (more than 50% of patients), surgical treatment may be used for left lateral hepatic segmentectomy or left hepatic lobectomy and extended hepaticojejunostomy (Roux-en-Y) with permanent cutaneous access. The right intrahepatic stones are then removed percutaneously. Some would however disagree with this and recommend percutaneous treatment for bilateral stones as the first option before recourse to surgical treatment.

Percutaneous transhepatic approach

The percutaneous transhepatic approach has several advantages. Jaundice, when present, is relieved by PTBD. Provided the site of PTBD has been adequately selected, it will provide access for the insertion of the flexible endoscope used for the percutaneous treatment. This treatment is applicable to patients with multiple bilateral intrahepatic stones. Various modalities, e.g. electrohydraulic lithotripsy, laser lithotripsy, mechanical basket, can be introduced to remove or fragment stones. Strictures can be dilated by balloons or by bougienage and the passage of Yamakawa catheters through the tract.

However, percutaneous transhepatic cholangioscopic stone removal requires an experienced interventional endoscopist, preferably working with an interventional radiologist. The long-term results of percutaneous transhepatic cholangioscopy are similar to those of surgery. The most important factors affecting the recurrence are the presence of strictures and bile stasis.

Cholangitis

Acute bacterial cholangitis is a serious, life-threatening emergency caused by infection of an obstructed biliary tract. The systemic manifestations of the acute illness result from bacteraemia secondary to cholangiovenous reflux induced by the biliary hypertension ($<20\,\text{cmH}_2\text{O}$). The most common obstructing agent is an occluding stone in the common bile duct, followed by bile duct strictures (including sclerosing cholangitis) and tumours of the bile ducts, pancreatic head and periampullary lesions. Less commonly, cholangitis is secondary to bilioenteric anastomoses, spontaneous bilioenteric fistulas, cystic disease of the biliary tract and duodenal diverticula. Cholangitis may also occur following instrumentation of the biliary tract. Thus, it is encountered in 7% of patients undergoing ERCP. The risk factors for cholangitis following this investigation are the presence of fever before the procedure and malignant biliary obstruction. Thus, early decompression is indicated in these patients soon after the ERC. Cholangitis caused by contamination

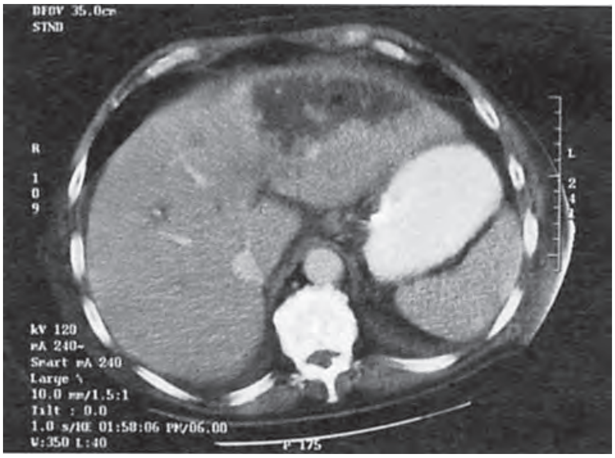

Figure 25.54 Intrahepatic segmental portal vein thrombosis with necrosis and abscess formation (central gas shadow) in a patient with severe cholangitis following preoperative stenting of a cholangiocarcinoma. The infected segmental necrosis developed after resection of the tumour. At operation gross purulent cholangitis was observed as the biliary tract was transected above the tumour. The condition proved fatal despite resection of segments II and III.

of the endoscopes (*Pseudomonas* spp.) has also been reported. Cholangitis occurs frequently (38%) as a complication of PTBD and is the main reason for abandoning preoperative decompression by this technique prior to surgical treatment in patients with severe obstructive jaundice. In Asia, recurrent pyogenic cholangitis is a frequent cause of recurrent bacterial cholangitis and is known as recurrent oriental cholangitis.

In severe cases of cholangitis there is neutrophil infiltration of the sinusoids and microabscess formation in the hepatic lobules. Portal thrombi and areas of hepatic necrosis are present in patients with severe disease accompanied by hypotension (Figure 25.54).

The infection is most commonly caused by Gram-negative organisms. The classical triad of symptoms consists of pain in the right hypochondrium, intermittent fever and jaundice (Charot's biliary fever), but the complete triad is present in only 70% of cases. Aside from toxicity, the high intermittent pyrexia is accompanied by severe rigors. The pain varies in intensity and may be severe. There is usually tenderness in the right hypochondrium, which, if marked, suggests the presence of abscess formation (honeycomb liver). The liver is often enlarged although this may be difficult to ascertain because of the abdominal tenderness. Nausea and vomiting are frequent accompaniments. Hypotension is present in patients with severe cholangitis, when renal failure is usually present.

Prompt and energetic treatment is mandatory. Resuscitative measures include crystalloid and colloid solutions. A blood culture is taken and systemic antibiotics are commenced (cephalosporin with metronidazole or piperacillin, or imipenem). The majority respond to this treatment but some (up to 30%) do not, and these patients require emergency biliary decompression. The patients who do not usually respond to conservative therapy include:

- females
- patients aged >50 years
- patients with acute renal failure
- patients with liver abscesses
- patients with bile duct stricture
- cirrhotic patients
- patients in whom the cholangitis is secondary to biliary instrumentation.

Biliary decompression may be accomplished surgically, endoscopically or by percutaneous techniques. For most patients with cholangitis and ductal calculi, endoscopic decompression by sphincterotomy and extraction of calculi is generally favoured, especially if the patient is elderly. If the calculi cannot be extracted a temporary pigtail stent draining the proximal biliary tree into the duodenum is inserted endoscopically. The alternative is surgical exploration with ductal clearance and insertion of a T-tube. Surgical intervention is the treatment of choice if the stones are large. Cholangitis secondary to biliary instrumentation often requires operative treatment. Percutaneous transhepatic drainage is useful in patients with cholangitis complicating strictures and malignant obstruction. The overall reported mortality of patients requiring urgent decompression for severe cholangitis is 15–20%.

Sclerosing cholangitis

This is an obscure disorder of uncertain aetiology, which results in a progressive fibrous obliteration of the biliary tract. The prevalence of primary sclerosing cholangitis (PSC) approximates to 20–40 per million population. Although sclerosing cholangitis has well-recognized histological, radiological and clinical features, there are no pathognomonic findings that reliably differentiate this disease from other hepatobiliary disorders. The distinction between primary and secondary types is no longer held to be valid. The term primary was formerly used to indicate no previous biliary surgery or biliary tract disease. Often, however, sclerosing cholangitis occurs as a secondary complication of inflammatory bowel disease, usually ulcerative colitis and, much less commonly, Crohn disease. The condition is currently regarded as an immune-complex disorder evoked by endotoxin–antibody complexes that have been identified in the peripheral blood of patients with inflammatory bowel disease.

The classification of the disorder is based on the extent of involvement of the biliary tree by the fibrous obliterative process (Table 25.3)

The disease results in extensive fibrosis which extends beyond the confines of the biliary ductal walls. Histologically, the fibrosis is concentric (onion shell) with patchy, chronic inflammatory infiltrate consisting of mononuclear cells and polymorphs (Figure 25.55). In addition, changes of cholestasis are seen. The gross fibrous thickening results in localized or multiple stricture formation. Although the ductal epithelium is frequently normal, it may become ulcerated and exhibit saccule formation. The

Table 25.3 Classification based on extent of involvement of the biliary tree

Type	Incidence (%)
Total diffuse	50
Localized hilar	25
Diffuse intrahepatic	10
Diffuse extrahepatic	10
Localized extrahepatic (distal)	5

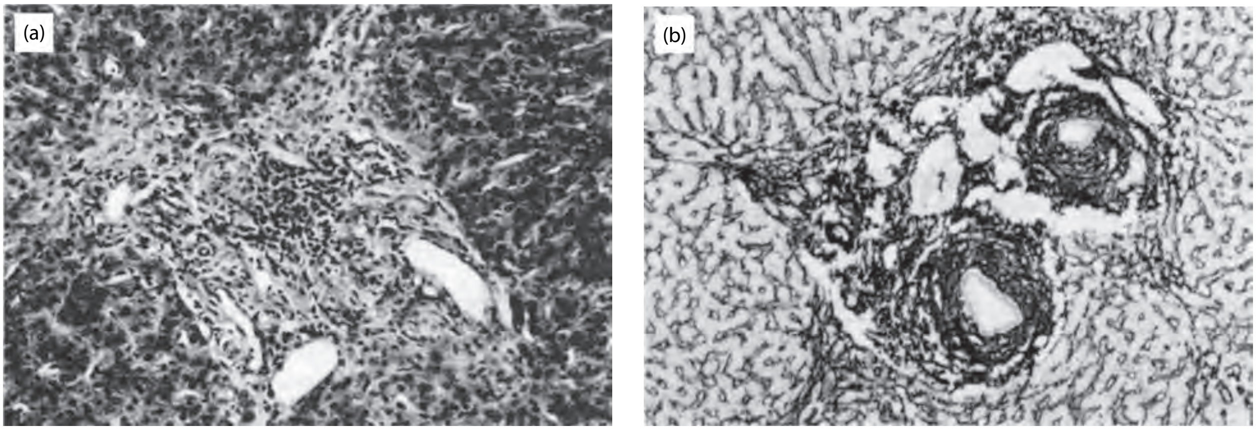

Figure 25.55 Sclerosing cholangitis: (a) histology of wedge liver biopsy (haematoxylin and eosin) showing narrowing of the intrahepatic ducts, fibrosis and cellular infiltrate; (b) reticulin stain of the same biopsy illustrating concentric deposition of fibrous tissue around the bile ducts.

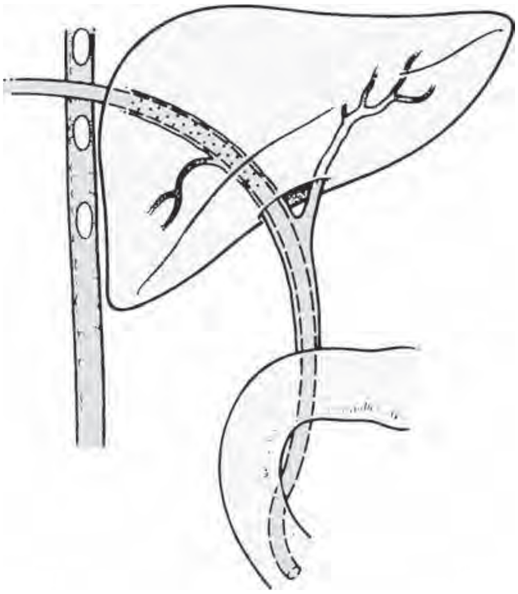

Figure 25.56 Technique of transhepatic stenting for total diffuse sclerosing cholangitis.

disease progresses invariably to cirrhosis and the development of portal hypertension.

Sclerosing cholangitis occurs more commonly in males (3:2) and usually presents in the fifth decade. The symptoms include vague ill health, asthenia, pain in the right hypochondrium, jaundice and itching, pyrexia and attacks of rigors. The liver is often palpable and tender. The liver function tests demonstrate a cholestatic picture and bilirubin is detected in the urine. The serum transaminases are mildly elevated. The majority of patients are hepatitis B surface antigen negative. Antimitochondrial, antismooth muscle and antinuclear antibodies are absent. Contrast radiological visualization shows pruning of the biliary tree (scanty ducts) and stricture formation which may be localized or diffuse (Figure 25.56). Globular dilatations (sacculations) are often seen in patients with diffuse disease. Differentiation from hilar disease and CC is often difficult on radiological grounds and may not be possible even after histological examination of biopsy specimens. In these patients, only the subsequent clinical outcome can identify the true diagnosis.

The majority of patients are symptomatic at the time of presentation. However, the correlation between symptoms and liver histology and disease progression is weak. In general, the median survival between presentation and the development of end-stage liver disease is 12 years. However, the rate of progression of the disease is very variable and is influenced by the frequency of episodes of bacterial cholangitis and the development of CC (central or peripheral), the diagnosis of which is often difficult in these patients. The most commonly used prognostic model is that of the Mayo Clinic:

- 0.535 $\log_e$ serum bilirubin (mg/dL)
- +0.486 histological stage
- +0.041 age (years)
- +0.705 if splenomegaly is present.

Unfortunately, there is no effective medical therapy for the condition. The pruritus may be controlled by cholestyramine. Episodes of cholangitis are managed by antibiotic therapy. Surgical intervention may be considered when adequate control of symptoms is not achieved by medical therapy, the specific indications being progressive jaundice and recurrent cholangitis. Surgical treatment gives best results for localized hilar disease. The hilar bifurcation is accessed through an anterior segmentectomy IV and a Roux-en-Y hepaticojejunostomy to the right and left hepatic ducts performed proximal to the stricture. Direct surgical intervention on the biliary tract for predominantly hilar disease is contraindicated in the presence of cirrhosis as the results are poor and the mortality is high.

For diffuse disease, intraoperative dilatation of the intrahepatic biliary tree via a choledochotomy using both metal and balloon dilators is followed by a large silicone stent introduced transhepatically down the bile duct into the duodenum. The stent is exteriorized through the right lowest intercostal space in the anterior axillary line. Daily irrigation with heparinized saline and prolonged antibiotic therapy are essential components of the postoperative management. The stent is left in place for at least 12 months and progress is assessed by repeat cholangiograms carried out through the stent (Figure 25.57). Replacement of the stent may be necessary if it becomes blocked by encrustation with calcium bilirubinate. Both percutaneous transhepatic and endoscopic

The patient showed a dramatic clinical and biochemical improvement. (a) Operative cholangiogram; (b) postoperative cholangiogram (4 weeks later); (c) postoperative cholangiogram (19 weeks later).

balloon dilatation and stent insertion have been employed to deal with strictures in patients with sclerosing cholangitis. Generally the results have been inferior to those achieved in patients with iatrogenic strictures following bile duct damage.

However, the results of surgical treatment for diffuse disease have been disappointing and these patients are better served by hepatic transplantation. The optimal timing of hepatic transplantation for PSC has not been defined and thus early referral to a transplantation centre is currently recommended. Certainly a Mayo score of ≥5 or Child C constitute definite indications for transplantation. The problem in these cases is the exclusion of a superadded CC, the presence of which is accompanied by a dismal prognosis and is a contraindication to transplantation.

Biliary disorders in AIDS

Biliary disorders seen in AIDS patients are AIDS cholangiopathy (AC) and acalculous cholecystitis (ACC). Since the advent of highly active antiretroviral therapy (HAART) the incidence of AIDS-associated biliary disease has declined. The two diseases can occur concurrently.

AIDS cholangiopathy

The average age of AC diagnosis is 37 years with a range of 21–58 years. AC is regarded as an infectious form of sclerosing cholangitis. *Cryptosporidium parvum* is the most common organism associated with AC but other pathogens include cytomegalovirus, *Giardia lamblia*, *Mycobacterium avium-intracellulare*, *Cyclospora cayetanensis*, *Isospora belli*, *Histoplasma capsulatum* and *microsporidia*.

Clinical features

The clinical features are the same regardless of the opportunistic organism involved. AC presents with right upper quadrant and/or mid-epigastric abdominal pain in 90% of patients. Other symptoms include fever, nausea, vomiting and diarrhoea, which is due to the small bowel involvement. In addition, 75% of patients experience significant weight loss, and jaundice associated with pruritus is present in 10%. Patients who develop AC typically have a CD4 count <100/mm^3 at presentation. LFTs show a cholestatic pattern (elevated γ-glutamyl transferase and an increased alkaline phosphatase of 700–800 IU/L). Most patients also have a mild increase in transaminases and total bilirubin. However, nearly 20% have normal liver function tests. The most common findings on an abdominal ultrasound include common bile duct dilatation in 65–75% of cases, and thickening of the common bile duct wall in 20–40%. In addition, an echogenic nodule is often present at the distal end of the common bile duct caused by oedema of the papilla of Vater. ERCP is the definitive test and is used therapeutically for symptomatic relief in patients with papillary stenosis. ERCP identifies four common patterns of cholangiographic abnormalities:

- papillary stenosis (36%)
- intra/extrahepatic sclerosing cholangitis (≤15%)
- papillary stenosis combined with sclerosing cholangitis in 44%
- isolated long extrahepatic duct stenosis or stricture in 5%.

Treatment

Papillary stenosis is treated by endoscopic sphincterotomy, which provides symptomatic relief of pain in 87–100% of patients, although it does not improve survival. Despite sphincterotomy, the serum alkaline phosphatase often continues to rise, indicative of progression of intrahepatic disease. Biliary stents and balloon dilation of strictures are also used in some patients. Ursodeoxycholic acid has also been used as an additional treatment and can result in symptomatic improvement accompanied by a fall in serum alkaline phosphatase. Combination antiretroviral therapy is used to suppress viral replication and usually leads to elevation in CD4 count. The reported median survival of 30–35 months is attributable to HAART. A normal or slightly elevated serum alkaline phosphatase is associated with a better outcome, whereas high levels (>1000 IU/L) are associated with increased mortality.

Acalculous acute cholecystitis

The actual incidence of ACC in HIV patients is unknown. Patients with ACC usually have end-stage HIV disease with low CD4 counts, coexisting opportunistic infections and significant malnutrition. The organisms implicated are cytomegalovirus, *Cryptosporidium*, microsporidia, *Salmonella enteritis*, *Pneumocystis carinii*, *Campylobacter*, *I. belli* and *Candida albicans*. However, in a substantial cohort (50%) of patients, no definite pathogen is identified on microbiological studies. ACC can also be caused by obstruction of the cystic duct, due to Kaposi's sarcoma.

Clinical features

The diagnosis of ACC is clinical and should be considered when HIV patients complain of right upper quadrant pain with right upper quadrant (90%) tenderness, unexplained fever or signs of peritonitis. Other features include nausea (80%), diarrhoea (60%) and weight loss (40%). The serum bilirubin is usually normal but the serum alkaline phosphatase is elevated. The serum transaminases are either normal, or mildly elevated. Ultrasound is used to establish the diagnosis in the first place (pericholecystic fluid, intraluminal gas, gallbladder wall thickening ≥3.5 mm, sloughed mucosal membrane, echogenic bile, subserosal oedema and distended gallbladder in the absence of gallstones). The diagnostic criteria of CT are similar but it may also demonstrate other intra-abdominal pathologies.

Treatment

The treatment is cholecystectomy. Percutaneous CT or ultrasound-guided cholecystostomy is performed for gallbladder decompression in ACC patients who are extremely ill or pose a high surgical risk. It can serve as definitive therapy or a temporizing procedure until the patient's condition improves to enable safe cholecystectomy. If cholecystectomy is performed the resected specimen is sent for both microbiological and histological examination. Postoperative mortality after cholecystectomy in HIV-seropositive patients ranges from 2% to 22%. The deaths are the result of complications. The CD4 lymphocyte count does not influence postoperative mortality.

Duodenal diverticula

The prevalence of periampullary duodenal diverticula in patients undergoing ERCP is 12.5% and appears to increase with age. Their importance is twofold. In the first instance, they predispose to bacterial infection. Thus patients with duodenal diverticula have a higher incidence of infected bile than normal subjects and the bacterial count of their duodenal contents is elevated (with proliferation of *Enterobacteriaceae* spp.) compared with patients without diverticula. Second, duodenal diverticula increase the difficulty of cannulation of the papilla during ERCP and thus the failure rate of this procedure, especially when the opening of the duodenal papilla lies inside a diverticulum.

The duodenum is the second most common site of gastrointestinal diverticula. Duodenal diverticula occur in approximately 20% of adult individuals but the vast majority are asymptomatic and discovered by chance during investigation of the upper gastrointestinal tract. Duodenal diverticula rarely cause symptoms, which are usually non-specific unless they develop complications. Duodenal diverticula are nowadays classified as primary (the vast majority) or secondary to another disease such as chronic duodenal ulceration, i.e. prestenotic diverticulum. In clinical practice, duodenal diverticula are discovered mainly in middle age (50–60 years). Their reported incidence varies with the investigating modality used, being low in upper gastrointestinal contrast studies (up to 6%) and much higher in reported ERCP series (up to 23%), which approximates to the incidence reported in autopsy series (averages 22%). More than 95% of duodenal diverticula project from the inner (pancreatic) border of the duodenal curve of the second to fourth parts of the duodenum, with the second part being the commonest site (85%). Duodenal diverticula may be single or multiple and are spherical unless very large, when they assume a flask shape. There are various classifications which are rather confusing (ampullary, periampullary, etc.). The current classifications based on CT or MRI collectively address these as juxtapapillary duodenal diverticula (JPDD), and undoubtedly these are the surgically important in view of their pathogenetic potential. The CT-based classification of JPDD proposed by Weisner *et al.* is shown in Box 25.2.

A similar but more anatomical detailed classification based on MRI contrast study has been proposed by Morita *et al.* and is illustrated in Figure 25.58.

BOX 25.2 Radiological (CT) classification of juxtapapillary duodenal diveticula

- Type 1: Diverticulum is located ventral to the ampulla of Vater extending into the pancreas at the site of fusion of the dorsal and ventral anlage of the pancreas (commonest)
- Type II: Diverticulum is dorsal to the ampulla of Vater (second commonest)
- Type III: Bilobulated diverticulum extending above and below the ampulla of Vater (rare)
- Type IV: Diverticulum ventral to the minor papilla (least common)

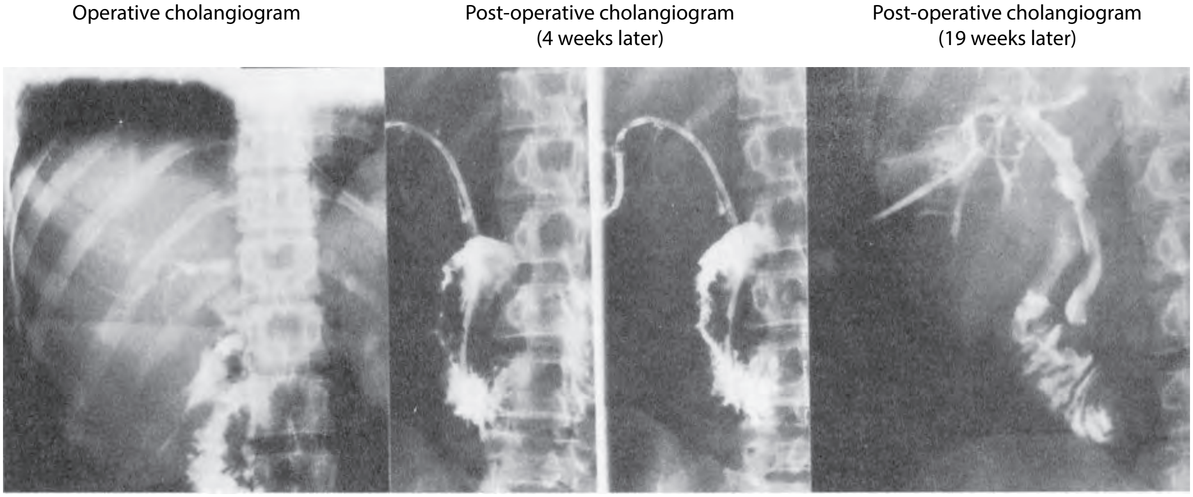
Aetiology and pathology

Except for a rare small subgroup in childhood, duodenal diverticula are acquired and consist of a sac of mucosal/mucosal + submucosal layers herniated through muscular defects in the duodenal wall although the exact mechanism for this herniation is not known. One hypothesis is that herniation occurs through localized mural weakness caused by pancreatic ducts/blood vessels traversing the duodenal wall. Once the diverticulum forms, it slowly increases in size with time. A large duodenal diverticulum may lie alongside or extend behind the pancreas and occasionally common bile duct, and the duct of Wirsung may open into the duodenal diverticula.

Pathologically all large duodenal diverticula lack a muscular coat. The distinction between true (congenital) and false diverticula depending on the presence or absence of muscle coat is no longer tenable. In the first instance, there is no evidence to prove that certain pouches are congenital and that others are acquired. Second, in duodenal diverticula the amount of muscle fibres in the pouch depends on its size. In the majority of duodenal diverticula, the circular and longitudinal muscle coats of duodenum are missing, the wall of the diverticulum being composed of mucosa and muscularis mucosae.

Clinical features

The vast majority of duodenal diverticula remain asymptomatic. Clinical symptoms when present are non-specific and consist of abdominal discomfort usually located in the epigastrium, right upper quadrant or umbilical region, which is made worse



Operative cholangiogram
Post-operative cholangiogram (4 weeks later)
Post-operative cholangiogram (19 weeks later)

Figure 25.58 Schematic classification of juxtapapillary duodenal diverticula (JPDD) with respect to its location to the papilla: type 1, no JPDD; type 2, JPDD with the papilla opening inside it; type 3, JPDD with the papilla located on its dorsal side; type 4, JPDD with the papilla located on its ventral side; type 5, JPDD with the papilla located between two diverticular openings (bilocular). (From Morita M, Ueno E, Masukawa A, *et al. Jpn J Radiol* 2009;**27**:423–9, with permission.)

or precipitated by eating and relieved by vomiting or belching. These symptoms may be caused by delayed emptying of duodenal diverticula or pressure on the common bile or pancreatic duct, or subacute obstruction of the duodenum. Others attribute these symptoms to inflammatory changes following stasis in the duodenal diverticula. Some duodenal diverticula produce peptic ulcer-like dyspepsia. Intermittent diarrhoea and constipation, weight loss and steatorrhoea may also occur in some patients. Some patients with duodenal diverticula located near the ampulla of Vater may simulate biliary tract disease and when inflamed (peri-Vaterian diverticulitis) may give rise to obstructive jaundice. There is an established association between duodenal diverticula and brown pigment stones which is not fully understood although colonization with β-glucuronidase-producing bacteria of the common bile duct has been proposed. Since choledocholithiasis is an established pathogenetic factor in the aetiology of acute biliary pancreatitis, the increased incidence of pancreatitis (acute and chronic) in patients with duodenal diverticula has been attributed to the high prevalence of ductal calculi.

JPDD are not uncommonly associated with biliary or pancreatic disease and can cause cholangitis without choledocholithiasis, known as *Lemmel syndrome*. JPDD can cause difficult cannulation of the common bile duct and complications during ERCP. JPDD can also be mistaken for cystic neoplasms of the pancreas. The complications of JPDD are caused by:

- pressure on adjacent structures (mechanical compression): jaundice, cholangitis, pancreatitis
- diverticulitis
- ulceration
- acute obstruction
- perforation
- duodenocolic, gastrojejunocolic fistula (rare)
- distal small bowel intraluminal obstruction.

Diverticulitis ensues as a result of stasis and bacterial proliferation in duodenal diverticula, which cannot drain their contents and may lead to perforation with either localized abscess formation or generalized peritonitis. Perforation may also be caused by enteroliths or foreign ingested material. The perforation may be acute (majority of cases) or chronic leading to a bile-stained phlegmon in the paraduodenal region, retroperitoneal oedema or a right subhepatic abscess. Ulceration can occur because of the presence of ectopic gastric mucosa or inflammation. Diverticular ulceration may give rise to occult bleeding or very rarely massive gastrointestinal haemorrhage leading to hypovolaemic shock due to erosion of a large mesenteric vessel. Duodenocolic and gastrojejunocolic fistula formation secondary to inflammation in duodenal diverticula have been reported but are rare. Pancreatic and/or biliary fistula do not arise *de novo* but may develop as complications after surgery. Intestinal obstruction as a result of blockage by large enteroliths derived from duodenal diverticula has been reported.

A number of disorders are associated although there is no firm evidence for a causal relationship except for duodenal ulcer. The associated disorders include:

- duodenal ulcer
- hiatus hernia
- jejunal and ileal diverticula in 4–13% of all patients with duodenal diverticula
- higher than expected incidence of coexisting congenital anomalies: annular pancreas, choledochocele, omphalocele, hypoplastic kidney, situs inversus, malrotation, Ladd band, portal vein anomalies and Down syndrome.

The diagnosis may be established by enteroclysis, upper gastrointestinal endoscopy and ERCP. CT or MRI are performed when perforation is suspected and may demonstrate a soft-tissue mass between the duodenum and the pancreatic head containing an air–fluid level, duodenal wall thickening and surrounding free air. MRI facilitates precise delineation of the complicated duodenal diverticula while MRCP allows assessment of the effects of duodenal diverticula on the biliary and pancreatic duct.

Treatment

Asymptomatic duodenal diverticula do not require treatment and only a minority of diagnosed duodenal diverticula (up to 5%) require surgery because of symptoms or complications. Acute obstruction of a diverticulum is treated by endoscopic clearance. Operative treatment requires complete Kocherization of the duodenum. The diverticulum is then dissected free and opened to establish its relation to the ampulla of Vater before its excision. The supraduodenal common bile duct is opened and a T-tube inserted. If the ampulla of papilla is inside the duodenal diverticula, some advocate a choledochoduodenostomy or choledochojejunostomy rather than direct surgery on the duodenal diverticula. However, this approach may not deal with problems arising from involvement of the pancreatic duct. In cases where excision is deemed hazardous, exclusion by division of duodenum some 2.0 cm distal to the pylorus with drainage by a Roux-en-Y duodenojejunostomy may be performed.

The surgical treatment for perforated duodenal diverticula carries a high postoperative mortality and morbidity from iatrogenic injury to the ampulla of Vater leading to impaired drainage of bile or pancreatic drainage with the development of jaundice, pancreatitis or duodenal fistula.

Haemobilia

Major (profuse) haemobilia is rare; when it occurs spontaneously, it is caused by rupture of an intrahepatic aneurysm. Nowadays, significant haemobilia is most commonly encountered as a complication of percutaneous radiological interventions on the liver and following hepatic trauma. The vascular injury within the hepatic parenchyma caused by transhepatic radiological interventions results in an arteriovenous fistula or pseudoaneurysm or direct vascular–biliary connection. If the bleeding is marked, blood clots with biliary colic complicate the clinical picture. Minor haemobilia may also be caused by stones, primary hepatic tumours including angiomas, gallbladder and bile duct polyps, parasitic infestations, severe cholangitis and coagulation disorders. Haemobilia may complicate ESWL for ductal calculi.

In descending order of frequency the causes of haemobilia are:

- iatrogenic trauma
- accidental trauma
- gallstones
- acalculous inflammation
- vascular conditions
- neoplastic disease
- others.

Post-traumatic haemobilia is the commonest cause (55–80%) and may complicate both blunt and penetrating abdominal injuries and percutaneous interventions used commonly nowadays in the management of hepatobiliary disorders. Iatrogenic haemobilia may also follow operations on the liver and biliary tract. Upper gastrointestinal bleeding due to gallstones accounts for 9–15% of all reported cases of haemobilia but is invariably minor. The bleeding results from mucosal erosions of the gallbladder mucosa or haemorrhagic necrosis in severe cholecystitis. Haemobilia is also well documented in acalculous inflammatory conditions of the biliary tract, with the incidence being higher in regions where parasitic infestations are endemic. The leading cause in this category is ascariasis. Haemobilia may also complicate other conditions: hepatic abscess and cholangitis.

A primary vascular cause is present in 11–15% of reported cases of haemobilia, e.g. aneurysms of the hepatic artery and portal hypertension although the latter is nowadays regarded more as a predisposing rather than a primary cause. The bleeding from vascular causes tends to be massive and life-threatening. Neoplastic disease is a relatively rare cause and accounts for 6% of reported cases of haemobilia, the most common tumour being hepatocellular carcinoma followed by haemangioma, CC and carcinoma of the gallbladder.

Clinical features

In postoperative patients with biliary drains, the diagnosis may be obvious with the appearance of blood and clots in the drain. Otherwise the diagnosis may not be readily apparent. The clinical features include biliary colic (70%), jaundice (60%) and gastrointestinal bleeding, which may be occult or massive. The diagnosis may be established by endoscopy, angiography and CT (for hepatic injuries) or during surgery by intraoperative cholangiography.

Treatment

Expectant therapy with observation and close monitoring is indicated when haemobilia occurs as a complication of liver biopsy and percutaneous transhepatic cholangiography as these usually subside with supportive measures. Endoscopic techniques include nasobiliary drainage, endoscopic sphincterotomy and laser/electrocoagulation. The therapeutic modalities used for persistent haemobilia from any source are:

- angiography with embolization
- surgical intervention
- electrocoagulation
- photocoagulation.

Angiography is the most effective therapy for controlling bleeding from intrahepatic causes and has a reported efficacy of 95%. Surgical treatment is indicated for extrahepatic causes: bleeding from the gallbladder mucosa (stones, acalculous cholecystitis, etc.), bile duct and gallbladder cancers. Surgical treatment is also indicated for haemobilia after blunt trauma for which limited debridement, vessel ligation and drainage are important

Bilioenteric fistulas

The various types and causation of biliary fistulas are shown in Table 25.4.

Spontaneous external biliary fistulas are exceedingly rare and the few reported cases have been instances of neglected empyema of the gallbladder or extensive carcinoma of the gallbladder invading the abdominal wall. The vast majority of

Table 25.4 Biliary fistulas

Category	Type	Causation
External		Trauma and operative injuries therapeutic (T-tube, stents, cholecystostomy)
Internal	Bilioenteric	
	Cholecystoduodenal	Gallstones
	Cholecystocolic	Gallstones, Ca
	Cholecystogastric	Gallstones, Ca, peptic ulceration
	Choledochoduodenal	Ductal calculi, iatrogenic, duodenal ulcer, Ca
	Biliobilial	
	Cholecystocholedochal	Gallstones (Mirizzi syndrome)
	Others	Trauma, operative injuries, liver abscesses/hydatid, subphrenic abscesses
	Broncho/pleurobilial	
	Cholecystorenal	Gallstones

external biliary fistulas occur in the postoperative period and may result from the following:

- leakage of bile from a slipped cystic duct ligature or cut accessory bile duct
- trauma to the extrahepatic biliary tree during cholecystectomy, gastric surgery or pancreatectomy
- dislodged T-tube after common bile duct exploration
- leakage from bilioenteric anastomosis
- hepatic resections.

Leakage of bile after removal of a T-tube is short-lived and requires investigation by ERCP if it persists beyond 2–3 days. Other external biliary fistulas may follow blunt or penetrating hepatic trauma. The external biliary fistula usually occurs after surgical treatment of the hepatic injury and is then often accompanied by sepsis. External biliary fistulas do not result in skin excoriation but may cause significant fluid and electrolyte depletion if the output is high and prolonged. They are not usually accompanied by systemic manifestations unless sepsis is present. Abdominal tenderness and rebound indicates the concomitant presence of bile in the peritoneal cavity. Postoperative external biliary fistulas occurring in association with jaundice indicate bile duct trauma or a missed obstructive lesion of the biliary tract. These patients require urgent investigation with ultrasonography/CT and ERCP. Otherwise, a conservative management regimen is adopted as the biliary fistula usually closes spontaneously. Persistence of the fistula beyond a reasonable period (7–10 days), the development of jaundice, pyrexia or deterioration of the patient's condition are indications for urgent reassessment and investigation.

Internal fistulas are usually spontaneous and arise from chronic or acute perforation of the gallbladder into an adjacent organ. Others are due to malignant infiltration arising from or involving the gallbladder, e.g. carcinoma of the hepatic flexure, duodenum or gallbladder. The symptoms of the non-malignant internal fistulas involving the gallbladder are similar to those of chronic cholecystitis but jaundice and cholangitis are more common and radiology of the abdomen shows gas or barium in the biliary tree. The most frequent of the internal fistulas is the cholecystoduodenal fistula followed by cholecystocolic and cholecystogastric fistulas. The Mirizzi syndrome refers to a condition characterized by obstructive jaundice caused by a stone impacted in the neck of the gallbladder which compresses the common hepatic duct and which eventually ulcerates through into the common hepatic duct causing a cholecystocholedochal fistula (Figure 25.59).

A fistulous tract between the lower end of the bile duct and the duodenum (choledochoduodenal fistula) may arise spontaneously (secondary to ductal calculi or chronic duodenal ulcer) or be the result of iatrogenic injury from ill-advised

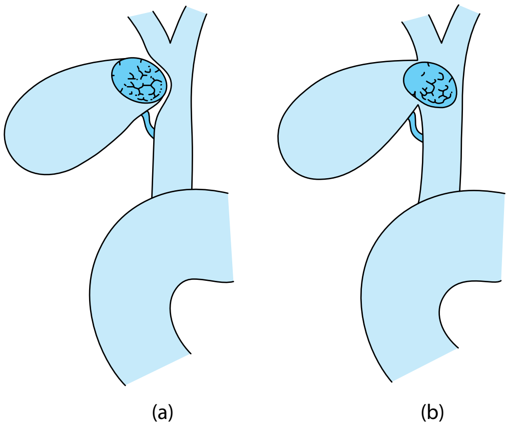


Figure 25.59 The Mirizzi syndrome: (a) a stone impacted in the neck/Hartmann's pouch causes extrinsic compression of the common hepatic duct followed by (b) fistula formation between the gallbladder and the common hepatic duct.

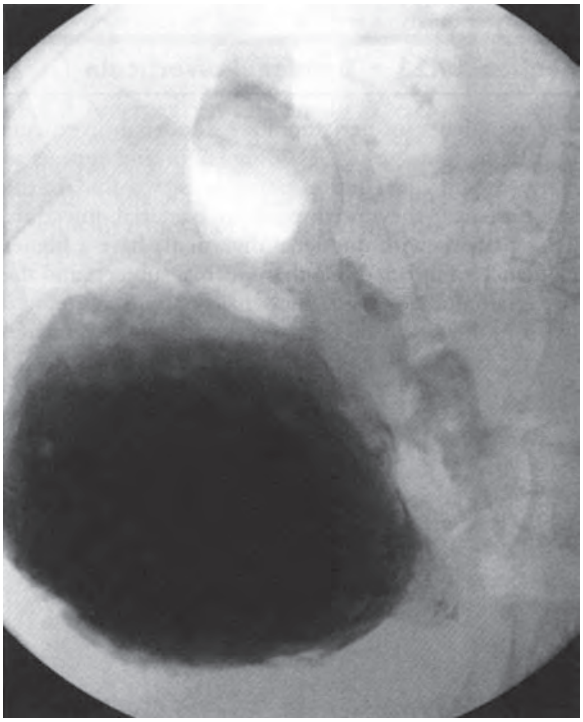

Figure 25.60 Contrast study of a large hepatic abscess with communication with the bronchial tree. At operation the abscess had burrowed through the diaphragm to involve the lower lobe of the lung which required resection.

probing of the Vaterian segment of the common bile duct during biliary surgery. Biliopleural and bronchobilial fistulas are usually the result of hepatic abscesses (Figure 25.60) and hydatid disease of the liver, although some follow hepatic injuries complicated by the development of subphrenic abscesses.

The treatment of bilioenteric fistulas due to gallstone disease consists of a cholecystectomy and closure of the fistulous communication. Exploration of the common bile duct is frequently necessary and is dictated by the findings at peroperative cholangiography. Unless the Mirizzi syndrome is recognized at operation, damage to the common hepatic duct is inevitable. The surgical treatment of this condition entails leaving a small cuff of gallbladder wall, which is used to close the fistulous opening. The common bile duct is explored (if necessary) through a choledochotomy lower down. The management of bronchobiliary fistulas consists of adequate drainage of the underlying hepatic/subphrenic abscess and decompression of the biliary tract when necessary.

Gallstone ileus

This condition, which characteristically affects elderly people, is due to intraluminal intestinal obstruction by a large gallstone that enters the intestinal tract subsequent to the establishment of a fistula, usually between the gallbladder and the duodenum and, less commonly, the gallbladder and the colon. Rarely gallstone ileus may occur as a complication of endoscopic sphincterotomy with stone extraction. Naturally occurring gallstone ileus occurs in 2% of patients with gallstone disease and, in some reports, accounts for up to 20% of mechanical intestinal obstruction in elderly people.

The patient, who may give a history of gallbladder disease, presents with acute intestinal obstruction, which in the vast majority of cases affects the small bowel, colonic obstruction being distinctly uncommon. Characteristically, the level of the obstruction is changing until the stone becomes firmly impacted, usually in the terminal ileum (70%), as this is the narrowest part of the intestinal tract, and much less commonly in the duodenum. Colonic obstruction due to impaction in the colon is the result of a cholecystocolic fistula.

The condition should be suspected in the elderly patient with mechanical intestinal obstruction in the absence of the more common causes of this condition. It can be diagnosed preoperatively if gas can be demonstrated in the biliary tract or the gallstone is visualized, usually in the right iliac fossa (Figure 25.61).

The treatment requires emergency surgical intervention in all patients. The operative management depends on the findings and the general condition of the patient. In the elderly and frail patient with ileal obstruction, removal of the impacted calculus through a small enterotomy is performed and the cholecystoduodenal fistula is dealt with at a subsequent operation. A one-stage enterolithotomy with cholecystectomy and closure of the duodenal fistula can be performed in patients who, despite their age, are considered fit enough for this procedure. The treatment of patients with colonic obstruction and a cholecystocolic fistula consists of removal of the calculus through a colotomy, cholecystostomy (cholecystectomy if the patient is fit) and exteriorization of the colotomy as a temporary proximal (diverting) colostomy.

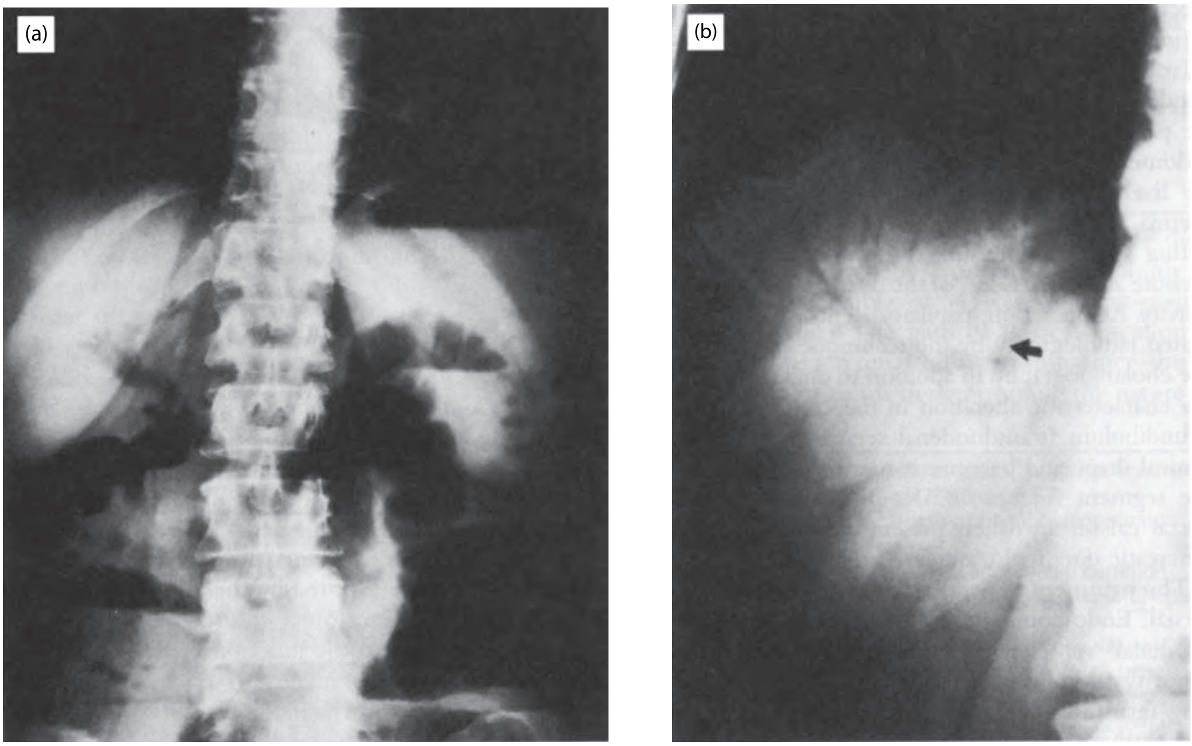

Figure 25.61 (a) Plain radiograph of the abdomen – gas outlines the common bile duct. The patient presented with cholangitis and gallstone ileus. A spontaneous cholecystoduodenal fistula was found at operation. (b) Gas outlining the right hepatic duct. The patient had an empyema of the gallbladder and a cholecystocolic fistula due to a carcinoma of the hepatic flexure.

Postcholecystectomy syndromes

These refer to the persistence of symptoms referable to the biliary tract after cholecystectomy. As currently defined, the syndromes exclude those patients whose symptoms are due to organic disease outside the biliary tract. These constitute a significant percentage of patients with persistent symptoms after cholecystectomy and they are usually a reflection of failure of proper evaluation and investigation of patients prior to the cholecystectomy.

The reported incidence of postcholecystectomy syndromes varies widely and correlates with the duration of follow-up. There is a female preponderance, particularly in the 40–50 years age group. A careful evaluation and a full investigation of the biliary tract including an MRCP is advisable in all patients with persistence or recurrence of symptoms after cholecystectomy. The common causes of postcholecystectomy syndromes are:

- retained or recurrent calculi
- gallbladder/cystic duct remnants
- bile duct strictures and other unrecognized iatrogenic injuries (choledochoduodenal fistula)
- papillary stenosis and biliary dyskinesia.

Persistent or recurrent symptoms after cholecystostomy are common and are one of the reasons for subsequent cholecystectomy in all patients who are considered fit for surgery. Controversy still exists regarding the role of a 'long cystic duct remnant' as a cause of persistent symptoms after cholecystectomy. There are undoubtedly patients in whom a dilated long cystic duct remnant containing stones is demonstrated on investigation, and its removal together with the stones results in sustained symptomatic improvement. However, these cases are few and far between and at present there is no evidence to incriminate an otherwise normal long cystic duct remnant as one of the important causes of postcholecystectomy syndrome.

Papillary stenosis (also known as choledochoduodenal junctional stenosis) is nowadays regarded as a rare but definite entity, which results from fibrosis or fibromuscular hyperplasia of the sphincter of Oddi. An associated duodenal diverticulum is common, and cannulation of the papilla is difficult. In addition to pain in the upper abdomen, the patient may exhibit slight abnormalities in LFTs, including mild hyperbilirubinaemia and elevated alkaline phosphatase activity. The resting sphincter pressure is elevated as is the passage pressure and there is loss of the normal phasic sphincteric activity. At operation, papillary stenosis is best demonstrated radiologically by the technique of contact selective cholangiography. In addition to duct dilatation, there is a characteristic alteration in the configuration of the infundibulum (transduodenal segment), which loses its conical shape and becomes wider than the intrapancreatic segment (Figure 25.62). Biliary sludge and small ductal calculi are often present. Reflux into a dilated pancreatic duct is also observed in some cases.

The treatment of papillary stenosis is equally controversial. Endoscopic sphincterotomy or surgical transduodenal sphincteroplasty is recommended by the majority although there has not been an adequate long-term assessment of these procedures for this rare and elusive condition. In addition to the sphincteroplasty, Moody advocates the excision of the septum between the pancreatic duct and the bile duct in patients with chronic pain which he maintains is of pancreatic origin. An alternative surgical treatment for papillary stenosis favoured by the author is transection choledochoduodenostomy with reimplantation of the mobilized duct into the junction of the first with the second part of the duodenum (Figure 25.63).

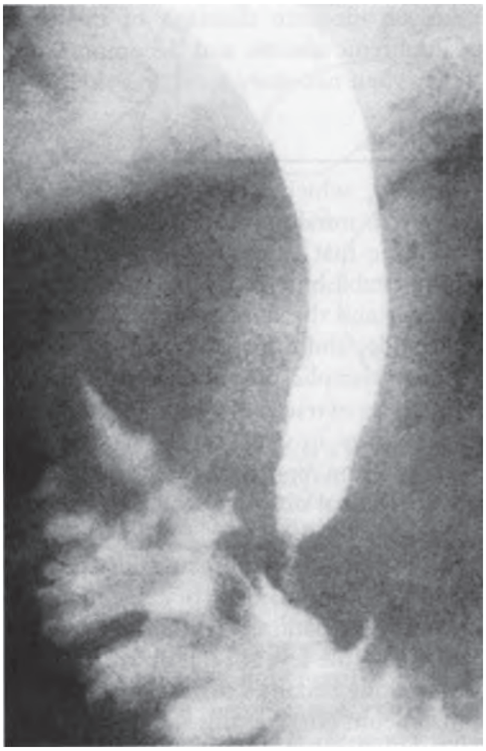

Figure 25.62 Operative contact selective cholangiogram demonstrating papillary stenosis. There is minimal dilatation of the bile duct and the infundibulum becomes globular. Biliary sludge/small ductal calculi are often present.

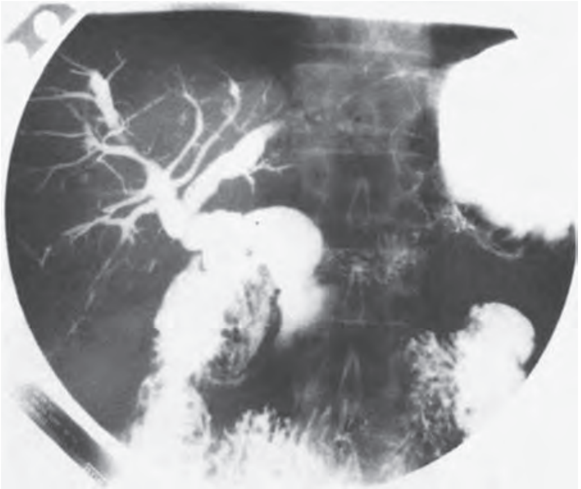

Figure 25.63 Barium meal contrast study after transection choledochoduodenostomy performed for papillary stenosis 3 years previously.

The term biliary dyskinesia is used to denote those patients who have persistent pain after cholecystectomy and no other abnormality on physical examination and routine testing but who exhibit the following abnormalities during ERCP manometry:

- elevated resting pressure
- tachyarrhythmia (increased phasic activity of the sphincter)
- retrograde contractions of the sphincter
- paradoxical response to CCK.

Treatment with endoscopic sphincterotomy has been advocated for these patients but the efficacy of this in the long-term relief of symptoms remains to be ascertained.

Benign bile duct strictures

The causes of benign bile duct strictures are:

- operative bile duct injury (iatrogenic)
- penetrating and non-penetrating abdominal injuries
- chronic duodenal ulcer
- chronic pancreatitis
- recurrent pyogenic cholangitis and parasitic infestations
- sclerosing cholangitis.

In the clinical context, benign strictures of the extrahepatic bile ducts do not exhibit a benign course since they are always attended by significant symptoms and serious complications that are life-threatening in both the short and the long term and carry a definite mortality. Thus they pose serious health and economic problems and may expose the surgeon to expensive medicolegal litigation. In addition, they increase substantially the economical burden to the patient, hospital and the community, and some have needed hepatic transplantation for survival. The costs of repair of cholecystectomy-related bile duct injuries is high, varying from 4.5 to 26 times the cost of the uncomplicated procedure. In one reported series, patients with LC-related bile duct injuries were billed a mean of US$51 411 for the remedial surgery and incurred an average of 32 days of inpatient hospital stay. Both the costs of treatment and the outcome (mortality) of bile duct injury are related to early recognition. Thus in one large reported series, bile duct injuries recognized immediately at the time of the initial surgery incurred a significantly lower cost and reduced hospital stay than those in whom recognition was delayed. As the surgical management of these injuries requires special multidisciplinary expertise, referral to and treatment in specialized centres offers the best chance of reversal from a potentially fatal condition to long-term restoration of good health with freedom from symptoms and return to normal liver function.

A long stricture of the lower end of the common bile duct, which characteristically forms an angle with the proximal dilated duct, is encountered in 15–20% of patients with chronic pancreatitis (Figure 25.64a). However, the differentiation between this disease and pancreatic carcinoma is often difficult in these patients. Bile duct strictures are also a feature of recurrent pyogenic cholangitis and sclerosing cholangitis. A similar long but less angulated stricture of the distal common bile duct may

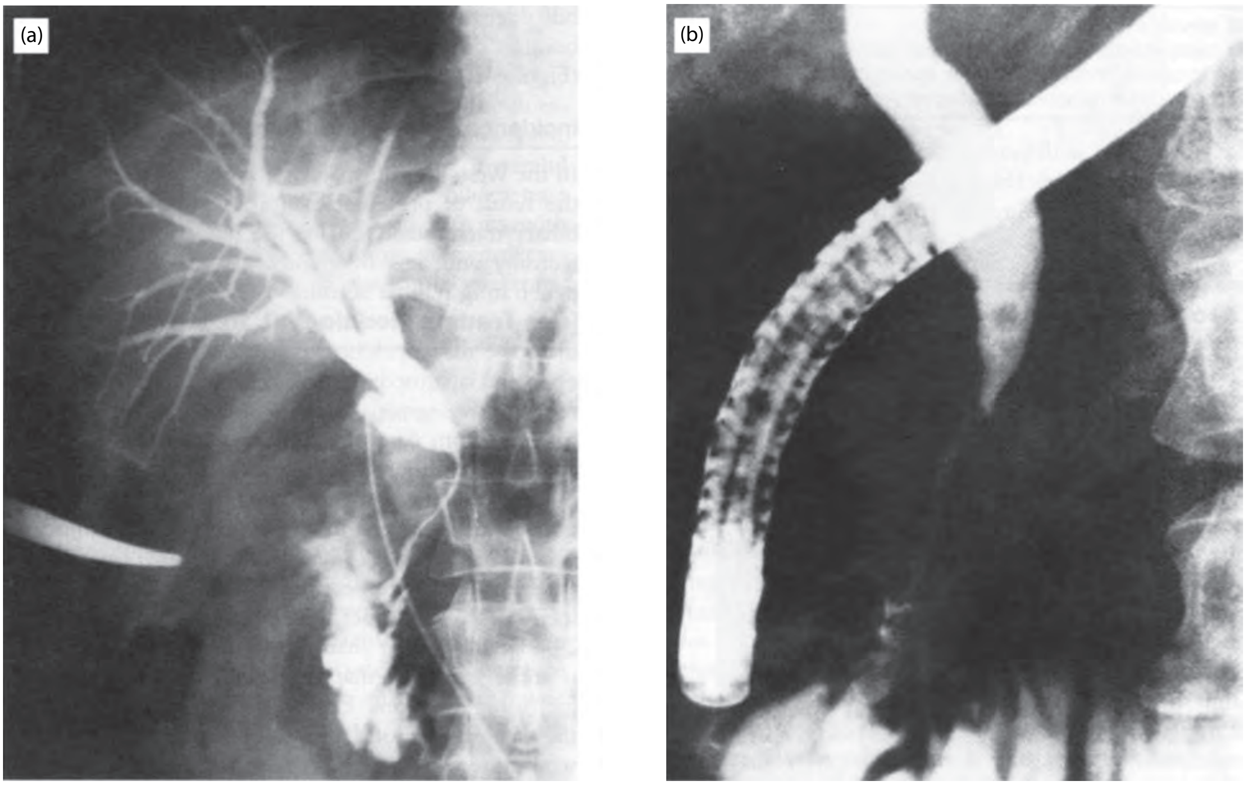

Figure 25.64 (a) Long stricture of the distal bile duct in a patient with chronic alcoholic pancreatitis of 12 years' duration. There is an angle between the stricture and the proximal dilated duct. The stenosis is due to the pancreatic fibrosis which constricts the transpancreatic segment of the common bile duct. (b) Stricture of the lower end of the common bile duct following blind stone fragmentation of an impacted stone and forcible passage of metal bougies.

be caused by trauma inflicted with metal bougies during open common bile duct exploration (Figure 25.64b).

Incidence of bile duct injury

In the West, the vast majority of bile duct strictures are the result of preventable injuries to the extrahepatic biliary tract, usually during the operation of cholecystectomy and, less frequently, gastrectomy. Blunt and penetrating trauma accounts only for a small minority

It is difficult to estimate the real incidence of bile duct injury after both open cholecystectomy and LC from published retrospective series. Accurate incidence can only be gathered from data of regional or national prospective audits that ensure complete data collection. Surveys from different countries reviewed by Strasberg *et al.* in 1995 showed an incidence of iatrogenic bile duct injury of 0.125% and 0.55% during open cholecystectomy and LC respectively. Based on this review, the incidence of bile duct injuries during sustained LC is 2–4.5 times higher than in the open technique. There is some evidence that the incidence decreases with increasing experience of the surgeons. This is suggested by the data of a national prospective audit in Switzerland, where the incidence of bile duct injury following LC fell from 0.6% to 0.3%. More recent reported series seem to confirm this positive trend and indicate that the incidence of biliary injury during open cholecystectomy and LC may be converging. The reason for this is probably twofold: increased experience with the laparoscopic technique and allocation of the more difficult cases to the open technique. In a recent population-based study of iatrogenic injury associated with cholecystectomy in Western Australia the risk of iatrogenic injury during LC was found to be 1.79 times that of open cholecystectomy.

Classification of bile duct injuries

The most commonly used classification of bile duct injuries is that reported by Corlette and Bismuth in 1981 based on an analysis of 643 cases of postoperative biliary strictures. The basis of this classification is the length of the proximal biliary stump, since this is the most important factor in determining the nature of the biliary repair.

- type 1 – low common hepatic stricture, length of common hepatic duct stump >2.0 cm (Figure 25.65)
- type 2 – middle stricture, length of hepatic duct stump <2.0 cm
- type 3 – high (hilar) stricture – no serviceable common hepatic duct but the confluence of the right and left hepatic ducts is preserved (Figure 25.66)
- type 4 – high stricture where the confluence is involved and there is no communication between the right and left hepatic ducts. The thickness of the fibrosis separating the two branches depends on the extent of the injury, i.e. thin or thick septum (1–2 cm) (Figure 25.67)
- type 5 – combined common hepatic and aberrant right hepatic duct injury separating both from the distal biliary tract.

The Corlette–Bismuth classification has proved useful because it provides essential information on the nature, risks and prognosis after the repair. There is an established correlation between the types of injury and the morbidity, mortality, success and recurrence after repair. However, the Corlette–Bismuth classification does not stipulate the length of the injury. This information is becoming increasingly important, as nowadays short strictures can be managed by non-operative treatment, such as percutaneous or endoscopic dilatation or stenting. A subclassification that indicates the extent of the lesion is desirable, i.e. discontinuity following excision of bile duct, short- or long-segment stenosis.

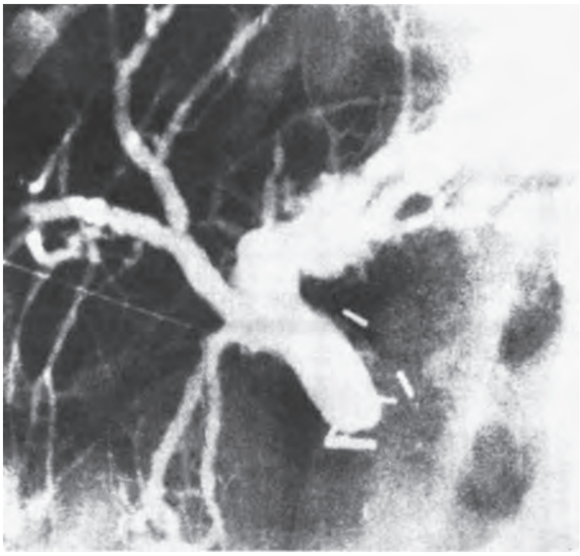

Figure 25.65 Type 1 Corlette–Bismuth injury.

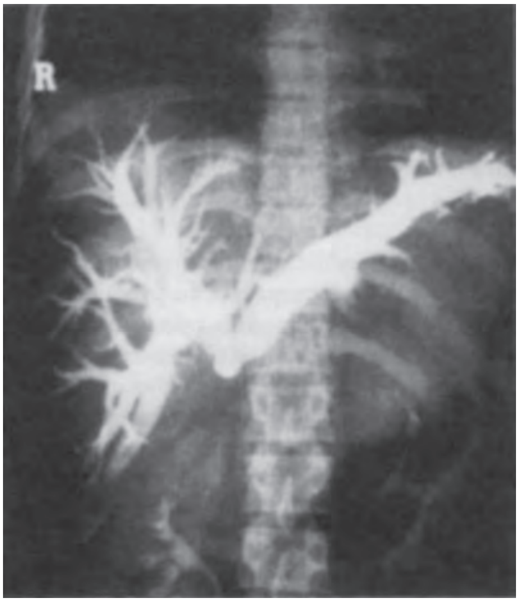

Figure 25.66 Obliteration of the hepatic duct with an intact confluence of the right and left hepatic ducts – type 3 stricture.

The more recent Strasberg classification considers bile injuries from a clinical perspective and includes biliary *complications* excluded in the Corlette–Bismuth types, e.g. bile leaks and bilomas, and isolated occlusion of the right hepatic duct. In essence it distinguishes two main categories:

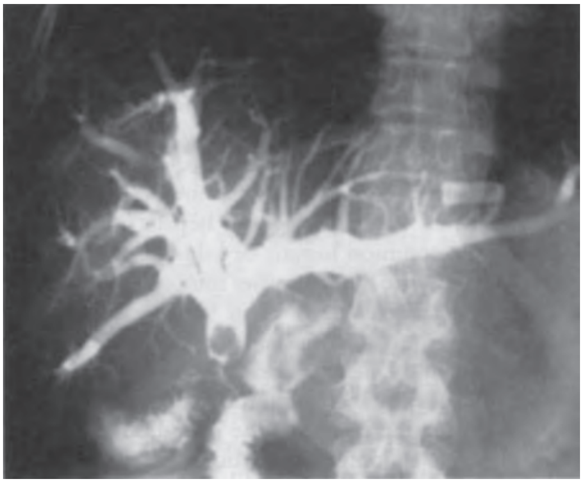

Figure 25.67 High stricture with destruction of the hilar confluence. A primary ductal stone straddles the two ducts – type 4 stricture.

- injuries that separate hepatic parenchyma from the biliary tract
- those where the continuity is maintained.

The classification also groups together injuries that have similar presentation and management, as distinct from those that require different management despite having similar presentations.

- *Type A* is a bile leak from a minor duct that is still in continuity with the common bile duct. These leaks occur either from the cystic duct stump or from the liver bed. These are not really bile duct injuries. Their importance lies in early recognition and appropriate management. They do not cause strictures or require tertiary referral.
- *Type B* is occlusion of part of the biliary tree – usually occlusion of an aberrant right hepatic duct mistaken for the cystic duct. In 2% of patients the cystic duct enters the right hepatic duct instead of the common hepatic duct. These injuries are often asymptomatic, or may present later with pain or cholangitis. The related hepatic segments drained by the occluded duct atrophy with variable hypertrophy of the rest of the hepatic parenchyma (disconnecting injury).
- *Type C* injury is bile leak from duct not in communication with the distal common bile duct. It is usually the result of transection of an aberrant right hepatic duct with drainage of bile into the peritoneal cavity. This lesion usually presents in the early postoperative period (disconnecting injury).
- *Type D* is lateral injury to the extrahepatic bile ducts. The hepatic parenchyma remains in communication with the distal end of the biliary tree and duodenum. Unlike type A, however, the consequences of type D injuries are potentially more serious. They require laparotomy for repair, and may result in stenosis. Type D injuries may involve the common bile, common hepatic, right and left hepatic ducts.
- *Type E* is circumferential injury of major extrahepatic bile ducts with separation of liver parenchyma from the lower ducts and duodenum (major disconnection injury).

The Strasberg classification is more suited to a multidisciplinary approach to the management of bile duct injury and for this reason is gaining wider acceptance.

Pathology of bile duct injuries

There is little doubt that the majority of bile duct injuries sustained during operation result from failure of appreciation of the precise anatomy of the area. The situations which predispose to or result in damage to the bile ducts at operation are varied and are usually but not always related to the degree of technical difficulty of the operation. Moossa *et al.* identified four mechanisms of bile duct injuries in open cholecystectomy, and later added a fifth one for LC:

- ligating or transecting the wrong duct
- occluding the lumen of the common bile duct during 'flush ligation' of the cystic duct
- compromise of the blood supply of the duct by excessive dissection
- trauma to the lumen of the common bile duct during exploration by manipulation or forceful 'dilatation'
- injury due to inappropriate application of energy source.

Although these are important, a more practical consideration of the mechanisms involved in bile duct injuries during LC identifies two basic error groups:

- misinterpretation of the anatomy
- technical errors.

Misinterpretation of the anatomy

All the available evidence indicates this as the dominant factor in the aetiology and it accounts for 70% of biliary duct injuries sustained during LC. This primary error is related to the fact that during LC the surgeon is operating on images of the operative field rather than reality. Visual psychological studies have shown that humans scan pictures by slow pursuit eye movements and, on the basis of the visual information relayed on the retina by this scanning process, the brain makes an interpretation. If the surgeon makes a snap interpretation, success or disaster depends on whether this is right or wrong. The vast majority of bile duct injuries during LC would be avoided if the surgeon questioned the initial identification of key structures to the point of absolute certainty. In one report based on review of operative videotapes of patients who sustained a duct injury, various misinterpretations were identified.

Technical errors

The most important technical error is hilar bleeding. This may result from failure to secure the cystic artery or damage to the right hepatic artery that is particularly at risk when it is looped towards the gallbladder neck. As frantic attempts are made to control bleeding, adjacent structures may be injured by electrocautery or clips. These injuries can be prevented if the surgeon has a strategic plan for this eventuality. The first step is to apply pressure on the bleeding area using adjacent tissues that can be easily grasped and laid over the bleeding area. Two instruments are then used: an atraumatic grasper and suction irrigation. When these are in the operative field, the compression is relaxed and the bleeding point identified by suction and grasped. If control is not achieved within a few minutes, conversion with application of the Pringle's manoeuvre is mandatory.

Other technical errors include excessive tenting of the cystic duct–common bile duct junction by too much traction on the gallbladder such that a clip used to secure the cystic duct grips the lateral wall of the bile duct resulting in a lateral injury/

partial occlusion. Bile leakage and bilomas in the absence of significant bile duct injuries are due to slippage of a clip on the cystic duct or too deep a plane of dissection on the liver bed during the detachment of the gallbladder.

Risk factors

These relate to surgeon, patient and local pathology.

Training and experience – the proficiency-gain curve

Studies in the pre- and postlaparoscopic era found this to be a more important risk factor than local operative factors such as inflammation or bleeding. The fact that iatrogenic injuries can still be inflicted by experienced surgeons if they ignore basic surgical principles has been documented by reports in both open cholecystectomy and LC. In laparoscopic surgery experience is important not only in respect of technical competence but also in terms of correct visual perception and interpretation of the image displayed on the monitor. The *proficiency–gain curve* (erroneously called learning curve in the surgical literature) appears to affect the risk of bile duct injury. For open cholecystectomy a large Swedish survey showed that most biliary injuries were made between the 25th and 100th operation per surgeon. The Southern Surgeons Club reported an initial high rate of bile duct injury (2.2%) during the first 13 laparoscopic cholecystectomies per surgeon. This rate fell to 0.1% for subsequent operations. Although experience is important in the reduction of bile duct injuries, it is clear that in the laparoscopic era there is no norm and the proficiency-gain curve is surgeon related. Thus bile duct injuries sustained during LC occur over a larger spectrum of experience by individual surgeons.

Improper use of energized dissection systems

With the deployment of energized systems, the important fact is that any thermal source (whether high-frequency electrocoagulation, laser or ultrasonic dissection) can cause damage to the portal structures if used incorrectly. The damage may not be apparent during the operation but can be severe and cause intractable strictures later. The perceived notion that ultrasonic dissection does not cause collateral proximity damage is not supported by experimental studies.

Patient factors

The problem of morbid obesity in the laparoscopic era varies considerably from patient to patient. Some present fewer problems than with open surgery, whereas others are less easy because of their internal fat deposition that obscures the anatomy of Calot's triangle. Fatty livers may be difficult to elevate and are easily lacerated. Although increased age and male gender are associated with increased postoperative mortality after cholecystectomy, they are not significant risk factors for major bile duct injuries.

Anomalous and morbid anatomy

This includes 'dangerous anatomy' and 'dangerous pathological conditions' predisposing to biliary injury. These are present in 15–35% of injuries.

Dangerous anatomy embraces aberrant (anomalous) anatomy, pathological conditions that obscure the view of vital structures such as adhesions, inflammatory phlegmon and excessive fat in the porta hepatis. Anomalies of the biliary tree are present in 10–15% of patients and are not usually identified preoperatively. The anomaly most likely to be involved in ductal injury is when an aberrant right hepatic duct inserts low into the common hepatic or bile duct, and is mistaken for the cystic duct. Another important anomaly is a short cystic duct. Variations in vascular supply also present dangerous situations, not only from the risk of compromise of the hepatic arterial supply (usually right hepatic) but also by increasing the likelihood of haemorrhage during the course of the operation. Adhesions from previous abdominal operations and pathological conditions such as inflammation can distort the anatomy and predispose to injury.

Dangerous biliary pathology includes chronic inflammation with dense scarring (the Mirizzi syndrome and the scleroatrophic gallbladder), fibrosis in the triangle of Calot and acute cholecystitis. A significant iatrogenic injury rate has been documented in patients undergoing LC for acute cholecystitis. Oozing of blood during the procedure with impaired visualization and anatomical distortion associated with the acute inflammation contribute to this increased risk. Nonetheless, the benefit of LC vs open cholecystectomy for acute cholecystitis has been confirmed by a prospective randomized clinical trial. This study showed a significant reduction in the postoperative morbidity in the LC arm (only 3% minor complications vs 23% major complications and 19% minor complications in the open cholecystectomy group). In adopting LC as the routine option, it must be stressed that the need for conversion is encountered in 20–25% of cases, and an early decision should be made to convert electively in the presence of obscured anatomy. Thus the valid approach to LC for acute cholecystitis is a flexible one. The procedure starts with an exploratory laparoscopy to assess the technical difficulty of the operation with particular reference to the structures in the triangle of Calot. A large distended gallbladder should be aspirated and lifted by a retractor rather than grasped. Large stones impacted in Hartmann's pouch that cannot be dislodged may prove problematic. The practical axiom is a simple one, i.e. if adequate exposure for a safe dissection cannot be obtained, or the gallbladder is gangrenous or perforated, the case should be converted. In some cases, a fundus first dissection of the gallbladder may be required. Dangerous biliary pathology also includes polycystic disease of the liver and portal hypertension caused by cirrhosis or schistosomiasis.

Prevention of bile duct injuries

Prevention of iatrogenic injuries to the bile ducts during LC relies on (1) thorough understanding of the anatomy, risk factors and the mechanisms of injury described, (2) image interpretative skills, (3) meticulous technique and (4) timely decision for elective conversion in the presence of difficult anatomy. There are no reliable preoperative indicators of the risks of biliary and vascular injuries during LC. Prevention of these complications, therefore, depends on the adoption of correct surgical technique and a low threshold for conversion. Since the major direct causes of biliary injury are misidentification of anatomy and technical errors, safety is entirely dependent on complete visualization, display and identification of the structures in the triangle of Calot. In this respect, the 30° laparoscope provides a better view of the anatomy, especially the common bile duct.

The vast majority of surgeons use clips to secure the medial end of the cystic duct, and only a minority ligate this duct. Bile leakage without bile duct damage is usually due to slippage of the clip. There are well-documented reports of internalization of these cystic duct clips into the bile duct where the clip acts as a nidus for stone formation several months later. These patients usually present with jaundice and cholangitis suggestive of bile duct stricture. The diagnosis becomes apparent on ERCP. These problems can be prevented by use of absorbable clips or ligation of the medial end of the cystic duct.

During the detachment of the gallbladder from its liver bed the dissection should be kept close to the gallbladder and above the fascial covering of the gallbladder bed. This avoids both bleeding from the hepatic parenchyma and injury to segmental ducts in segments IV/V of the liver. This is a much commoner cause of postoperative bile leakage than damage to a duct of Luschka, which is a very rare anomaly.

Differences between open and laparoscopic bile duct injuries

There are some important differences between the pathology of bile duct injuries sustained during open cholecystectomy versus LC. The laparoscopic injuries tend to be more extensive involving excision of a segment of the common bile duct, and extend to higher levels often involving proximal hepatic ducts (Figure 25.68). The majority (60–75%) are not immediately recognized during surgery. The average age of patients with laparoscopic bile duct injury is 43 years, compared with 56 years in open cholecystectomy. Instances of combined bile duct and vascular injuries have been reported after LC and they carry a poor prognosis. In one reported series four patients had simultaneous occlusion or extirpation of the right hepatic or common hepatic artery. In the immediate postoperative period, three of four patients with combined injuries had hepatic necrosis and/or abscesses with two patients requiring percutaneous or operative drainage. None of the remedial biliary anastomoses failed in the patients with isolated bile duct injuries. By contrast, two patients with combined injuries have had recurrent stenosis following reconstruction. Thus patients with major bile duct injuries should be evaluated for concomitant hepatic arterial injury as management and outcome are influenced by the absence of arterial blood flow to the injured bile ducts and to the liver.

Clinical features

Only one-third of bile duct injuries sustained during LC are detected at the primary operation with the majority being discovered at an average of 10 days postoperatively. If the lesion is not recognized at operation, the bile duct injury usually declares itself postoperatively by the development of pain, fever and external biliary fistula if a drain had been placed at operation. Evidence of peritoneal irritation with guarding and rebound is present due to leakage of bile in the peritoneal cavity, and subphrenic/subhepatic collections are detected on ultrasound. Overt signs of sepsis including positive blood cultures rapidly supervene and the patient develops jaundice, but this may not be severe or progressive in the presence of an external biliary fistula. Apart from LFTs and culture of the discharge and blood, visualization of the biliary tract by an ERCP to ascertain the presence of bile duct damage and its severity is mandatory and should be performed without any delay. MRCP is inferior to ERCP in this situation as, despite documenting the damage and collection of bile, it does not determine whether the leak is active. If the ERCP establishes the diagnosis, the patient should be referred to a tertiary hepatobiliary centre.

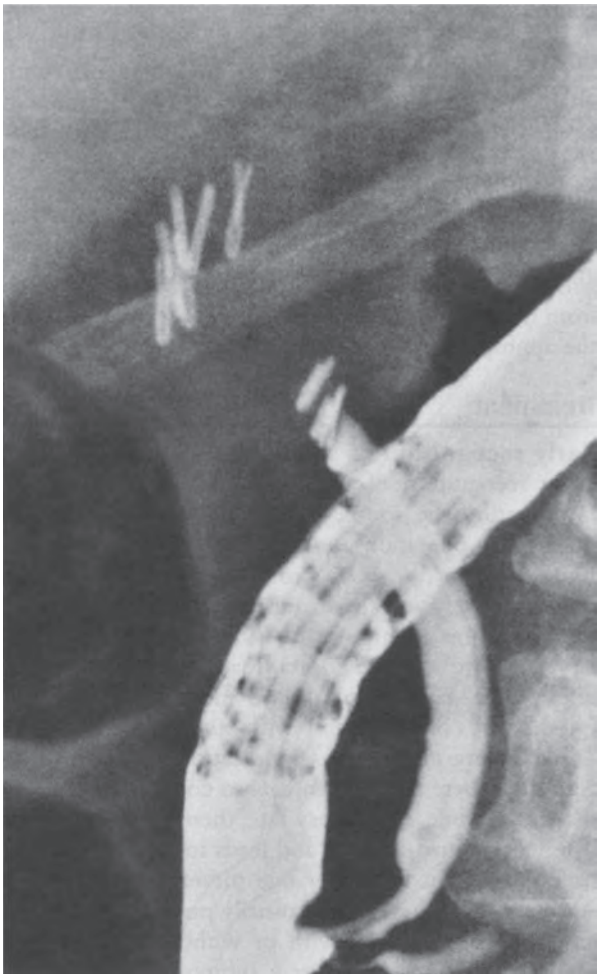

Figure 25.68 Bile duct injury after laparoscopic cholecystectomy: resection of the common hepatic duct. Note excessive shrapnel!

Some patients are actually discharged from hospital after LC and then admitted as an emergency with established sepsis and peritonitis. If a laparotomy is needed, the general surgeon should simply insert a self-retaining catheter into the proximal biliary tree through the defect in the bile duct, place a subhepatic drainage, evacuate any peritoneal bile collections and wash the peritoneal cavity. *Attempts at repair should be resisted at this stage.* As soon as the patient has recovered from the laparotomy, urgent referral to a tertiary unit is the appropriate course of action.

Treatment

Early recognition

Early recognition of the injury can be achieved by investigating the source of any biliary leak observed during the operation and routine IOFC. Only a few surgeons use IOFC routinely during LC, some only selectively and the majority not at all. Proponents of the routine use argue that IOFC delineates the biliary anatomy and provides a 'road map' of the entire biliary tree. Failure to outline the entire extra- and intrahepatic biliary tract with the patient in the Trendelenburg position is an indication for conversion. Although there are no firm data to confirm that IOFC reduces the bile duct injury rate, there is evidence that it reduces injury severity, and leads to detection at the time of surgery. Postoperative surveillance is crucial. Although bile duct injuries usually present postoperatively with a bile leak with or without jaundice and sepsis, some have only vague symptoms initially, e.g. persistent abdominal pain, anorexia, unwillingness to leave the bed. Abdominal pain persisting more than 12 hours after LC always requires investigation.

Definitive treatment

This depends on whether the injury is recognized at operation or subsequently because the patient either develops serious complications postoperatively or presents after discharge from hospital with recurrent episodes of pain, fever and jaundice.

Injuries recognized at operation

The treatment depends on the site and extent of the damage. For high complete transections, a Roux-en-Y hepaticojejunostomy is considered preferable to a difficult direct suture repair as this usually becomes strictured in time. For lower complete injuries with a serviceable proximal duct stump, primary suture repair with fine interrupted absorbable sutures over a T-tube is the treatment of choice (Figure 25.69). The long limb of the T-tube must not be exteriorized through the repair site as this enhances the risks of stricture formation. Partial (lateral) injuries are often treated by the insertion of a T-tube and a Roux-en-Y serosal patch. The long limb of the T-tube is exteriorized through the mobilized jejunum (Figure 25.70). Other techniques include repair with a vein patch over a T-tube (Figure 25.71).

There is an undoubted high incidence of stricture formation following primary repair of bile duct injuries (up to 60%). All these patients, therefore, require long-term follow-up with radiological assessment if they develop symptoms or abnormalities of the liver function tests.

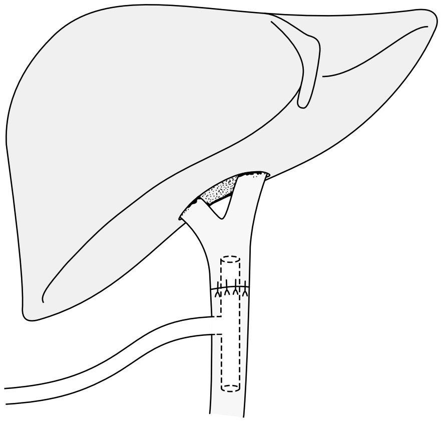

Figure 25.69 Primary repair of a complete injury recognized at operation. The long limb of the T-tube is exteriorized below the suture repair. The risk of stenosis is considerably enhanced if the long limb of the T-tube is brought out at the site of repair.

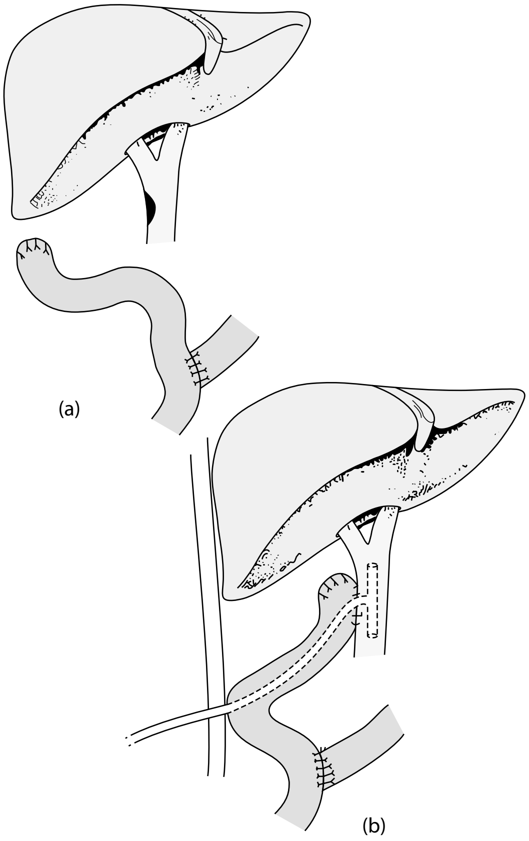

Figure 25.70 Serosal patch Roux-en-Y technique with T-tube intubation for lateral injuries discovered at operation. (a) Construction of a Roux-en-Y loop. (b) The Roux loop is sutured over the defect after the insertion of a T-tube, the long limb of which is brought out through the jejunal loop.

Injuries recognized in the postoperative period

The initial management is supportive. Fluid and electrolyte disorders, if present, are corrected and the patient is put on systemic antibiotics. Surgical intervention is required for drainage of collections/abscesses and development of peritonitis. Otherwise, the patient is initially managed conservatively. An ostomy bag is used to collect the bile leakage from the fistula, which may close. Persistence of the external biliary fistula does not constitute a serious problem since skin excoriation does not occur and the daily losses are seldom severe enough to cause significant fluid and electrolyte depletion. The bile collected in the bag is returned to the gastrointestinal tract via a nasoenteral tube, which is also used for feeding. Surgical intervention to deal with the bile duct injury at this stage is ill advised as the repair is difficult due to inflammatory oedema and because the proximal ductal system is not yet dilated. Repair is, therefore, best postponed for several weeks, by which time the intra-abdominal

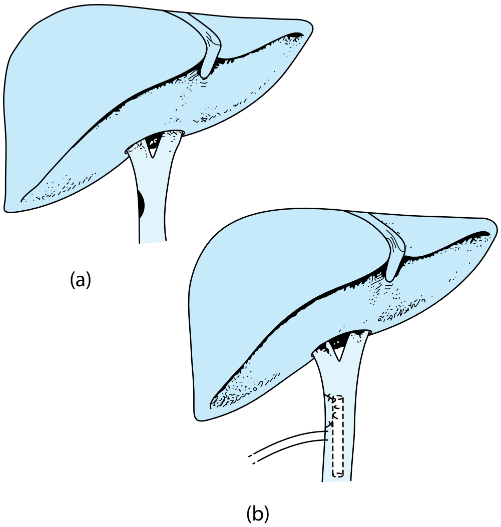

Figure 25.71 Repair of lateral injury recognized at operation by a vein patch. The T-tube is inserted via a small choledochotomy lower down.

sepsis has subsided, the stricture has matured and the proximal ducts have dilated, thus facilitating the procedure.

The definitive treatment of bile duct strictures is best carried out in specialized centres where the overall results, in terms of long-term freedom from jaundice and cholangitis and maintenance of good to normal liver function, are excellent (85–90%) and the operative mortality is low (1–5%). The exact treatment depends on the pathological anatomy of the stricture.

For type 1 injuries, the choice is between Roux-en-Y jejunostomy and choledochoduodenostomy (of the transection type). For common hepatic duct strictures with a serviceable extrahepatic duct stump (type 2), a Roux-en-Y hepaticojejunostomy is indicated (Figure 25.72). The establishment of a mucosa-to-mucosa anastomosis using absorbable fine sutures between the bile duct remnant and the jejunal mucosa is the single most important factor in the prevention of recurrent stricture formation. If good mucosal coaptation is achieved, there is no indication for stenting of the anastomosis and indeed this is undesirable under these circumstances. Some prefer to use an isolated jejunal isoperistaltic segment interposed between the stump of the common hepatic duct and the duodenum (Figure 25.73) instead of the Roux-en-Y loop.

For high strictures with no residual stump but with an intact hilar confluence (type 4), dissection of the liver plate (Glissonian sheath) to enter the hilum of the liver enables downward displacement of the hilar biliary confluence for a good mucosa-to-mucosa anastomosis between the bifurcation and the Roux-en-Y jejunal loop (Figure 25.74). The inside spur of the bifurcation is divided transversely and the edges are then sutured vertically to displace the junction of the two ducts proximal to the anastomosis. This technique does not require any splinting or resection of the liver parenchyma (Figure 25.75).

Destruction of the hilar confluence (type 5) constitutes the most difficult stricture to deal with and usually requires resection of the quadrate lobe to access the right and left hepatic ducts within the liver substance. Each duct is then anastomosed separately to the jejunal loop (Figure 25.76). In these high strictures, a silicone stent is placed across each anastomosis. These stents may be exteriorized transhepatically (Figure 25.77a) or preferably through the jejunal loop (Figure 25.77b) that is sutured to the abdominal wall at the exit site of the tube. The site of fixation of the jejunum is marked with metal clips. This allows easy identification of this access jejunostomy, thereby permitting the introduction of fine flexible endoscopes and balloon catheters for percutaneous dilatation in the event of restricturing after surgical repair. In the worst-case scenario when this technique is not technically possible because of dense fibrosis, the round ligament approach with anastomosis to the segment III duct (Figure 25.2) is used. This functions well

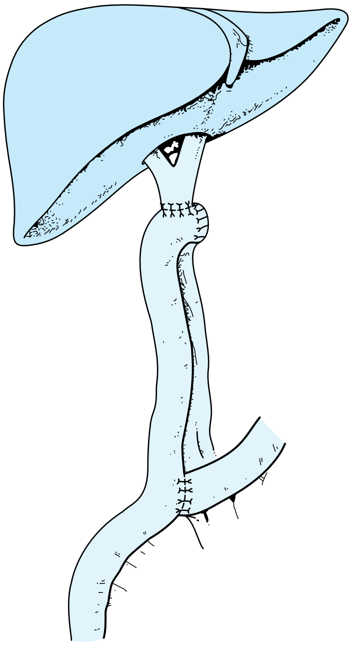

Figure 25.72 Roux-en-Y hepaticojejunostomy for a type 1 bile duct injury.

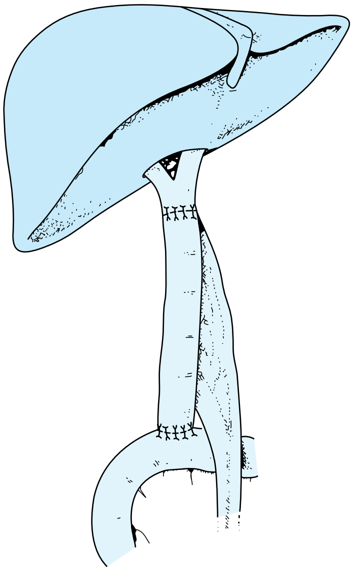

Figure 25.73 Isoperistaltic jejunal loop between the stump of the common hepatic duct and the duodenum.

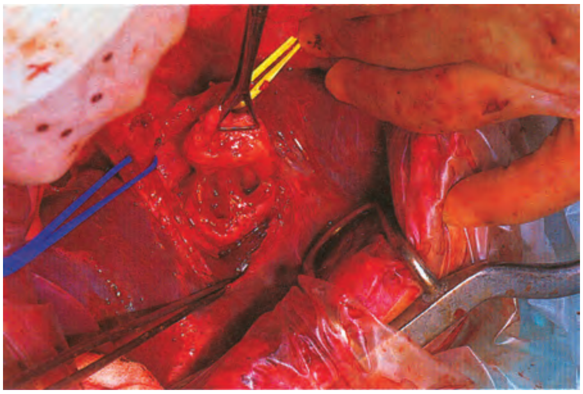

Figure 25.74 Operative photograph: repair of high stricture with no residual stump but with an intact hilar confluence (type 3). The liver plate (Glissonian sheath) has been divided anteriorly and posteriorly to enable entry into the hilum of the liver and downward displacement of the hilar biliary confluence for a good mucosa-to-mucosa anastomosis between the bifurcation and the Roux-en-Y jejunal loop.

provided there is a communication between the right and the left ductal systems.

Endoscopic treatment of bile leaks, clipped ducts and benign strictures

Bile leaks

Bile leakage from slippage of the cystic duct ligature or clips (after LC or open cholecystectomy) is best treated by endoscopic means. Three methods are available:

- insertion of a stent which traverses the papilla and the origin of the cystic duct
- sphincterotomy to reduce the outflow resistance
- nasobiliary drainage with low negative pressure suction.

All appear to be equally effective. Endoscopic cannulation of the common duct has been used to dislodge clips partially occluding the common bile duct after LC. If successful, this is followed by stent insertion. It is not known at present how many of these patients will go on to develop bile duct strictures.

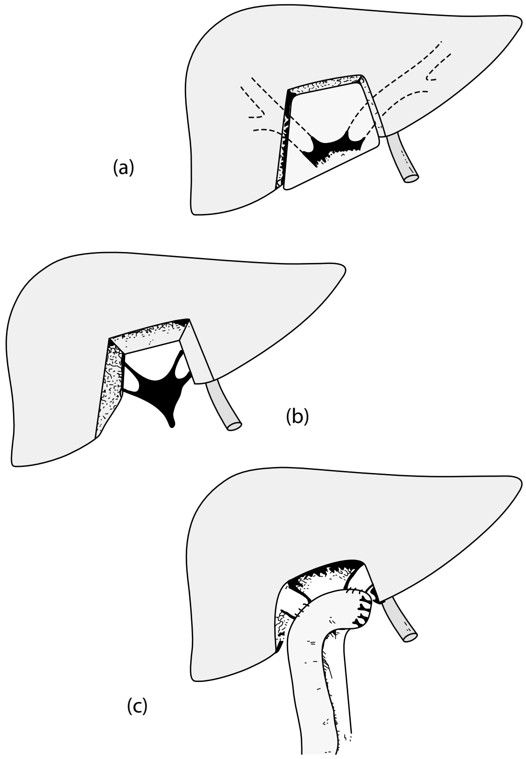

Figure 25.76 Hepaticojejunostomy for lesions with obliteration of the hilar confluence of the right and left hepatic ducts (type 4 injury): (a) the quadrate lobe (segment IV) anterior to the hilus is excised; (b) exposure of the obliterated confluence and identification of the right and left hepatic ducts; (c) the right and left hepatic ducts are anastomosed separately to the Roux-en-Y loop.

Bile duct strictures

Two techniques have been developed for the non-operative treatment of bile duct injuries:

- endoscopic balloon dilatation followed by stenting for 9–12 months
- PTBD using the Yamakawa prosthesis.

The ERCP technique is used whenever possible. A guide wire is passed through the stricture which is balloon dilated until the waist disappears, after which a plastic stent (10–11.5 Fr) is inserted. The stent is replaced every 3 months. Although metal stents have been used in the past, these have been abandoned because of two deaths associated with uncontrolled biliary sepsis. The reported long-term success of endoscopic stenting (stricture resolution) is 43% with a morbidity of 14% and mortality of 5%.

The PTBD is used when the ERCP technique is not possible. A special Yamakawa prosthesis is used. A peripheral bile duct is needled percutaneously under radiological control and a guide wire passed through the stricture into the duodenum (or jejunum following hepatojejunostomy). Initially a 10 Fr percutaneous drain is inserted over the guide wire. The drain is removed and the track dilated to 16 Fr some 7–10 days later when the Yamakawa prosthesis is inserted. The prosthesis is replaced every 3 months or sooner if it blocks and the treatment continued for

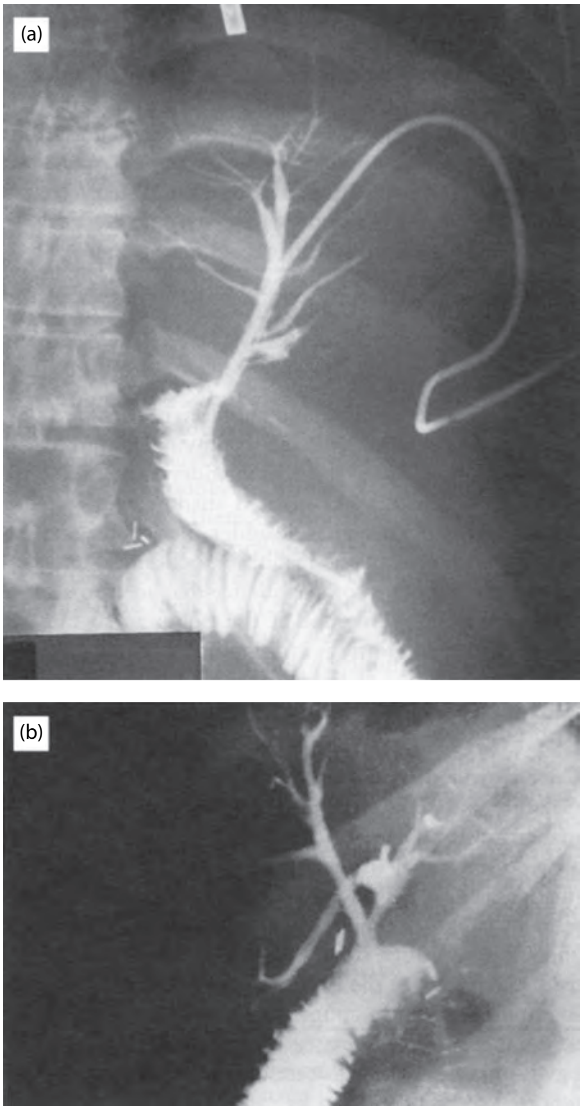

Figure 25.77 Postoperative cholangiograms after repair of type 4 injuries: (a) intrahepatic biliojejunal anastomosis has been stented transhepatically; (b) anastomosis has been stented through the jejunal loop.

12 months. The original Yamakawa prosthesis was manufactured from polyvinyl chloride. This material becomes brittle and breaks in bile. More recent versions do not have this problem. PTBD is more effective than the endoscopic technique is achieving stricture resolution but carries a higher morbidity (26%).

Obviously the results of non-operative treatment of bile duct strictures have steadily improved and there is now sufficient follow-up evidence to document stricture resolution by these methods. The treatment is however protracted and accompanied by a significant morbidity and a mortality of around 2–5%, i.e. similar to that of expert remedial surgery. The indications for non-operative treatment have not been clearly defined but recourse to endoscopic management seems sensible for:

- partial injuries
- poor-risk patients
- patients with portal hypertension
- failed surgical correction.

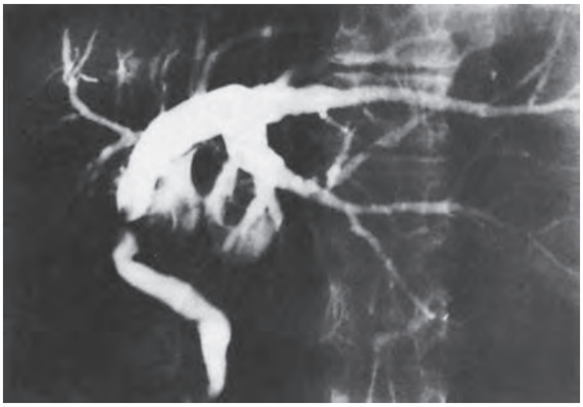

Figure 25.78 Localized stricture of the lower hepatic duct with ductal stones 10 years after cholecystectomy and exploration of the common bile duct. The patient had been completely symptom free until then and presented acutely with cholangitis. Some have ascribed these localized late strictures to impairment of the vascular supply.

Late bile duct injury

Rarely, there is no record of any untoward mishap during the operation and the patient has a smooth postoperative period and is discharged from hospital without symptoms or complications. Attacks of pain in the right hypochondrium with episodes of jaundice and cholangitis develop several months to years later. The majority of these cases are the result of unrecognized partial injuries sustained during the cholecystectomy. A vascular element due to damage to the ascending arteries of the bile duct has been postulated by some in the pathogenesis of some of the strictures. This is more likely to be the case in patients in whom a supraduodenal common bile duct exploration has been performed with T-tube drainage in addition to the cholecystectomy (Figure 25.78). Another cause of jaundice and cholangitis several months after cholecystectomy is internalization of metal clips used to secure the medial end of the cystic duct into the common bile duct. The clip acts as a nidus for the deposition of calcium bilirubinate. The biliary tract is infected in these patients. Not all 'strictures' of the bile duct presenting several years after a LC are the result of iatrogenic damage. The cholangiogram shown in Figure 25.79 of a patient who had undergone LC 5 years previously was misdiagnosed as a late stricture but turned out to be a CC at operation.

Tumours of the biliary tract

Tumours of the gallbladder

These consist of benign lesions and carcinoma of the gallbladder.

Benign tumours

Adenomas of the gallbladder form well-demarcated, polypoid lesions usually less than 2.0 cm in size. Most are discovered in clinical practice following pathological examination of the excised gallbladders, although some are identified as a fixed isolated shadow seen on the oral cholecystogram or gallbladder ultrasound scan in patients with unexplained right hypochondrial discomfort or

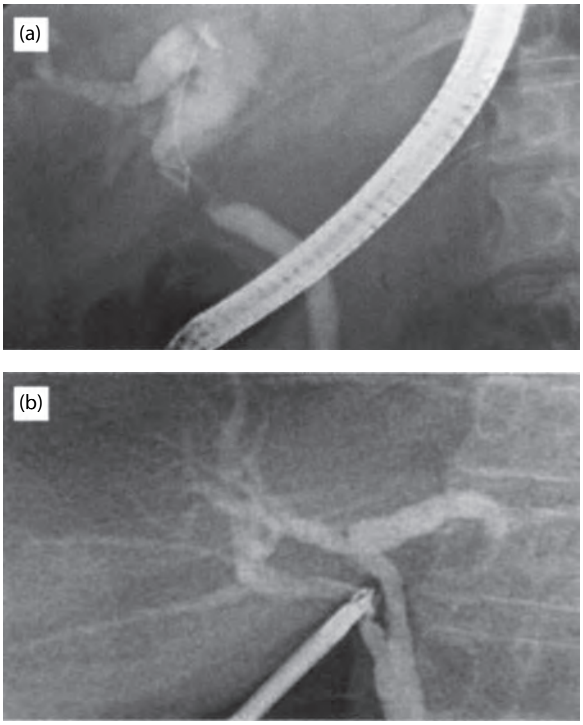

Figure 25.79 (a) Stricture of the common hepatic duct 5 years after laparoscopic cholecystectomy diagnosed preoperatively as iatrogenic injury with delayed presentation. (b) The operative cholangiogram at the time of surgery was normal. A cholangiocarcinoma was found and resected at operation.

pain. They are rare, being found in 0.3–0.5% of cholecystectomy specimens and are usually solitary. They are classified as tubular, papillary or tubulopapillary, depending on their growth pattern. There is some debate whether gallbladder adenomas may progress to carcinoma or not. On ultrasound they are typically echogenic when small, but become more heterogeneous as they enlarge. As ultrasound imaging alone does not identify any coexistent dysplasia or carcinoma *in situ* or indeed whether a polypoid mass in the gallbladder is benign or malignant, the current recommendation is for active intervention by cholecystectomy if the lesion is greater than 1.0 cm in size, in patients older than age 50 years for any polyp that is clearly growing in size on repeat ultrasound scanning even if less than 1 cm.

Carcinoma of the gallbladder

Gallbladder carcinoma represents 98% or more of all gallbladder malignancies; the rest comprise non-epithelial tumurs arising from the muscular or neurological components of the wall, metastases or lymphoma (lymphoma). Carcinoma of the gallbladder is the most common malignancy of the biliary tract and accounts for 3–4% of all gastrointestinal malignancies. The reported autopsy incidence is 0.6–1%. The disease is most commonly seen in elderly women (average age of 65 years) and affects females three times as commonly as males. Death from carcinoma of the gallbladder appears to be declining in many Western countries. This has been attributed to the increased cholecystectomy rate. The exact aetiology is unknown but gallstones are present in 75–90% of reported series of gallbladder cancer. Although the association with gallstones is well established, evidence that the stones are responsible directly for the cancer is not available. The role of infection and the consequent production of carcinogenic bile acid derivatives have been suggested but remain unconfirmed. There is undoubtedly an increased risk in patients with calcified gallbladder irrespective of whether this is patchy or diffuse (porcelain gallbladder). The increased risk is sufficiently great to warrant a cholecystectomy, even if the patient is asymptomatic. An increased incidence of gallbladder cancer is found in chronic typhoid carriers, South American Indians and obese individuals.

Pathology

The histological types of gallbladder cancer are:

- adenocarcinoma – vast majority, include papillary and undifferentiated
- squamous and adenosquamous – rare (5–7%)
- gallbladder neuroendocrine tumours and carcinoids – very rare (1%).

The *ras* family of genes consists of three functional genes that encode highly similar, guanine nucleotide-binding proteins (p21) with GTPase activity. The p21 protein is present on the inner aspect of the plasma membrane of a variety of cells. Strong ras p21 immunoreactivity has been documented in most gallbladder adenocarcinomas (62%) but not in gallbladder dysplasia or chronic cholecystitis. By contrast, ras p21 overexpression is encountered only in a minority of the cases of ampullary carcinoma and CCs. In gallbladder cancer, there is no significant correlation between ras p21 expression and patient survival or between ras p21 expression and p53 immunoreactivity. Furthermore there is no relationship to tumour grade. This suggests that ras p21 may be important in the development of gallbladder carcinoma but not in its progression. The lower rate of ras p21 overexpression in CCs and ampullary tumours indicates that these tumours probably have a different molecular origin.

The vast majority of gallbladder cancers are adenocarcinomas, with papillary, undifferentiated, squamous and adenosquamous constituting a minority. Rare tumours include carcinoid, melanoma and gallbladder neuroendocrine tumours (GB-NETs) which may secrete adrenocorticotrophic hormone.

There is limited published information on squamous cell and adenosquamous carcinomas of the gallbladder. In one recent large published series of 606 resected invasive gallbladder cancers, squamous differentiation was identified in 41 cases (7%). These were classified as pure squamous (without any identifiable glandular-type invasive component, $n = 8$) or as adenosquamous (tumours with the squamous component constituting 25–99%, $n = 26$). The incidence of adenosquamous carcinoma was 4%, and that of pure squamous cell carcinoma (without any documented invasive glandular component) was 1%. The clinicopathological characteristics of adenosquamous carcinoma/squamous cell carcinomas were contrasted with the more common gallbladder adenocarcinomas which constituted the vast majority. The average patient age was 65 years (range 26–81) with a female–male ratio of 3.8. Overall the diagnosis of gallbladder cancer was suspected peroperatively in a very small minority (13%). Macroscopically 58% presented with thickening and hardening of the wall and 6% were polypoid. Squamous metaplasia adjacent to the tumour was detected in 12%. All pure squamous cell carcinomas had prominent keratinization. Giant cells and tumour-infiltrating eosinophils were observed in 29% and 51% of the squamous cell carcinomas/adenosquamous carcinomas, respectively, vs 10% in gallbladder adenocarcinomas. All but three patients had 'advanced' (pT2 and above) disease. Follow-up of 31 patients showed that 25 died of disease (median survival of 5 months).

GB-NETs represent only 0.5% of all NETs. A recent review concluded that they originate from a multipotent stem cell or from neuroendocrine cells in intestinal/gastric metaplasia of the gallbladder mucosa secondary to cholelithiasis/chronic inflammation. GB-NETs are classified as typical and variant carcinoids. Clinically and at surgery, GB-NETs are indistinguishable from gallbladder cancer and are very rarely associated with the carcinoid syndrome (~1%). The median survival of GB-NETs is poor (10 months among 278 cases of GB-NETs reported in the Surveillance Epidemiology and End Results database). The 5 year survival rate for tumours classified as carcinoids/neuroendocrine carcinoma or small cell cancer is 36% and 0%, respectively. Thus GB-NETs have an aggressive behaviour, and, once diagnosed, extensive surgical treatment with careful follow-up with CT scan is mandatory to facilitate early detection of recurrence.

The Union of International Cancer Control (UICC) staging of gallbladder cancer is based on the depth of invasion as follows:

- stage I – confined to the mucosa/submucosa
- stage II – involvement of the muscle layer
- stage III – serosal involvement
- stage IV – spread to the cystic node
- stage V – invasion of the liver and adjacent organs.

Stage V is referred to as advanced gallbladder carcinoma and is classified into four types in accordance with the extent of involvement of adjacent organs:

- type I – hepatic involvement with or without gastrointestinal invasion (Ia, Ib)
- type II – bile duct involvement with or without gastrointestinal invasion (IIa, IIb)
- type III – hepatic and bile duct involvement with or without gastrointestinal invasion (IIIa, IIIb)
- type IV – major gastrointestinal involvement without hepatic or bile duct invasion.

Clinical features

The median age at presentation of gallbladder cancer is 65–70 years, with a female-to-male ratio of 3:1. The major risk factor is chronic cholecystitis, which is associated with dysplasia and carcinoma *in situ* and which subsequently progresses to invasive carcinoma. Other risk factors include (1) PSC, (2) anomalous junction of the pancreaticobiliary ducts and (3) choledochal cysts. Gallbladder carcinoma is found incidentally in 1% of cholecystectomy specimens and in up to 6% of cholecystectomies performed for polypoid lesions. It is usually not suspected clinically nor detected by preoperative imaging. Indeed when diagnosed by imaging, gallbladder cancer is usually advanced. The lack of serosa in the portion of the gallbladder attached to the hepatic parenchyma in essence means that the connective tissue on the undersurface of the gallbladder is part of the hilar plate and hepatic interlobar fissure, accounting for the early tumour invasion of the bloodstream, lymphatics, adjacent liver parenchyma and hepatoduodenal ligament.

The disease is either discovered accidentally during cholecystectomy or presents with non-specific symptoms or acutely with an inflammatory mass in the right hypochondrium (acute cholecystitis). The non-specific symptoms include upper right abdominal pain, which is the commonest symptom (76%), anorexia, nausea and vomiting (32%) and weight loss (39%). Jaundice is present in 38% at the time of presentation and is due to involvement of the common hepatic duct. The liver may be enlarged or the gallbladder may be palpable. Ascites is encountered in advanced disease. Anaemia is present in 50% of patients and is due to chronic haemobilia. Even in the presence of a normal serum bilirubin, the majority of patients have an elevated alkaline phosphatase activity. Few patients with stage I or II disease are diagnosed preoperatively.

Although ultrasound examination of the gallbladder readily identifies advanced disease, it misses the early potentially curable lesions. The most common ultrasound imaging presentation of the gallbladder is that of a mass completely replacing the gallbladder (40–65%), less commonly focal or diffuse wall thickening (20–30%) or an intraluminal polypoid mass (15–25%). Large gallbladder carcinomas which replace the entire gallbladder are often heterogeneous with obliteration of the normally distinct plane which separates the gallbladder from the adjacent liver. Other suggestive ultrasound findings include immobility of gallstones displaced by the mass. Hepatic arterial Doppler waveforms within an intraluminal mass are also suspicious for malignancy. Any solitary mass greater than 1.0 cm with internal vascularity should raise suspicion for gallbladder carcinoma. Although moderate wall thickening alone is not enough to distinguish gallbladder cancer from more common benign disorders, such as chronic cholecystitis or adenomyomatosis, marked wall thickening greater than 1.0 cm or loss of the normal mural layers of the wall should raise suspicion of gallbladder malignancy. Useful diagnostic information is obtained by angio-CT or MRI scan, which are used for tumour staging preoperatively. The highest diagnostic yield is obtained by laparoscopy with contact ultrasonography and this is nowadays regarded as the gold standard for the diagnosis and staging of this tumour.

Treatment

The treatment of cancer of the gallbladder is surgical though opinions vary as to the exact operative procedure that should be done. For stages I–III, the best results are reported with extended cholecystectomy. Initially, the gallbladder is removed and the diagnosis is confirmed by frozen section. If this is positive and the tumour is stage I–III, a 3.0 cm resection of surrounding hepatic parenchyma is performed together with radical lymph node clearance. Resection of the extrahepatic bile duct in continuity is performed if the tumour encroaches on the common hepatic duct.

If the tumour is advanced (stage V), some advocate an aggressive approach with right lobectomy or excision of segments IV and V together with extensive lymphadenectomy (cystic, hepatoduodenal, retroduodenal and coeliac nodes) and claim reasonable disease-free survival periods. Long-term survival has been reported after aggressive major resections of this nature only in patients with type I advanced gallbladder cancer. The other types of advanced disease, even if resectable (II–IV), are generally regarded as incurable and only palliative treatment is indicated in view of the uniformly poor prognosis.

A frequently encountered problem relates to patients in whom an unsuspected gallbladder cancer is found after LC on pathological examination of the resected specimen. Most would agree that the port wound through which the gallbladder was extracted should be excised full thickness. Thereafter, there are no firm guidelines, but it would seem sensible that if the cancer is pT1 (confined to mucosa/submucosa) then no further action is needed except for careful follow-up of the patient. If the tumour involves the muscularis or serosa, then hepatic resection (segments IV and V) and lymph node clearance is wise provided the patient's general condition is good.

In inoperable patients with jaundice and itching, palliation can be achieved either by endoscopic/radiological stenting with metal expanding endoprostheses or surgically by the round ligament segment III bypass. The palliation produced by this simple surgical bypass that is well tolerated is very good. The response of gallbladder cancer to radiotherapy and chemotherapy is poor.

Survival

The overall 5-year survival of patients with gallbladder cancer is 4%. The reported cumulative 5 year survival after extended cholecystectomy is 90–100% for stage I and 50–65% for stage II disease. Long-term survivors may also be encountered in patients with stage III, node-negative tumours (T3N0). The survival of patients with squamous cell carcinomas/adenosquamous carcinomas is significantly worse than that of gallbladder adenocarcinomas, even when compared with stage-matched advanced gallbladder adenocarcinoma cases.

Tumours of the bile ducts

Benign tumours

A variety of benign tumours of the bile duct including adenoma and papilloma have been reported but they are rare and far less common than CCs. Benign bile duct tumours have a tendency to recur after excision and some have been reported to undergo malignant change. Benign bile duct tumours present with jaundice and occult chronic gastrointestinal haemorrhage (haemobilia).

Malignant tumours

The reported autopsy incidence of malignant bile duct tumours ranges from 0.01% to 0.5%.

Malignant bile duct tumours are by tradition in two groups: (1) CCs and (2) periampullary tumours.

Cholangiocarcinoma

CC arises from the epithelium of the intrahepatic and extrahepatic ducts excluding the gallbladder and the papilla of Vater. The annual age-standardized incidence in Europe is 1.0–1.5 cases per 100 000 population although in both Europe and the USA the incidence has been gradually rising over the last three decades. CC is more common in males (in contrast to gallbladder cancer) and this is largely attributed to the higher incidence of PSC in men since this disorder predisposes to CC. There is a marked geographical variability in the incidence of CC attributed to regional environmental risk factors. The highest incidence of CC is in Thailand closely followed by Japan. In Europe, the highest incidence is in Denmark. The majority of patients are old (>65 years) with the peak incidence occurring in the seventh decade. The prognosis is generally poor with a 5 year survival of less than 5%. Most patients present with advanced disease which precludes surgical resection. These patients die within 1 year of diagnosis from cachexia, liver failure and recurrent sepsis due to biliary obstruction. The reported 5-year recurrence rate after surgical resection varies from 60% to 90% although the 1 year survival has increased from 16% in 1975–1979 to 28% in 1995–1999. However, as expected the 5-year survival has not.

Aetiology

Most CCs arise sporadically and the exact cause remains unknown. However, there is good evidence that chronic inflammation and biliary duct cell injury induced by the obstruction are responsible for the development of CC. Cytokines released by the inflammation are held responsible for the malignant transformation. In some 10% of patients there are established risk factors/disorders, all of which cause a chronic inflammation of the bile ducts. In Western countries the most common disease associated with CC is PSC. One large Swedish study documented a CC incidence of 8% in patients with PSC during a mean follow-up period of 5 years. Seventy per cent of these patients also suffered with ulcerative colitis. Occult CC is reported in up to 36% of autopsies and in 40% of livers removed in patients undergoing hepatic transplantation for PSC. CC in PSC patients tends to occur at a younger age (30–50 years), is frequently multifocal and is usually not resectable. Another risk factor is fibropolycystic malformation of the biliary tree, e.g. choledochal cysts, and especially Caroli disease. As in PSC, the CC presents at an earlier age than the sporadic form. The increased risk of tumour is thought to be related to an abnormal choledochopancreatic duct junction, which predisposes to reflux of pancreatic secretions into the biliary tree, chronic inflammation and bacterial contamination. Parasitic infestation of the liver prevalent in Japan and Southeast Asia (*Opisthorchis viverrini, C. sinensis*) also predisposes to CC, which develops in 8–10% of cases. Infestation occurs from consumption of raw or undercooked fish containing adult worms, which then lay their eggs in the biliary system. The parasite induces a chronic inflammation in the biliary tree, which increases the risk of CC. Infestation with *O. viverrini* is a major public health problem in north-east Thailand, where approximately one-third of the population is infected. CC is one of the leading causes of death in this region. The median age at presentation of CC in areas of endemic infestation with *O. viverrini* is 52 years (range 32–69) and the majority of patients are male. Population-based studies using ultrasonography to visualize early tumours have documented the close association between CC and heavy infestation with this parasite. Survival after surgical treatment of CC in patients with opisthorchiasis is broadly similar to that reported for CC without liver fluke infestation. There is also evidence that CC is associated with cirrhosis of any cause. Patients testing positive for hepatitis C virus or hepatitis B virus surface antigen have an increased risk of developing intrahepatic CC (ICC). Exposure to chemical agents and radionuclides has been identified as a risk factor for CC (nitrosamines, dioxin, asbestos, Thorotrast, radon). There is no firm evidence that excess alcohol consumption predisposes to the disease. Recently obesity was identified as a risk factor for the development of extrahepatic CC.

The association with gallstones is much less marked than it is with carcinoma of the gallbladder, but ductal calculi are found in 20–50% of patients who develop CC. Bacterial induced endogenous carcinogens derived from bile salts (e.g. lithocholate) have been implicated and their role is supported by the findings of some epidemiological studies and the higher incidence in typhoid carriers. Thus aside from sporadic cases, CC is seen with increasing frequency in certain clinical disorders, which include:

- parasitic infestation of the biliary tract
- PSC
- ulcerative colitis
- cystic disease of the biliary tract, especially Caroli disease
- chronic typhoid carriers
- ulcerative colitis.

Molecular oncology of cholangiocarcinoma

Several mutations in oncogenes and tumour suppressor genes have been identified in CC, and these are thought to induce and drive the pathogenesis of CC through a stepwise transformation of normal epithelium into carcinoma *in situ* and invasive CC. The mutations which have been identified include the genes k-*ras*, c-*myc*, c-*neu*, c-*erbB2*, c-*met*, *p53* and *bcl*-2. The overexpression of the *p53* tumour suppressor gene or mutations of the k-*ras* oncogene are associated with increasing cytological atypia and tumour aggressiveness. The increased c-*met* expression is thought to play a role in promoting metastases. Experimentally, overexpression of Bcl-2 reduces apoptosis in CC cell lines, while defective Fas receptor or increasing Fas ligand expression enable the tumour to escape immune surveillance. Two markers (fascin and mesothelin) are expressed with transition from carcinoma *in situ* to invasive adenocarcinoma, implicating a role of these markers in neoplastic progression. The majority of CCs (85%) express *p53* to a varying extent. By contrast the bile duct epithelium adjacent to the tumour and dysplastic areas do not. Thus overexpression of *p53* is thought to play an important role as a late event in the pathogenesis of these tumours. Marked diffuse p53 staining encountered in 30–40% of CC is associated with a significantly poorer survival than tumours with low/focal positivity. This adverse effect of high *p53* expression on survival is reported to be independent of age, sex, tumour size, radicality of resection, histopathological grading, lymph node status, perineural invasion and vasoinvasive growth.

Pathology of cholangiocarcinoma

The tumours are best classified into the anatomical site of origin:

- ICC – from the minor hepatic ducts (10%)
- hilar CC – from the right and left hepatic ducts, hilar confluence and proximal common hepatic duct (Klatskin tumours) (50–60%) (Figure 25.80)
- middle CC from the distal common hepatic duct, cystic duct and its confluence with the common bile duct (Figure 25.81)
- distal CC from the distal common bile duct (Figure 25.82); note that middle and distal are often grouped together as distal.

The classification of ICCs and their treatment remains controversial. Some are indeed diffuse (multicentric) and difficult to differentiate from primary hepatocellular carcinomas with which they are grouped because of similar clinical course and poor prognosis. However, the majority of ICCs fall into two macroscopic forms: *mass-forming type* (the majority) and the *periductal infiltrating type.* ICCs of the periductal infiltrating type have a marked tendency to spread along the nerves and lymphatics of the Glissonian sheath, whereas ICCs of the mass-forming type tend to invade the hepatic parenchyma via the portal vein, and exhibit perineural and lymphatic invasion of

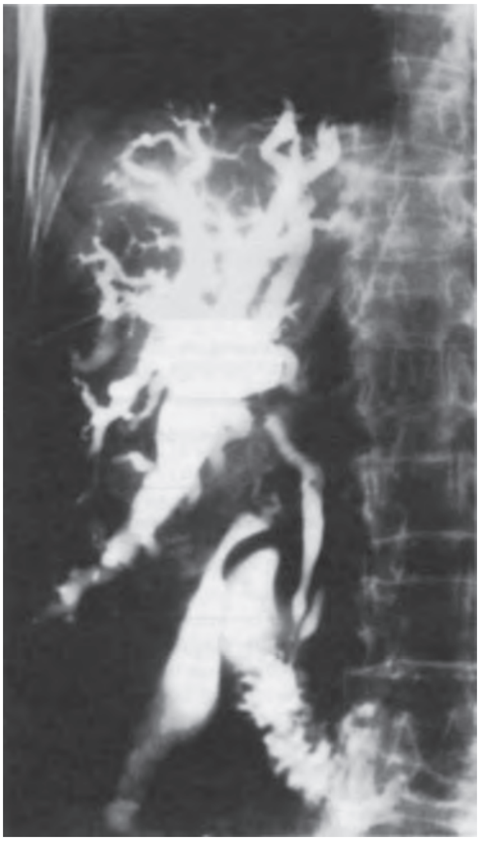

Figure 25.80 Percutaneous transhepatic cholangiogram in a 75-year-old female who presented with marked cholestatic jaundice showing a hilar (Klatskin) tumour.

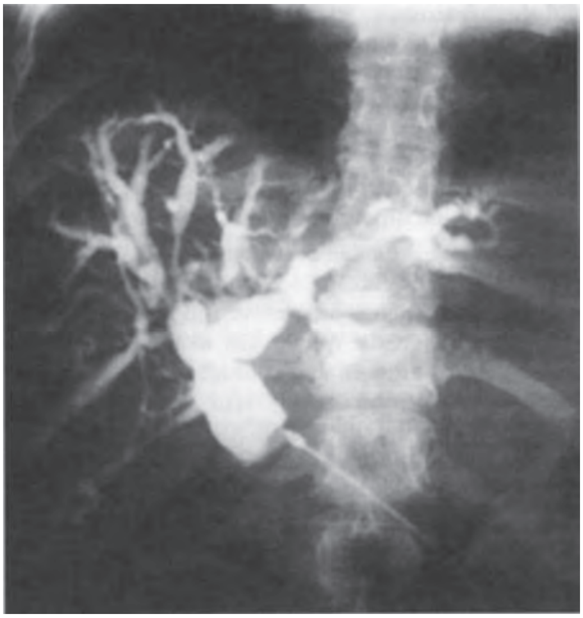

Figure 25.81 Operative cholangiogram showing a tumour at the junction of the cystic duct with the common bile duct. The patient presented with jaundice and acute cholecystitis.

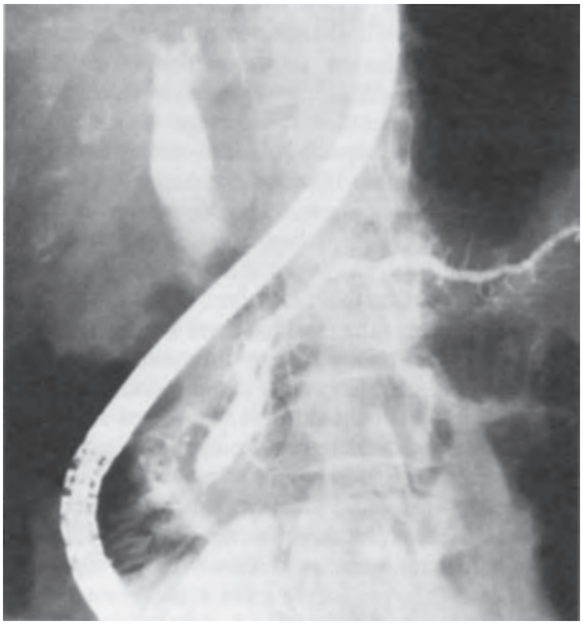

Figure 25.82 Endoscopic retrograde cholangiopancreatography showing a papillary tumour of the distal bile duct extending to the periampullary region.

the Glissonian sheath only when large. Both types can produce satellite hepatic deposits. Therefore, major hepatectomy with combined resection of the extrahepatic bile duct is recommended for all ICCs of the periductal infiltrating type and for those of the mass-forming type with invasion of the Glissonian sheath.

The gross appearances of extrahepatic CC (hilar and distal) assume one of three forms: stricture (scirrhous variety); nodular; or papillary. The scirrhous variety can be very difficult to distinguish from sclerosing cholangitis even on histological grounds. These tumours are generally confined to the proximal ducts (hilar) and form grey annular thickenings with clearly defined edges. The nodular tumours form extraductal nodules in addition to intraluminal projections. The papillary variety is most commonly found in the distal bile duct. These lesions are friable and may fill the duct lumen with vascular neoplastic tissue and tend to bleed in the ductal lumen causing haemobilia. The majority of tumours are adenocarcinomas of varying differentiation. The scirrhous variety is intensely fibrotic and relatively acellular, often with a few well-differentiated ductal carcinoma cells grouped as acini in a dense connective tissue stroma. Rare types include squamous cell carcinoma, adenosquamous carcinoma, adenoacanthoma, lymphoma, carcinoid tumours and melanoma. Malignant smooth muscle tumours of the bile duct have also been reported, as have instances of primary non-secreting apudoma of the hilar region. All CCs are slow growing, locally infiltrative and metastasize late. CCs have a special predilection for perineural spread and do not metastasize beyond the liver.

The commonest type is hilar CC (Klatskin tumours). These have been classified by Bismuth and Corlette into four types which are important in the surgical management:

- type I – tumour involves the common hepatic duct
- type II – tumour involves the bifurcation of the common hepatic duct
- type IIIa – tumour involves the right hepatic duct
- type IIIb – tumour involves the left hepatic duct
- type IV – tumour involves both the right and left hepatic duct.

The special pathological features of CC can be summarized as follows:

- early invasion of adjacent organs (when the tumour is located to the hilus, direct invasion of the liver or perihepatic structures such as the hepatic artery and portal vein)
- invasive spread with neural, perineural and lymphatic involvement, and subepithelial extension
- limited tendency to metastasize, and only one-third of patients demonstrate lymph node, hepatic or peritoneal metastasis at the time of surgery.

Over 90% of CCs are well-differentiated and mucin-producing adenocarcinomas. The macroscopic subtypes of CC are (1) sclerosing tumours, (2) nodular, (3) mixed sclerosing and nodular and (4) papillary. The papillary type is a low-grade adenocarcinoma associated with a better prognosis. Survival is related to the pathological grade of the tumour. The prognosis is worse in younger patients (<40 years). The various histological types (UICC) are:

- UICC – CC (extrahepatic)
  - carcinoma *in situ*
  - adenocarcinoma, NOS
  - adenocarcinoma, intestinal type
  - mucinous adenocarcinoma
  - clear cell adenocarcinoma
  - signet-ring cell adenocarcinoma
  - adenosquamous carcinoma
  - squamous cell carcinoma

  - small cell (oat cell) carcinoma
  - undifferentiated carcinoma (spindle and giant cell type; small cell type)
  - papillomatosis
  - papillary carcinoma, non-invasive
  - papillary carcinoma, invasive
  - carcinoma, NOS
- malignant mesenchymal tumours (rare)
  - embryonal rhabdomyosarcoma
  - leiomyosarcoma
  - malignant fibrous histiocytoma.

Classification of extrahepatic cholangiocarcinoma

This is based on the UICC–TMN (2002) classification.

Primary tumour (T)

- Tx: primary tumour cannot be assessed
- T0: no evidence of primary tumour
- Tis: carcinoma *in situ*
- T1: tumour confined to the bile duct histologically
- T2: tumour invades beyond the wall of the bile duct
- T3: tumour invades the liver, gallbladder, pancreas and/or unilateral branches of the portal vein (right or left) or hepatic artery (right or left)
- T4: tumour invades any of the following: main portal vein or its branches bilaterally, common hepatic artery, or other adjacent structures, such as the colon, stomach, duodenum, or abdominal wall

Regional lymph nodes (N)

- Nx: regional nodes cannot be assessed
- N0: no regional lymph node metastasis
- N1: regional lymph node metastases (at least three lymph nodes)

Distant metastasis (M)

- Mx: presence of distant metastasis cannot be assessed
- M0: no distant metastasis
- M1: distant metastasis

Stage grouping of extrahepatic cholangiocarcinoma

- Stage 0 (carcinoma *in situ*): TisN0M0
- Stage IA: T1N0M0
- Stage IB: T2N0M0
- Stage IIA: T3N0M0
- Stage IIB: T1N1M0; T2N1M0; T3N1M0
- Stage III: T4 any NM0
- Stage IV: any T any NM1

TNM classification of ICC (UICC 2002)

Primary tumour T

- Tx: primary tumour cannot be assessed
- T0: no evidence of primary tumour
- T1: solitary tumour without vascular invasion
- T2: solitary tumour with vascular invasion or multiple tumours but none >5 cm
- T3: multiple tumours >5 cm or tumour invading major branch of portal or hepatic vein(s)
- T4: tumour(s) with direct invasion of adjacent organs other than gallbladder or perforation of the visceral peritoneum

Regional lymph nodes (N)

- Nx: regional nodes cannot be assessed
- N0: no regional lymph node metastases
- N1: lymph node metastases in hepatoduodenal ligament (at least three)

Distant metastases (M)

- Mx: presence of distant metastases cannot be assessed
- M0: no distant metastases
- M1: distant metastases

Stage grouping of ICC

- Stage I: T1N0M0
- Stage II: T2N0M0
- Stage IIIa: T3N0M0
- Stage IIIb: T4 N0M0
- Stage IV: any T any N M1

Prognostic factors

Prognosis is not influenced by the location of the cancer if radical surgery is performed. After surgical resection of ICC, 5-year survival rates vary from 8% to 47%. The best prognosis has been observed in patients with negative resection margins. For extrahepatic CC, 5 year survival rates of 20–54% have been reported. Only histological margin status and lymph node involvement are the important prognostic factors influencing survival. In ICC recent data suggest that poor prognosis is related to angiogenesis and intrahepatic metastasis. Survival is also related to the macroscopic subtype (better for papillary) and grading of tumour (better if well differentiated). Some authors also suggest that younger patients (<40 years) with peripheral CC have a significantly worse survival rate than older patients.

Clinical features

These reflect the location of the tumour. Painless jaundice is the leading symptom (>90%) in patients with extrahepatic CC. It is less frequent in patients with ICC. The biliary obstruction is accompanied by pale stools, dark urine and pruritus. Physical signs include hepatomegaly, right upper abdominal pain, weight loss and fever. Weight loss is not evident until the disease is advanced and is usually accompanied by evidence of hepatic involvement and ascites. Dull upper abdominal pain is a frequent symptom. Some patients present acutely with cholangitis or acute cholecystitis. The duration of symptoms is usually short and measured in months. Physical examination reveals hepatomegaly. Anaemia is present in patients with papillary tumours. It is caused by chronic haemobilia. The faeces of these patients have a characteristic silvery appearance due to a combination of steatorrhoea and altered blood. A significant percentage of patients with hilar tumours have previously undergone recent cholecystectomy (within 6–12 months of diagnosis). Regrettably, these tumours are missed at operation since the small nodule in the porta hepatis is not easily palpable, the common bile duct is not dilated and there is free flow of contrast into the duodenum. Often the surgeon concerned ignores the fact that there is poor filling of the intrahepatic biliary tree or interprets a localized narrowing as extrinsic vascular compression. An operative cholangiogram should never be passed as normal unless there is adequate and complete filling of the intrahepatic biliary tree.

In the preoperative assessment the important disorders which require exclusion are cancer of the pancreatic head, duodenal, gallbladder, periampullary cancers, ductal calculi, PSC and Mirizzi syndrome. PSC can pose problems as it is one of the important predisposing disorders. Aside from full LFTs which confirm cholestasis, the serum level of the carbohydrate antigen 19-9 (CA19-9) is a useful marker as its elevation >100 U/mL has a sensitivity of 89% and a specificity of 86% for CC. Serum CA19-9 is thus useful in the diagnosis. It is also used after radical resection and in monitoring the effect of treatment. After curative resection, serum levels decrease from a preoperative value although this is not a universally reported finding.

The initial imaging tests used most commonly are ultrasound or CT scan, which document the level of biliary obstruction, dilatation of the biliary tract and the absence of stones. The sensitivity of ultrasound in demonstrating the site of biliary obstruction has improved over the years and now exceeds 90%. Indeed duplex ultrasound is now considered equivalent to CT scan, portography and angiography in predicting vascular invasion and resectability. A helical CT scan can detect CC greater than 1.0 cm, the relationship between tumour and adjacent organs and vascular structures. It predicts accurately resectability of the tumour in 60%. MRCP has a similar sensitivity and specificity to ERCP. MRI is currently regarded as the best imaging modality for diagnosis and staging of CC (Figure 25.83). In specialist centres, ^{18}F-fludeoxyglucose positron emission tomography is used to detect small CCs and distant metastases and appears to be very useful in detecting CC in patients with PSC. Cytological diagnosis is obtained by ERCP or PTC. However, both techniques are largely restricted to therapeutic biliary drainage when indicated. There is now good evidence that only laparoscopic exploration can define the true resectability.

In patients with ICCs, mild abdominal pain is the most frequent presenting clinical sign and always warrants investigation. Presentation with jaundice is uncommon (13%). If a mass lesion is detected by imaging (CT, MRI, etc.), preoperative biopsy is ill advised since it may result in local implantation and in one reported series was correct in only 40%. In high prevalence areas such as Taiwan, the preoperative diagnosis of ICCs is difficult because of the frequent association with hepatolithiasis (43%) and the high incidence of hepatocellular carcinoma. Thus in one large reported series of 125 patients from Taiwan, 25% of these patients underwent surgery for chronic cholangitis and 12.5% for hepatocellular carcinoma rather than CC.

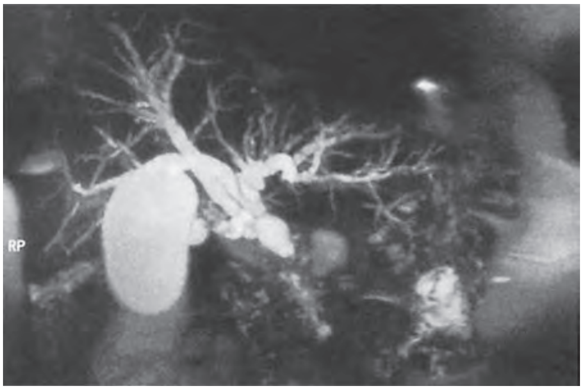

Figure 25.83 MRI/magnetic resonance cholangiopancreatography showing an advanced cholangiocarcinoma with involvement/thrombosis of the portal vein. The patient was treated by stenting.

Radiological signs of non-resectable extrahepatic CC include (1) bilateral hepatic duct involvement up to secondary radicals, (2) encasement or occlusion of the portal vein proximal to its bifurcation, (3) atrophy of one liver lobe with contralateral portal vein branch encasement, (4) involvement of both hepatic arteries, atrophy of one liver lobe with contralateral bile duct involvement and (5) distant metastases.

Preoperative tissue diagnosis of CC can be difficult because of its location, size and desmoplastic fibrous nature of many lesions. Bile cytology can be obtained with fine-needle aspiration with ultrasound or CT guidance; brush cytology can also be procured during ERCP, or by endoscopic transpapillary biopsy or PTC.

In the West, distal bile duct stones and proximal extrahepatic malignant biliary obstructions may coexist. These stones probably predate the development of the malignant obstruction and are found in 12–18% of patients with proximal tumours. In most instances the stones are distal to the malignant obstruction. They may interfere with stent function in inoperable cases.

The proximal (hepatic) longitudinal extension of hilar CC is difficult to predict before surgery. In this respect, the cholangiographic findings may be misleading. In one reported study of 54 patients, histological examination of specimens indicated proximal longitudinal spread of the tumour in 41%. Cholangiography was unreliable in detecting this spread (63% accuracy). A significantly higher frequency of longitudinal spread was observed when the cholangiographic images showed a main tumour with collapsed edges as distinct from tumours with sharp edges on the cholangiographic films. The authors recommend a mapping biopsy performed by percutaneous transhepatic cholangioscopy to establish the limit of the proximal spread but this is not practised in other centres.

Treatment

Surgical treatment

Surgery provides the only means of cure if a potentially curative resection is performed (complete excision of tumour with negative margins). However, the radical resection rate varies with the location of the CC: up to 70% in distal cancers as distinct from 15–20% in high CC. Radical resection is indicated if:

- the patient's general condition and nutritional status are good based on clinical assessment and laboratory tests (serum bilirubin and normal albumin levels); fit but overtly jaundiced patients should have preoperative biliary drainage
- imaging tests exclude extensive tumour, vascular invasion, hepatic lobar atrophy, metastatic disease. Portal vein involvement is always an independent predictor of unresectability.

However, preoperative assessment of resectability is not always possible, and in some cases the resectability can only be determined at operation. Either preprocedural laparoscopy or a limited laparotomy via a right subcostal incision can be performed for adequate staging in these patients. Management of perihilar CC depends on the structures involved and the degree of right or left hepatic duct or common bile duct involvement. The goals of surgical resection are complete excision of tumour with negative margins with restoration of bilioenteric continuity. Aggressive surgery (bile duct excision and partial hepatectomy with *en bloc* caudate lobectomy) is indicated for microscopically negative margins (R0 resection). Some surgeons advocate a more limited hepatic resection for centrally located tumour: resections which include segments IV and V or IV and I. Hilar CC is deemed unresectable in the presence of bilateral portal venous involvement or bilobar extensive hepatic involvement. Middle/distal CC is treated with pancreaticoduodenectomy and hepatojejunostomy.

Treatment options for peripheral cholangiocarcinoma

Approximately 10% of CCs arise within the intrahepatic ducts of the liver parenchyma (peripheral or ICC). Unlike hepatocellular carcinoma, peripheral/ICCs are relatively avascular lesions and the hepatic parenchyma does not show cirrhosis. Resection usually requires a lobectomy; the extent depending on the size and location of the tumour(s) and on the presence of satellites. Hepatic resection with negative margins is the only curative treatment option. After complete resection, 5 year survival is 25%, with the majority of recurrences being intrahepatic. Some authors have reported 5 year survival rates of 39–41% but only in patients with negative margins. The clinicopathological factors which predict good overall survival after hepatectomy include absence of clinical symptoms, presence of mucobilia, early-stage tumour, papillary type and postoperative chemotherapy.

Liver transplantation as a primary treatment for ICC remains controversial in view of the limited organ availability and the high recurrence rate. The results of liver transplantation for ICC are however good with 2 and 5 year survival rates of 48% and 23%, respectively, although more than 50% of patients develop a recurrence within 2 years. The best results are obtained in patients with a single lesion and small tumour size. Selected patients with early-stage ICC can be treated with liver transplantation but currently only within clinical trials. Preliminary results with a neoadjuvant chemoradiation protocol have shown a 45% survival rate with a median follow-up >7 years. It is likely that the greatest benefit from neoadjuvant radiochemotherapy and subsequent liver transplantation may be derived by younger patients (<45 years) who develop CC as a result of PSC.

Adjuvant radiotherapy

Adjuvant radiotherapy is used in many centres to sterilize the surgical margins in an attempt to reduce recurrence. Although there are no prospective randomized trials adjuvant radiotherapy (both external beam radiotherapy with or without brachytherapy and intraoperative radiation therapy) is considered standard treatment for patients with CC following resection with curative intent. The results of several retrospective studies seem to confirm benefit of this policy. One study showed a statistically improved 5 year survival rate (39%) in those treated with surgery alone (14%). Others use an adjuvant chemoradiotherapy regimen consisting of postoperative radiotherapy and bolus 5-fluorouracil (5FU) for the first 3 days of each course. Adjuvant chemoradiotherapy is specially indicated in patients with positive resection margins, and/or if regional lymph nodes are involved.

Neoadjuvant treatment

Neoadjuvant chemoradiotherapy is used in selected patients. In this instance, chemoradiotherapy is administered before surgery. Although the reported data are limited, neoadjuvant therapy has been reported to achieve pathological complete response in some patients and to increase significantly the negative margin rates after resection. In patients with stage I or II CC Rea *et al*. reported a 1-, 3- and 5-year survival of 82%, 48% and 21%, respectively, after neoadjuvant radiotherapy. Despite these encouraging reports, the role of neoadjuvant therapy remains unproven and is currently used only in clinical trials.

Palliative treatment for inoperable/incurable disease

This includes photodynamic therapy, stenting, palliative radiotherapy and palliative chemotherapy. The choice depends on local expertise and the condition, motivation and performance status of the patient

Stenting

In patients who are considered inoperable on preoperative assessment and those who are too old and frail or have serious cardiorespiratory disease, palliation of the jaundice is best achieved by percutaneous transhepatic or endoscopic stenting. The endoprosthesis has to be large (8–10 Fr) and may require replacement if it becomes blocked with calcium bilirubinate encrustation. Self-expanding stainless steel wire biliary endoprostheses are now used frequently for these malignant strictures. The big advantage of this type of endoprosthesis over plastic stents is that it can be introduced through a small-calibre sheath. When the latter is removed, the stent expands to achieve an internal diameter much greater than that of conventional plastic endoprostheses. In addition, the wire framework of the stent becomes buried in the wall of the duct and is thus less liable to cause infection and encrustation with calcium bilirubinate. This contributes to their high patency rate, which is reported to be 90%. These self-expanding metal stents are, however, contraindicated in patients with polypoid tumours as the fronds of the neoplasm project through the wire framework into the lumen. In addition, there is a risk of haemorrhage in these cases.

The controversy in the management of inoperable CC has until recently even extended to the endoscopic palliation in respect of the choice of stent (plastic vs metallic). This has now been resolved by a large prospective study of 101 patients who were followed until death or at least 1 year after inclusion into the study. By multivariate analysis, only tumour size predicted survival. Thus, a threshold of 30 mm at diagnosis distinguished two survival profiles: the median survival of patients with a tumour greater than 30 mm was 3.2 months as distinct from 6.6 months for patients with tumour size <30 mm.

The recommended strategy involves the use of metal stents for patients with an inoperable tumour smaller than 30 mm, while larger tumours are efficiently palliated by a plastic stent.

Approximately 15% of patients develop stent occlusion at a mean interval of 4 months after insertion of metal stents. In 80% occlusion is due to tumour overgrowth and in 20% to debris. When the occlusion is caused by tumour ingrowth, the survival is limited to a maximum of 3 months and these patients are best treated by internal plastic stents. Occlusion of metal stents by debris is effectively cleared by sweeping the stent with a balloon catheter.

Photodynamic therapy

Photodynamic therapy with the photosensitizer porfimer and endoscopic direct illumination of the tumour by laser light of 630 nm can provide effective palliation due to recanalization. The photodynamic therapy may be repeated after 6 months. In a randomized study of 39 patients, those receiving photodynamic therapy plus stenting had a longer survival than patients treated by stent insertion alone (16.4 months vs 3.3 months; Ortner 2003). However, photodynamic therapy is only available in some specialized centres.

Palliative radiotherapy

Patients with locally advanced disease without distant metastases are treated with palliative radiotherapy usually with external beam irradiation combined with intraluminal iridium-192 application. Conformational radiotherapy with locoregional chemotherapy is used in some centres. The percutaneous insertion of iridium-192 wire has been used to provide local irradiation (brachytherapy) with good results and reported median survival of 11–23 months. Iridium-192 brachytherapy administered via the transhepatic approach has been shown to provide worthwhile palliation in patients with unresectable disease and after recurrence following previous complete or partial resection. The most common acute complication after brachytherapy is cholangitis followed by duodenal ulceration.

Chemotherapy

Systemic chemotherapy is indicated in patients with a good performance status who are not candidates for locoregional treatment. The evidence on the efficacy of systemic chemotherapy for advanced CC is however limited. 5FU alone or combined with leucovorin results in response rates up to 10%. Combination chemotherapy with the ECF regimen (epirubicin, cisplatin, 5FU) improves the response rate to 40% with a median survival of 11 months. Moderate single-agent activity has been documented for capecitabine and gemcitabine. Both may be administered in combination with leucovorin and infusional 5FU. The combination of gemcitabine with platinum compounds is also effective in patients with good performance status and adequate liver function. In practice, the selection between single agent and combination chemotherapy depends on performance status and motivation of the patient.

Ampullary tumours

Although these are often grouped with periampullary tumours, there is growing evidence based on detailed histochemical and gene expression studies that ampullary tumours form a separate category. They can either be adenomas or adenocarcinomas. The ampulla of Vater encompasses two distinct types of mucosa: intestinal and pancreatobiliary. Hence, ampullary cancers can originate from either and thus constitute two groups: intestinal and pancreatobiliary with distinct immunohistological staining. Published studies suggest that patients with intestinal types tend to have better prognosis than those with pancreatobiliary cancers. Primary ampullary carcinomas are uncommon tumours (six cases per million population) and carry a better overall prognosis than periampullary cancers.

Some ampullary tumours arise in association with familial polyposis coli. Additionally, ampullary carcinomas have a higher resectability rate than periampullary carcinomas, although the prognosis is poor when the disease is advanced. Several studies have now shown that the preoperative staging is best achieved by endoscopic ultrasound (EUS), which has an overall accuracy of tumour (T) staging of 75%, although it is less reliable in detecting lymph node involvement (60%). Its most important contribution, however, is in the detection of pancreatic invasion, for which EUS has an accuracy of 86%, a sensitivity of 83% and a specificity of 87%.

Ampullary cancer is more common in men. Its usual presentation is with painless obstructive jaundice and itching. Physical examination usually reveals a palpable distended gallbladder (Courvoisier's sign) and moderate smooth hepatomegaly.

Treatment

The options for treatment of ampullary tumours include local excision, pancreaticoduodenectomy and endoscopic management (endoscopic papillectomy and debulking, endoscopic stenting). If the lesions can be confidently diagnosed as benign by endoscopic biopsy, treatment is by transduodenal excision of the ampulla of Vater. This can be performed surgically or by endoscopic papillectomy. Local excision is also used for malignant ampullary lesions if:

- the patient is unfit for major surgery
- the tumour is limited to the ampulla of Vater as diagnosed by preoperative EUS (uT1 and UICC-staging pT1); and the histological grading is G1 or G2 without lymphatic infiltration.

Close postoperative follow-up with duodenoscopy and ERCP are necessary in all patients treated by local excision. For all other operable tumours in fit patients the best treatment is obtained by pancreaticoduodenectomy.

Endoscopic management (laser debulking and stenting) is reserved for patients who are unfit for surgery and for advanced inoperable disease.

Periampullary tumours

The periampullary region represents a cross road of three mucosal surfaces: pancreatic, biliary and duodenal mucosa. Excluding the ampulla itself, these tumours (usually carcinomas) can arise from (1) terminal common bile duct, (2) pancreatic duct or (3) adjacent duodenal mucosa. The histochemical distinction between periampullary cancer and ampullary cancer is based on the type of mucin secreted. Thus whereas ampullary cancer tends to secrete sialomucins, periampullary cancer produces sulphated mucins. They are considered to be distinct from primary duodenal carcinoma. By definition these include tumours that are located within 1.0 cm of the papilla. Periampullary cancers are generally more advanced than ampullary cancer at presentation. Their symptoms include jaundice and pruritus, anorexia, nausea, vomiting or weight loss. Many patients also complain of abdominal pain. Some also complain of diarrhoea (steatorrhoea) due to malabsorption of fat consequent on the absence of lipase.

The staging of periampullary cancer is based on the TNM system giving the following stage grouping:

- stage 0: TisN0M0
- stage I: T1N0M0
- stage II: T2–3N0M0
- stage III: T1–3N1M0
- stage IV: T1–4N0-1M1

Treatment

When operable and in fit patients, the treatment is excision by pancreaticoduodenectomy. Local excision (transduodenal papilloduodenectomy) is indicated in frail patients. The resection includes the papilla, the distal bile duct and the pancreatic duct with surrounding pancreatic tissue. Following excision, the pancreatic and common bile duct are sutured together and then to the defect in the medial wall of the duodenum. The reported experience with this procedure is limited but the operation appears safe.

Results after radical resection of periampullary cancer (pancreaticoduodenectomy) have been improving with 5 year survival rates in recent years ranging from 20% to 61% with a median of 35%. Furthermore, the reported postoperative mortality rate has fallen to single figures in high-volume centres. However, only 63% of patients have curative (R0) resection and 50% have involved lymph nodes, most commonly the posterior pancreaticoduodenal nodal group. Survival after surgical resection is related to the extent of local invasion of the primary lesion, lymph node involvement, vascular invasion, perineural invasion, cellular differentiation, and uninvolved surgical margins.

Parasitic infestations of the biliary tract

In addition to infestations with schistosomes and the larvae of *Taenia echinococcus*, the liver and biliary tract is involved with various other parasitic disorders. Some infestations, such as toxocariasis, remain subclinical in the majority of cases. Children usually acquire infection with *Toxocara canis* from their pets. In addition to hepatic granulomas, there may be central nervous system and eye involvement. The latter is serious and leads to endophthalmitis which can be mistaken for retinoblastoma in these children.

The parasitic disorders which are of significance in surgery of the biliary tract include infestation with *A. lumbricoides, C. sinensis* and *Fasciola hepatica*.

Ascaris lumbricoides

Infestation with this nematode is endemic and prevalent in Asia, China and Africa. It is also found in the rural areas of Europe, the USA and Latin America. The adult worms live in the upper reaches of the small intestine but migrate to and from the bile duct through the ampulla of Vater, up the oesophagus and down to the appendix. The ova are excreted in the stools of infected individuals and contaminate soil and vegetables. Following ingestion of the encysted larvae and dissolution of the cyst wall by the gastric juice, the free larvae penetrate the intestinal mucosa to reach the portal venous system and thus the liver or the lung via the intestinal lymphatics and the thoracic duct. The pulmonary larvae are carried from the alveoli to the pharynx and then swallowed to reach the upper part of the small intestine where they mature into adult worms. The larval migration may involve other organs, e.g. central nervous system and kidneys.

The majority of adult worms migrating into the biliary tract die after a few weeks and may form a nidus for stone formation. Secondary infection of the bile with *E. coli* and other enteric organisms is common and is thought to play a role in the formation of calcium bilirubinate stones and the development of CC. Pyogenic liver abscess may complicate the disease. The usual hepatic lesions are granulomas surrounding the ova, which are deposited in the smaller bile ducts.

Clinical features

The stage of larval migration is accompanied by systemic symptoms: rigors, generalized aches, malaise, cough and asthmatic attacks. Eosinophilia is invariably present. Migration of the adult worms into the bile duct induces episodes of pain in the epigastric region. Jaundice is encountered in 20%. *A. lumbricoides* infestation is one of the commonest causes of jaundice in children and young adults in Africa. At this stage, the clinical picture is usually dominated by recurrent attacks of cholangitis due to calculus formation and secondary infection.

Treatment

Surgical intervention is necessary to deal with the biliary complications. An initial laparotomy is required to look for and remove (by enterotomy) adult worms which can be easily palpated through the intact bowel wall. Exploration of the bile duct, and removal of stones and worms, is performed next. A completion cholangiogram or, preferably, an inspection with the choledochoscope is advisable at the end of the duct exploration. T-tube drainage is essential in all cases and should be carried out with a large tube (16–18 Fr) to enable subsequent percutaneous stone and parasite extraction through the T-tube tract, if necessary. Surgical intervention should be followed by antihelminthic therapy.

Clonorchis sinensis

Man is the definitive host of this trematode which is widely distributed in China and East Asia. The adult worms live in the biliary tract and occasionally in the pancreatic duct. The eggs are excreted in the faeces and ingested by freshwater snails (e.g. *Parafossarulus manchouricus*) where they develop into cercariae. The free-swimming cercariae then penetrate freshwater fish and encyst themselves in the muscles of the host as metacercariae. Man becomes infected by eating contaminated fish, the encysted metacercariae being released in the duodenum. They then migrate into the biliary tract via the ampulla of Vater and mature into adult worms. These cause dilatation of the biliary tract with fibrosis of the ducts and adenomatous bile duct hyperplasia. Secondary infection of the biliary tract with enteric organisms is extremely common and results in death of the worm and stone formation. Recurrent episodes of cholangitis and septicaemia, and the development of CC, account for the appreciable mortality of this parasitic infestation. The diagnosis is confirmed by the demonstration of the typical ova in the faeces.

Treatment

Mild cases can be managed conservatively with chloroquine (300 mg for 2–6 months). Surgical intervention is needed for jaundice and cholangitis. In addition to removal of worms and calculi from the bile duct, an internal biliary drainage (choledochoduodenostomy/jejunostomy or sphincteroplasty) is performed.

Fasciola hepatica

This is primarily an infestation of sheep and cattle. Man is an accidental host, acquiring the disease by eating wild watercress contaminated with metacercariae. The disease has a worldwide distribution and is common in Latin America and the USA. In the UK outbreaks of the disease have occurred in Hampshire and the Lake District at Silverside. The ova are excreted in the faeces of infected animals, develop into miracidia in freshwater and subsequently colonize the intermediate host, a freshwater snail (*Lymnaea truncatula*). Within this host, they mature through various stages into metacercariae which become encysted on neighbouring water plants. Subsequent to ingestion, the free metacercariae are released in the upper part of the small intestine and penetrate the bowel to reach the peritoneal cavity. They then migrate across the peritoneal cavity and enter the liver parenchyma after penetration of the liver capsule. Maturation occurs in the bile ducts. Migration of the metacercariae may occur to other organs: kidneys, muscles, brain and subcutaneous tissue.

Clinical features

The disease is often asymptomatic if the infestation is mild. Systemic symptoms signify heavy infestations and include malaise, anorexia, nausea, vomiting, fever and weight loss. An urticarial rash, jaundice or hepatosplenomegaly may develop. Diagnosis is confirmed by the demonstration of ova in the stool.

Treatment

The disease is usually treated medically with bithionol (50 mg daily for 3 weeks). Surgical intervention is indicated only in cases of biliary obstruction and cholangitis.

CHAPTER 26

Disorders of the spleen and lymph nodes

SIR ALFRED CUSCHIERI

Introduction

The spleen and lymph nodes combined constitute the bulk of the reticuloendothelial (monocyte–macrophage) system. During fetal development, the spleen serves a transient role of haematopoiesis. In adult life the spleen and lymph nodes share many functions with regard to immune processing, and are, therefore, not surprisingly, commonly involved in similar disease processes.

Surgical anatomy of the spleen

Embryology

The spleen appears at the fifth week of intrauterine life as mesodermal thickenings in the coelomic epithelium of the left leaf of the dorsal mesogastrium. These proliferating areas undergo condensation and vascularization forming distinct tissue aggregates which then fuse to form the organ but with retention of the segmental nature of the adult spleen.

The development of either a ‘compact’ or ‘diffuse’ multinotched organ is determined by the initial number of the mesenchymal masses. Reticular cells provide the connective tissue support of the fetal spleen and contribute to the white splenic pulp. The formation of the white pulp is associated with an influx of lymphoid cells. These are primarily B lymphocytes and express surface immunoglobulin (Ig)G and IgD. Follicular dendritic cells are also found with the –cells. The initial –cell accumulation develops in the marginal zone, separating red from white pulp. The reticular cells form sheaths around the central arterioles of the red pulp and ultimately form the periarteriolar lymphatic sheath (PALS). At 19 weeks further lymphoid cells accumulate around the central arteriole. These represent precursor T-cells and interdigitating reticular cells. At 23 weeks, –cells and follicular dendritic reticulum cell precursors are present in the primary follicles of PALS. The spleen increases its size during intrauterine life until birth, when it starts to shrink from reduction of the erythrocyte reservoir of the red pulp.

Anatomy of the adult spleen

The spleen is normally situated in the left upper quadrant tucked under and against the left dome of the diaphragm and overlaid by the lower ninth to eleventh left ribs such that it is impalpable and has to enlarge two to three times before it becomes palpable on examination. It is overlapped anteriorly by the fundus of the stomach with its long axis lying along the line of the tenth rib. The adult spleen has an anterior and posterior extremity (referred to as superior and inferior poles respectively), superior and inferior border and a visceral and diaphragmatic surface. The visceral surface is intimately related to four abdominal organs: stomach (gastric impression), tail of the pancreas, left kidney (renal impression) and the splenic flexure (colic impression).

The gastric impression is directly related to the posterior wall of the stomach from which it is separated by the lesser sac. The spleen is intimately related to the tail of the pancreas as this lies in the lienorenal ligament and is liable to injury unless care is taken during splenectomy (Figure 26.1). Although usually located in the left hypochondrium, abnormal locations are well documented, including the retrorenal space, pelvis and even the scrotum.

The normal dimensions of the spleen are 13 cm in length (distance between the superior and inferior pole), with a range 9–16 cm, breadth (distance from the anterior to posterior border) of 9 cm with a range of 6–11 cm, and width (distance between the diaphragmatic to the visceral surface at the widest point) of 3 cm. Hence size varies considerably between healthy adult individuals. Three distinct morphological types of the human adult spleen are recognized: crescentic, triangular and rhomboid; however, the shape can change with enlargement of the organ by disease. Crescentic spleen refers to organs with regular hila extending from prominent superior to inferior poles. Triangular spleens consist of organs with three borders (anterior, posterosuperior and posteroinferior) and three poles (superior, inferior and posterior). In rhomboid spleens, the poles are expanded into borders, particularly the inferior pole, producing an organ with four unequal sides.

The spleen is attached to the diaphragm and retroperitoneal organs by a fascia and peritoneal folds: splenocolic, diaphragmatic and lienorenal. The attachment to the fundus of the stomach is via the gastrosplenic section of the greater omentum that contains the short gastric vessels. Especially in obese subjects, the spleen is often covered with greater omentum, which indeed may be adherent to the surface of the organ. The splenic substance consists of red pulp (80%) made up of sinuses and sinusoids and cellular cords containing macrophages and white pulp consisting of lymphoid tissue (20%). The red pulp is concerned with maturation and the removal of damaged and senescent red cells, whereas the white pulp forms a major component of the cellular immune surveillance and protection of the body.

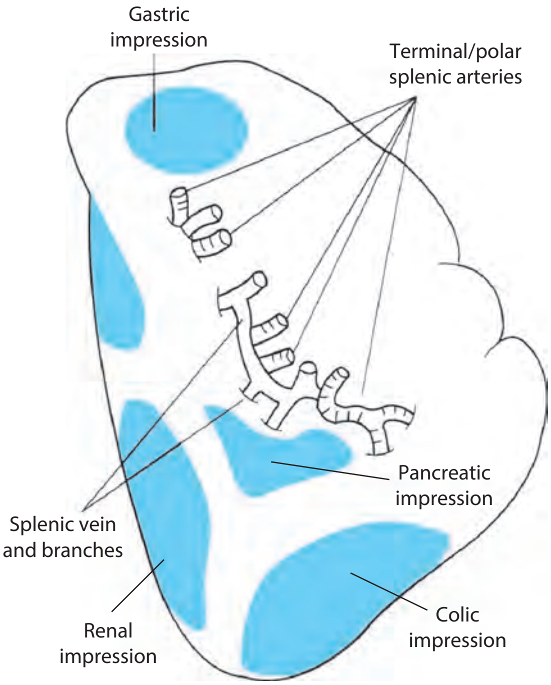

Figure 26.1 Visceral surface and hilum of the spleen.

Splenic vasculature and segmentation

The main arterial supply is from the common splenic artery (origin from the coeliac axis) which is tortuous and runs along the upper border of the pancreas and is anatomically divisible into four segments: suprapancreatic (longest segment), pancreatic (looped or coiled segment lying in a groove on the superior border of pancreas), prepancreatic (commonest site of division of the splenic artery particularly with the distributed vascular pattern) and prehilar segment (lies between the tail of the pancreas and splenic hilum).

The surgically significant morphological distinction in the blood supply to the spleen is between 'compact' (magisteral) and 'diffuse (distributed)' as this determines the nature of the terminal branching of the splenic artery (Figure 26.2a,b).

The division of the common splenic artery into its two terminal arteries (superior and inferior) occurs at a variable distance from the spleen. The two terminal arteries give off the segmental arteries to the spleen. The central segmental arteries always arise from the two terminal arteries, but the segmental arteries to the poles of the spleen (polar) have very variable origin (directly from the common splenic artery, from the terminal arteries and, in the case of the lower polar artery, from the gastroepiploic artery). The segmental vasculature nature of the spleen is important in relation to partial splenectomy and to splenic preservation. The splenic segments, which are separated by avascular planes, are usually four in number: two central and two polar.

The venous drainage mirrors the arterial supply with the splenic vein joining the superior mesenteric vein behind the neck of the pancreas to form the portal vein. The spleen also drains through the short gastric veins and these assume importance in two situations. In the first instance, they become varicose and lead to gastric varices when there is splenic vein thrombosis. Second, they provide the basis of transsplenic decompression of oesophageal varices by the distal splenorenal shunt (DSRS) of Warren. The microcirculation of the spleen is unique and has two systems: closed and open circulation (Figure 26.3).

Segmentation

The splenic segments are anatomically distinct areas of splenic tissue, identified by corrosion casting and numbering 3–7 with a mean of 4, which extend from the anterior to posterior borders perpendicular to the long axis of the spleen. Each segment has its own arterial and venous territory, but two morphological types are recognized: central and polar, with the central segments being wedge-shaped and larger than the polar segments. The polar segments are pyramidal and located at either end of the spleen. The individual splenic segments are separated by a relatively avascular plane and are important in conservative splenic surgery.

Accessory spleens

These are also known as splenunculi and are present in 10% of adults (Figure 26.4). They can be multiple but rarely exceed 10 and

most are situated near the hilum (tail of the pancreas, gastrosplenic ligament, lienorenal ligament and greater omentum). However, they can be located in other sites including the omentum along the greater curvature of the stomach, the mesenteries of the small and large intestine, the broad ligament of the uterus and the pouch of Douglas. They have even been reported in the left testis. The various sites for accessory spleens are grouped as follows:

- perisplenic area: hilum, splenic vascular pedicle, tail of pancreas
- greater omentum: along the greater curvature of the stomach
- mesenteries: small and large bowel
- pelvis/groin: left broad ligament, pouch of Douglas, left testis.

There is some evidence that accessory spleens decline in frequency with advancing years presumably secondary to atrophy, and are thus rare in elderly people. Accessory spleens probably result from failure or incorporation of subsegments during embryological development. They have an organized splenic architecture and separate arterial supply, usually from the inferior polar artery. Accessory spleens are important during splenectomy for haematological conditions such as immune thrombocytopenic purpura, for if left behind they may hypertrophy and cause recurrence of the disease. There is some evidence that accessory spleens are less easily identified during laparoscopic splenectomy.

Histology, cytology and blood flow through the spleen

The spleen is covered by a capsule which consists of two layers, an external serosal and an internal fibroelastic coat, which extend as trabeculae of mainly fibrous tissue containing some muscle cells. The trabeculae blend with a reticular internal framework forming the stroma of the organ. The splenic pulp is composed of two distinct tissues: the *red pulp*, which occupies 80% and is concerned with elimination of effete red cells, and the white pulp, containing lymphoid tissue and accounting for the remaining 20%. A schematic diagram of the of the red and white pulp of the spleen is shown in Figure 26.5.

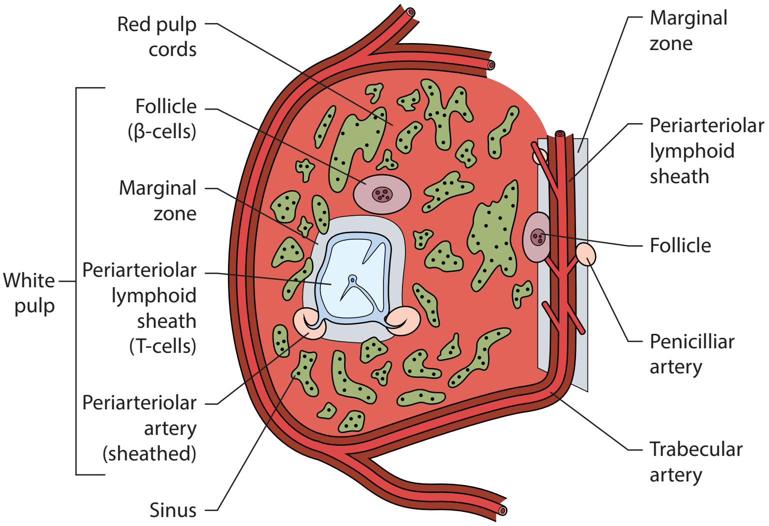

Figure 26.5 Histological appearance of the red and white pulp of the spleen. (Adapted from Buckley.)

Table 26.1 Cellular components of the spleen

Tissue	Cell type
Red pulp	
Cords	Macrophages Reticular cells
Sinuses	Lymphocytes Interendothelial cells
White pulp	
Periarteriolar lymphoid sheaths	T lymphocytes (central) B lymphocytes (peripheral)
Follicles	Dendritic cells Tingible body Macrophages B lymphocytes
Marginal zone	B lymphocytes Marginal zone macrophages

The spleen together with lymph nodes, tonsils, Peyer's patches, etc., constitute the secondary lymphoid organs of the body as distinct from the primary lymphoid organs (thymus and bone marrow) which are the site of lymphopoiesis. Lymphocytes and antigen-presenting cells are found in all the secondary lymphoid organs. The cellular components of the spleen are shown in Table 26.1.

Functions of the spleen and lymph nodes

Haematological functions of the spleen

Because of the peculiar anatomical arrangements of its blood vessels, the spleen is ideally suited as a site of 'quality control' of the erythrocyte population. It removes fragmented, damaged or senescent red cells from the circulation – a process known as culling. It also plays a role in the remodelling of the surface of maturing erythrocytes and in preserving the normal relationship between their membrane surface area and volume. Target cells, which have a relatively high ratio of membrane to intracellular haemoglobin, appear in the peripheral blood soon after splenectomy. A variety of intraerythrocyte inclusions are removed by the spleen by a process known as pitting, after which the red cells are returned to the circulation. Among the inclusions removed are Howell–Jolly bodies, which are probably nuclear remnants (Figure 26.6), siderotic granules (haemosiderin aggregates laid down during normal erythroid maturation) and Heinz bodies, which are pathological aggregates of denatured haemoglobin. Thus after splenectomy, Howell–Jolly bodies and siderotic granules may be seen in the peripheral blood, and red cells show striking changes in shape and size, including the appearance of acanthocytes, irregularly crenated cells and target forms.

The spleen is very effective in the clearance of particulate matter from the circulation – an important function for the timely immune response to bloodborne antigens. The human spleen, contrary to that of other animals, holds relatively little blood in relation to the circulating blood volume, and as such has no significant role in blood storage. Within its volume, however, is a large number of sequestered platelets. Following splenectomy, there is a transient thrombocytosis that can lead to a clinically significant hypercoagulable state.

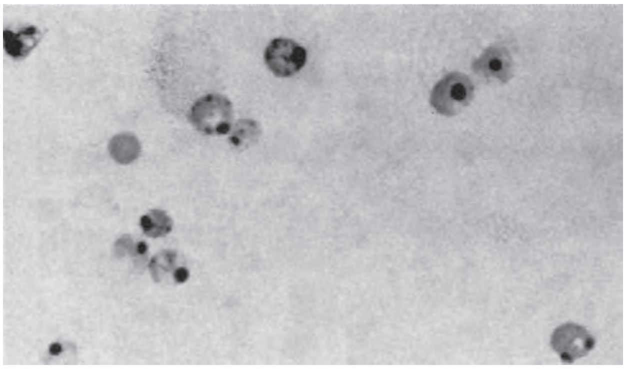

Figure 26.6 Blood film after removal of the spleen. The red cells contain ribonucleoprotein granules (Howell–Jolly bodies) which are normally pitted out by the spleen (Giemsa stain × 680).

The spleen is involved with haemopoiesis only in fetal life, with virtually no blood formation in the organ after birth. However, there may be a reversion to this fetal pattern of erythropoiesis in certain disease states and it is thought that the spleen may become an important organ of red cell production in at least some patients with progressive fibrosis of the bone marrow, i.e. myelosclerosis (Figure 26.7). A variable amount of splenic haematopoiesis also occurs in children with congenital haemolytic anaemia.

Immunological functions of the spleen and lymph nodes

The basic arrangement of lymphoid tissue in spleen and lymph nodes is shown diagrammatically in Figure 26.8. Each population of lymphocytes is in constant flux, with a continuous recirculation of lymph into the bloodstream at the thoracic duct. About one-half of the small lymphocytes of the spleen are migratory. Approximately one-quarter of the body's entire population of T-cells reside within the spleen at any point in time.

Lymphocytes enter the lymph nodes through the permeable walls of the postcapillary (epithelioid) venules of the paracortex; in the spleen, the site of transit is the marginal sinuses bordering the Malpighian corpuscles. T-cells tend to congregate in the paracortex of lymph nodes and form a periarteriolar lymphoid sheath in the spleen. –cells congregate between the T-cells to form small clusters, or primary follicles, at the periphery of the outer cortex of nodes or in the spleen, adjacent to the marginal sinuses. A humoral response following antigenic stimulation involves co-operation between T- and –cells possibly at the site of antigen localization on the surface of large dentritic cells. Immunoglobulin-synthesizing cells appear within days in the medullary cords of lymph nodes and in the red pulp of the spleen. Germinal centres, or secondary follicles, later appear within the primary follicles, and reach their maximum development about 8 weeks following antigenic stimulation. Mature lymphocyte populations exhibit numerous mitotic figures, and are enlarged and plump in comparison with senescent ones.

There is a described phenomenon of 'ineffective lymphopoiesis' within the spleen and lymph nodes. The nuclear remains of pyknotic cells are phagocytosed by macrophages, giving rise to so-called 'tingible bodies'. It may be that these represent 'forbidden clones' (capable of destroying self) and are recognized and destroyed at this stage within the spleen. The spleen may also be the major source for the production of suppressor T-cells. It is further thought that each secondary follicle produces polyclonal 'memory' -cells. Such follicles may also be responding to more than one antigen.

A cellular immune response can be recognized by T-cell enlargement within the paracortex, cytoplasmic RNA synthesis, and cell division. Some cells leave the lymph nodes by way of the efferent lymphatics travelling up the thoracic duct to populate other lymphoid areas via the bloodstream. Efferent lymphatics from the spleen run adjacent to the arterioles, but most lymphoid cells probably leave in vascular channels originating in the white pulp. These channels continue through the marginal zone and open into the red pulp sinuses.

These observations reinforce the fact that lymphoid tissues are not static collections of cells. There is a constant motion of cells through a reticulin scaffolding. Specific stimuli and reactions affect particular components of these populations. When clones of 'well differentiated' cells emerge, as for example, in chronic lymphatic leukaemia, they frequently retain the capacity to migrate, differentiate and form deposits in other distant body sites, e.g. the bone marrow. Structural tumours analogous to follicle centres can arise within a lymph node or group of nodes (follicle cell centre tumours of Luke), and as such may give rise to clones of circulating small cleaved cells that infiltrate and populate other lymphoid areas without causing architectural distortion. Such tumours of small, round, recirculating lymphocytes and follicle centre cleaved cells account for 80% of the acute non-Hodgkin's lymphomas (NHLs) seen in the UK.

Monocytes are sequestered in the white pulp, the marginal sinuses and the red pulp of the spleen. It is in the red pulp where they are converted to fixed macrophages, endowing the spleen with its significant phagocytic capability. It is thought that the spleen, in disease states such as malaria, releases a humoral substance that acts on the bone marrow to cause release of additional monocytes. They eventually circulate to the spleen and can repopulate or further augment its phagocytic capabilities.

Following splenectomy, the primary antibody response is decreased compared to normal, and the secondary response is abnormal in that there is an impaired switching from IgM to IgG antibody subtypes. In addition to antibody synthesis, the spleen produces non-specific effectors of the immune response, such as the tetrapeptide tuftsin. Tuftsin (named after Tufts University where it was identified and characterized) opsonizes particulate matter, and as such facilitates phagocytic activity. It is virtually absent in the blood of asplenic patients. The spleen also influences the opsonization of pneumococci in non-immune individuals and is involved in the alternative pathway of complement activation. All these mechanisms probably account for the increased susceptibility to postsplenectomy sepsis, especially in infants and children. The spleen and lymph nodes both contribute to the immunological surveillance of the host, whereas the spleen additionally performs an important haematological role (Box 26.1).

BOX 26.1 Functions of the spleen and lymph nodes

- Immunological (both spleen and lymph nodes)
  - Antibody production and cell-mediated responses
  - Phagocytosis
  - Maturation of lymphoid cells
  - Significant lymphopoiesis
  - Source of suppressor T-cells
- Haematological (primarily spleen)
  - Filtration of particles from blood: non-specific or antibody coated
  - Removal of red cell inclusions
  - Destruction of senescent or abnormal red cells
  - Compensatory haemopoiesis
  - Storage of platelets, iron and factor VIII

Disorders of the spleen

The most frequently recognized complication of the diseased spleen is the pathological destruction or pooling of blood elements. Splenic enlargement, as it occurs with venous thrombosis and congestion, causes entrapment and pooling that results in destruction of normal cells. This is an exaggeration of the normal function of the macrophage-laden vasculature of the spleen, i.e. the destruction of abnormal red cells, white cells or platelets as they are filtered through the spleen.

Hypersplenism

Hypersplenism is a syndrome of splenomegaly combined with decreased amounts of one or more circulating blood elements:

- anaemia – in patients with diseased bone marrow
- leucopenia $<4–5000/mm^3$
- thrombocytopenia $<100\,000/mm^3$.

Early on, hypersplenism was used to describe the essentially normal function of the spleen in destroying the abnormal cells of hereditary spherocytosis. Damashek broadened this definition to include *all conditions of splenomegaly with decreased numbers of one or more of the blood elements.* Although he postulated that the spleen was active in the control of haemopoiesis via humoral mechanisms, this has no current scientific basis. Some distinguish between primary (due to haematological disease) and secondary (e.g. liver disease with portal hypertension) hypersplenism.

Work hypertrophy of the spleen occurs when the spleen enlarges due to the constant exposure of the spleen's phagocytic machinery to abnormal cells. This is distinctly different from splenomegaly, where destruction of normal blood elements occurs because of a *primary lymphoreticular* process. The term primary hypersplenism is usually reserved for this latter group of disorders as distinct from hyperactivity following splenic enlargement from other causes, e.g. liver disease – *secondary hypersplenism*. In hypersplenism states, the bone marrow is unable to maintain normal numbers of circulating cells or platelets, and splenic enlargement signals the site of destruction. Splenectomy is potentially curative of the cytopenias that occur in hypersplenic states but there are other alternatives (see below).

The exact cause of the cytopenia that occurs with splenic enlargement is a matter of some speculation. The pooling of blood cells is probably the most important mechanism. With increasing splenic size, up to 50% of the total red cell mass may reside in the spleen. This effectively sequesters red cells in a location 'outside' the circulation. The amount of this isolation of red cells can be estimated by measuring peripheral venous haematocrit and comparing that with the red cell volume obtained by isotope dilution techniques.

In a similar fashion, platelets are abnormally sequestered in states of splenomegaly. Approximately 10% of circulating platelets are contained within the spleen in the healthy state. With significant splenomegaly and pooling of blood elements, up to 90% of the circulating platelets are trapped within the spleen. The same can occur with circulating granulocytes and lymphocytes.

The overall effect of such congestive splenomegaly is a dynamic balance between the trapping of blood elements and the ability of the bone marrow to compensate. In disorders with a diminished bone marrow reserve, such as myelosclerosis or chronic myeloid leukaemia, severe anaemia, thrombocytopenia and/or neutropenia may result. If the marrow is healthy or minimally diseased, the peripheral smear may be quite normal.

Hypervolaemia is also a feature of splenomegaly. Where red cell production is limited, the expanded blood volume is mainly plasma volume, with a resultant dilutional anaemia that can compound the destructive anaemia. It is thought that a hyperkinetic portal circulation from an increased splenic blood flow somehow causes an expansion of the splanchnic blood volume. The exact mechanism is far from clear, however. Because of the expanded circulating volume, transfusion in an attempt to restore appropriate numbers of cellular elements can easily cause circulatory overload.

Destruction of blood cells by the spleen

In addition to pooling and trapping within the spleen, the survival of red cells is probably shortened because of 'metabolic stresses'. These include glucose deprivation, lactate accumulation and cellular acidosis due to abnormally close packing of the red cells. The haemolytic component of this specific type of hypersplenism is mild, however. There is less solid evidence for the thrombocytopenia and neutropenia due to these mechanisms.

The spleen routinely destroys abnormal red cells. The cytoskeletal defect manifest as hereditary spherocytosis causes these abnormal red cells to be particularly susceptible to destruction within the spleen. In addition to destroying senescent and diseased red cells, the spleen is active in policing for red cell inclusions such as Heinz bodies (haemoglobin precipitates), via selective membrane disruption and capture of these undesirable intracellular defects.

The spleen also maintains surveillance of surface abnormalities of cells and platelets. In this way, red cells coated with antibody are destroyed via macrophage recognition of the constant portion of the IgG, producing autoimmune haemolytic anaemia. A similar mechanism is probably responsible for the destruction of platelets in certain forms of idiopathic or drug-induced thrombocytopenic states. Additionally, the neutropenia seen in *Felty syndrome* (rheumatoid arthritis and splenomegaly) has an immune basis, probably due to a circulating leucocyte-specific antinuclear factor. The conditions in which splenomegaly can occur with varying degrees of hypersplenism are listed below.

- Infections
  - Acute: hepatitis, mononucleosis, salmonellosis, toxoplasmosis, cytomegalovirus, tularaemia, abscess
  - Subacute: AIDS, bacterial endocarditis, tuberculosis, brucellosis, malaria, leishmaniasis, trypanosomiasis, histoplasmosis
  - Chronic: fungal disease, syphilis, bacterial endocarditis
- Congestive
  - Intrahepatic portal hypertension: cirrhosis, Wilson disease, haemochromatosis, congenital hepatic fibrosis
  - Prehepatic portal hypertension: portal vein thrombosis, obstruction, cavernoma, atresia
  - Posthepatic: Budd–Chiari, congestive cardiac failure
  - Segmental (left-sided portal hypertension): splenic vein occlusion by pancreatitis, pancreatic neoplasm, pancreatic pseudocyst, splenic artery aneurysm
- Haematological
  - Haemolytic disorders: hereditary cell membrane defects, autoimmune haemolytic states (warm antibodies), thalassaemia, sickle cell disease, haemoglobin C disease
  - Myeloproliferative disorders: myeloid metaplasia, polycythaemia vera, essential thrombocythaemia
  - Miscellaneous: primary splenic hyperplasia, megaloblastic anaemia, iron deficiency
- Malignant
  - Haematological malignancies: acute or chronic leukaemias, leukaemic reticuloendotheliosis, malignant lymphomas, malignant histiocytosis, myelomatosis
  - Primary intrinsic malignancies: lymphosarcoma, plasmocytoma, fibrosarcoma, angiosarcoma
  - Secondary malignancies: carcinoma, melanoma
  - Benign: hamartoma, fibroma, haemangioma, lymphangioma
- Inflammatory or granulomatous
  - Felty's syndrome, systemic lupus erythematosus, rheumatic fever, serum sickness, sarcoidosis, beryllosis
- Storage disease
  - Gaucher disease, Wilson disease, Niemann–Pick syndrome, histiocytosis X, Hurler syndrome, Tangier disease
- Miscellaneous
  - Cysts: parasitic, pseudocysts, congenital, traumatic
  - Others: hyperthyroidism, Osler–Weber–Rendu syndrome, splenic mastocytosis, Albers–Schonberg disease.

In practice however 45% of cases of hypersplenism are caused by haematological disease and 40% by liver disease with portal hypertension. Thus all the other causes together account for only 5%.

Management of hypersplenism associated with chronic liver disease

Whereas splenectomy is the recognized treatment for hypersplenism due to haematological disease as it usually normalizes all the components of the cytopenia, the management of hypersplenism associated with chronic liver disease remains non-standardized and currently there are a number of options with no comparative data on efficacy and morbidity. To a large extent, therefore, the treatment depends on local expertise and preferences. Factors that should influence management in the individual case include the severity (Child–Pugh stage) of the disease and the need for treatment of other complications, e.g. bleeding varices, the development of hepatoma in a cirrhotic patient or an end-stage cirrhotic patient requiring liver transplantation.

The most important aspect of hypersplenism in patients with chronic liver disease is the thrombocytopenia, and it is this that requires correction in these patients. Active management is considered only in patients in whom the splenic congestion and the thrombocytopenia are severe. In general, open splenectomy is ill advised in patients with liver disease and portal hypertension because it constitutes a major high-risk operation and may be followed by thrombosis of the portal vein.

The options for the treatment of severe thrombocytopenia in patients with liver disease and portal hypertension are:

- DSRS (Warren procedure)
- transjugular intrahepatic portosystemic shunt (TIPSS)
- laparoscopic splenectomy
- partial splenic embolization (PSE).

DSRS effectively reverses the profound thrombocytopenia resulting from presinusoidal portal hypertension or stable cirrhosis without sacrificing the spleen, and in some centres is considered the treatment of choice for this condition in children. It is used as the only procedure (Child A/B patients) or before hepatic transplantation (Child C disease).

TIPSS improves the hypersplenism in patients with portal hypertension. In one large reported series, the leucopenia was reversed in 50% and thrombocytopenia in 75% of patients. These results indicate that TIPSS is a minimal access intervention that is effective in the treatment of complications of portal hypertension including secondary hypersplenism and has largely replaced the use of DSRS. The problem with TIPSS is its poor long-term patency (beyond 6–12 months). The ideal indication seems to be patients with Child C disease awaiting liver transplantation.

In adult patients with end-stage liver disease and hypersplenism awaiting liver transplantation, and in patients with Child A/B disease requiring hepatic resection for small hepatoma, laparoscopic splenectomy prior to the liver resection/transplantation has been performed as an alternative to TIPSS. Others advise concomitant splenectomy at the time of hepatic resection.

The fourth option in the management of patients with portal hypertension and hypersplenism is PSE. This has to ablate 50% or more of the splenic parenchyma to be effective. It was initially reported to be successful in reversing the hypersplenism (thrombocytopenia and neutropenia) in 90% of patients undergoing embolization of hepatocellular carcinoma and appears to be safe with a low reported incidence of severe complications including splenic abscess formation. PSE was subsequently extended to Child A or Child B (but not Child C) patients with liver disease, where it is reported to also normalize the levels of cholinesterase, total cholesterol and prothrombin time in addition to haematological improvement of the hypersplenism.

Hyposplenism

The more common causes of asplenism and hyposplenism are:

- splenectomy
- splenic agenesis
- atrophy
- coeliac disease
- inflammatory bowel disease and collagenous colitis
- systemic amyloidosis
- alcoholism
- old age
- dermatitis herpetiformis
- sickle cell anaemia
- systemic lupus erythematosus.

The haematological features of hypo/asplenism are:

- abnormal red cells
  - Burr cells
  - target cells
  - pitted cells
- red cell inclusions
  - Howell–Jolly bodies
  - siderotic granules
  - abnormal platelet morphology
  - thrombocytosis
- leucocytosis
  - neutrophilia
  - lymphocytosis
  - monocytosis.

Hyposplenism is confirmed by the appearance of red cell defects (that normally would be culled from the circulation), and the degree of impairment may be qualitatively assessed by ^{99m}Tc-sulphocolloid scintiscanning. There is some evidence based on the percentage of pitted cells in the peripheral blood that splenic function is impaired in elderly people and in alcoholics. Pitted erythrocytes are found in 40% of alcoholics and this functional hyposplenism has been attributed to a direct effect of alcohol on the spleen as the pitted erythrocyte count drops in patients who give up the alcohol habit. However, the possibility that the high pitted erythrocyte count is caused by a direct effect of the alcohol on the red cell membrane can equally account for these changes and the controversy remains unresolved.

The most frequent cause of hyposplenism is surgical splenectomy. Congenital asplenia (*Ivemark syndrome*) is a truly rare disorder, associated with complex cardiac, gastrointestinal, genitourinary and neuromuscular abnormalities. Survival in such cases is largely determined by the ability to recognize and correct the complex cardiac defects. Gastrointestinal anomalies such as malrotation and situs inversus are frequently seen in congenital asplenia. In surviving infants, a common cause of death is overwhelming sepsis due to encapsulated organisms, particularly pneumococcal.

Splenic hypoplasia can also occur from birth as part of the syndrome of *Fanconi's anaemia*, i.e. congenital hypoplastic anaemia. Acquired hyposplenism occurs in about 76% of patients with coeliac disease. The cause is unknown, but may be related to the increased absorption of dietary antigen and subsequent overload of the spleen with circulating immune complexes. The hyposplenic state improves with a gluten-free diet in these individuals. A relationship has also been noted between the morphological state of the intestinal epithelium and splenic function. Hyposplenic states have also been described in other disorders involving the gastrointestinal mucosa including Crohn disease, ulcerative colitis, collagenous colitis and intestinal lymphangiectasia.

Circulating autoantibodies and immune complexes in clinical autoimmune disorders, e.g. systemic lupus erythematosus, have been noted to cause a functional hypoplastic state secondary to Fc-receptor blockage. The hyposplenism of sickle cell anaemia is related to the degree of splenic infarction. Hyposplenism is also a feature of systemic amyloidosis. Hyposplenism can also occur in patients with full-blown HIV and these patients usually present with the *Mycobacterium avium* complex (infection) complicating HIV-related immune thrombocytopenic purpura. This combination is usually lethal, as the severe thrombocytopenia does not improve with corticosteroids, intravenous immunoglobulin and splenectomy. The peripheral blood smear shows Howell–Jolly bodies. Pathological examination of the spleen shows multiple granulomas with numerous acid-fast organisms.

Postsplenectomy sepsis

There is now uniform consensus that the risk of overwhelming sepsis is increased significantly after splenectomy. There is good evidence that the greatest risk is in infants and children (first 5 years of life), and to some extent the risk in adults may have been overestimated in the past, although this is debatable. The problem of postsplenectomy sepsis has been compounded by the increasing incidence of penicillin-resistant pneumococci. The risk of postsplenectomy sepsis is also influenced by the nature of the disease for which the spleen is removed, with the lowest incidence of sepsis being reported after splenectomy for trauma as these individuals are otherwise healthy and have no other disease that impairs the immune defence against invading bacteria. The reported incidence of postsplenectomy sepsis in relation to indication for splenectomy is shown in Table 26.2.

Table 26.2 Incidence of postsplenectomy sepsis in relation to indication for splenectomy

Reason for splenectomy	Incidence of sepsis (%)
Trauma	1.4
Immune (idiopathic) thrombocytopenia	2.0
Incidental (iatrogenic injury)	2.1
Congenital spherocytosis	3.5
Acquired haemolytic anaemia	7.5
Portal hypertension	8.2
Primary anaemia	8.5
Reticulosis/lymphomas	11.5
Thalassaemia	24.8

Modified from Singer, *Persp Pediatr Pathol* 1973;**1**:285–311.

Although the absolute lymphocyte count is increased after splenectomy for trauma, the peripheral blood lymphocyte subpopulations of these otherwise healthy subjects are distinctly abnormal. There is a significant reduction in the percentage of CD4$^+$ T-cells due to a selective and long-term decrease in the percentage of CD4$^+$CD45RA$^+$ lymphocytes. These decreased levels of CD4$^+$CD45RA cells are accompanied by an impairment of the primary immune responsiveness in terms of both T-cell proliferation and antibody responses to newly encountered antigens. By contrast, levels of the reciprocal CD45RO$^+$CD4$^+$ T-cell subset, lymphoproliferative responses and interferon γ production to recall antigens remain normal. These findings suggest that the intact spleen is essential for the generation, maintenance and/or differentiation of unprimed T-cells or their precursors and may explain the impaired primary immune responses following splenectomy.

Splenectomy for trauma carries the lowest risk and thalassaemia the highest; but even for the lowest risk group, there is still a 40- to 50-fold increase in the incidence of overwhelming sepsis. Some of these estimates have been questioned largely because the majority of reported series have had small numbers, and indeed a substantial cohort of the data (on which estimates are based) are from single case reports of pneumococcal serious infections, often with bacteraemia. It is an undeniable fact that community-acquired pneumococcal pneumonia with bacteraemia is common in patients with normal splenic function and is seldom reported because of its established occurrence in susceptible groups. Because of this, there are some who argue that the risk of postsplenectomy pneumococcal sepsis may have been exaggerated.

Although *Streptococcus pneumoniae* is implicated in over 55–60% of septic episodes in asplenic patients, infections by other encapsulated bacteria, e.g. *Haemophilus influenzae, Haemophilus pertussis* and *Neisseria meningitidis*, are also more commonly reported in these individuals, as indeed are infections by Gram-negative bacteria, e.g. *Escherichia coli*. The functional deficits in asplenic patients are numerous, but impaired filtration, diminished phagocytosis, decreased IgM levels and loss of the opsonic tetrapeptide tuftsin all contribute to the increased risk.

The syndrome of overwhelming postsplenectomy infection (OPSI) often begins insidiously. From a non-specific viral-like illness or malaise, the course rapidly turns fulminant. High fever, nausea, vomiting, dehydration, hypotension and obtundation occur with alarming speed, death being the end result if the course of events is not quickly reversed by effective resuscitation and aggressive antibiotic therapy. Gram stain of the peripheral blood smears will occasionally reveal the causative organism and blood culture is invariably positive. The mortality rate of OPSI is 50–80% for all cases combined. Postmortem examination often reveals bilateral adrenal haemorrhage (*Waterhouse–Friedrichsen syndrome*).

The treatment of suspected episodes of OPSI should be aggressive and without any delay. Broad-spectrum antibiotics effective against encapsulated cocci in the first instance are administered intravenously. Intravenous colloids are used to correct the hypovolaemia using CVP and urine output monitoring within an intensive care setting. Altered haemostasis and disseminated intravascular coagulation can occur, and replacement products (fresh frozen plasma, platelets) are often required.

The prevention of OPSI is imperfect at best and is based on vaccination, administration of oral penicillins and patient education. Prophylactic antibiotic therapy is recommended (together with vaccination) in children and some would extend it indefinitely to adults. Although this is sensible for the high-risk groups, there is less of an argument for long-term prophylactic antibiotics in adults undergoing splenectomy for trauma or iatrogenic injury sustained during abdominal surgery. The vaccination should be carried out at least 10–14 days prior to splenectomy for maximum effective immunization. The vaccination programme should always include the polyvalent pneumococcal vaccine and *Haemophilus* vaccines. Unfortunately, the pneumococcal vaccine (against 23 of the most prevalent strains) does not provide immunity against all strains. Not all vaccinated patients develop immunity but the majority do, and the titres of antipneumococcal antibodies remain elevated for up to 42 months. The question of booster immunizations has not been resolved. Immunization after splenectomy (trauma cases) is much less effective but some advise it anyway.

Since no form of prophylaxis is completely effective, it is very important that all patients carry 'splenectomy' cards, and close surveillance and specific patient education are mandatory. At the first sign of infection, all patients with hyposplenic states should be strongly advised to seek medical attention and receive antibiotic therapy.

Splenic infarction

Infarction of the spleen is not uncommon and its clinical presentation is variable. Thus some patients have severe acute symptoms and signs, and may develop serious life-threatening complications (splenic rupture, splenic abscess), whereas others (up to 30%) have minor symptoms or are asymptomatic.

Aside from the predictable autoinfarction in patients with sickle-cell disease, splenic infarction occurs most commonly with splenomegaly due to congestive disorders such as chronic myeloid leukaemia and myelosclerosis. Thromboembolic disorders may cause splenic infarction, e.g. atrial fibrillation, arterial embolic (atheromatous) disease, diabetes-associated microvascular disease and acute torsion of an *ectopic* (*wandering*) *spleen*. A variety of other disorders may be complicated with the development of splenic infarction, e.g. falciparum malaria, Q fever, AIDS, severe necrotizing pancreatitis and pancreatic pseudocysts. Splenic infarction has also been reported as a complication of injection of gastric varices with Histoacryl. The splenic infarction in patients with AIDS is associated with the development of high titres of anticardiolipin antibodies, thrombocytopenia and a coagulopathy. Episodes of cerebrovascular infarction may also occur in these patients. The cause of the splenic infarction in these AIDS patients is arterial thrombosis of the coeliac trunk.

The age range of splenic infarction varies widely (children to old age) and 70% are symptomatic. The most common symptoms are acute upper left quadrant abdominal pain, fever, chills and malaise. However, some patients are asymptomatic and these are usually patients with non-malignant haematological disorders. Fever and leucocytosis are especially marked in patients with thromboembolism as the cause for the splenic infarction. Physical examination reveals tenderness and guarding maximal in the left upper abdomen. Splenic infarction results in a capsular inflammatory reaction frequently causing irritation of the left diaphragm. This may result in left basal pleurisy/effusion and pain referred to the left shoulder (Kerr's sign). Confirmation of the diagnosis is usually achieved by abdominal angio-CT scan.

Initially, the management should be conservative with analgesia and antibiotics. Surgery is indicated if the diagnosis is in doubt or for complications (splenic abscess, bleeding from splenic rupture) when splenectomy is indicated. The morbidity (mainly pulmonary complications) is high and the mortality averages 5% overall.

Pathological changes in spleen and lymph nodes

The pathological processes affecting the spleen and/or lymph nodes can be categorized as:

- reactive
- NHLs
- Hodgkin disease
- secondary tumour deposits.

Immunological reactivity

Reactive changes cause regional lymphadenopathy and, depending on the cause, may be non-specific, granulomatous, epithelioid congeries and angio-immunoblastic with or without accompanying changes in the spleen. These reactive changes are categorized in Table 26.3.

The spleen and lymph nodes normally respond to antigen loads with an expansion of the mononuclear–macrophage and lymphocyte cell lines specific to the challenge. An antibody response results in the increased numbers of immunoglobulin-secreting -cell proliferations in the medullary cords of the lymph nodes or red pulp of the spleen. Reactive follicle centres develop secondarily. Although bacteria that are coated with antibody are more rapidly cleared by the macrophage–monocyte/neutrophil system than non-coated cells, it may be that such coating is counterproductive in the surveillance against tumour cells. Antibody-coated tumour cells may be less easily recognized as 'foreign' by cytotoxic T-cells.

T-cell proliferation follows vaccination or cellular challenges, and the result is expansion of the paracortex surrounding the epithelioid venules. This situation can simulate neoplasia even to the extent of producing binucleate, large cells resembling Reed–Sternberg cells. However, in this situation the architecture of the spleen or lymph node is maintained, and secondary follicle reactivation with plasma cells is usually seen.

Non-antigenic material within lymphatics, such as carbon pigment, is trapped in the medullary sinuses of lymph nodes. Bloodborne material, such as haemosiderin, is trapped by splenic red pulp macrophages. Such non-antigenic entrapment can cause nodal enlargement, e.g. dermatopathic lymphadenopathy, Gaucher disease (lipid storage disease) or thalassaemia/haemolysis. Expansion of the histiocytic elements of lymph

Table 26.3 Reactive pathological changes caused by disease of lymph nodes and spleen

Reactive	Lymph nodes	Spleen
Non-specific		
Sinus histiocytosis	Expansion of medullary cords by histiocytes Removal of non-antigenic material (carbon, Hb) or fat (dermatopathic lymphadenopathy)	Increased numbers of macrophages in red pulp
Follicle centre reactivity	Expanded reactive follicle centres. Numerous mitoses and tingible body macrophages	Reactive secondary follicles in Malpighian bodies
Paracortical	Expansion of paracortex by transforming T-cells, e.g. viral infections	Expansion of periarterial lymphoid sheath by transforming T-cells
Plasma cell	Large numbers of polyclonal immunoglobulin-containing plasma cells in medullary cords	Large numbers of plasma cells in red pulp
Granulomatous		
Non-caseating	Cortical epithelioid granulomas with Langerhans giant cells, reticulin production with no necrosis – sarcoid reaction, e.g. draining tumours, beryllium poisoning	Similar granulomas Initially in the marginal zones
Caseating	Central caseous necrosis, with fibrosis, e.g. tuberculosis	May show amyloid deposition
Necrotizing	Stellate microabscesses with polymorphs and peripheral histiocytes, and multinucleated giant cells, e.g. cat scratch fever, lymphogranuloma venereum	
Epithelioid congeries	Collections of small numbers of epithelioid histiocytes without caseation or giant cells in paracortex with active secondary centres, e.g. toxoplasmosis, visceral leishmaniasis (basophilic Leishman - Donovon bodies)	Red pulp greatly expanded by histiocytes containing Leishman - Donovon bodies in leishmaniasis
Angioimmunoblastic lymphadenopathy	Reactive hyperimmune state with proliferation of epithelioid venules, interstices filled with transforming lymphoid cells, polyclonal immunoblasts and mature plasma cells. May burn out leaving sclerotic nodes or progress to malignant immunoblastic sarcoma	

nodes and spleen occurs with parasitaemia (leishmaniasis, malaria) and to a lesser extent with toxoplasmosis and systemic leprosy. Malarial infestation adds immunoproliferative responses to such histiocytic expansion.

Lymphomas

Lymphomas are the common primary tumours and are classified as Hodgkin's and non-Hodgkin's. Secondary tumours (deposits) affect largely the lymph nodes, as, although they may involve the spleen, splenic metastases are very rare. The spectrum of NHLs arises in cells that typically are migratory throughout the lymphatic system. As such, the more differentiated a tumour, the more difficult it may be to demonstrate malignancy before gross architectural distortion occurs. This spectrum is evident by describing two diseases: *chronic lymphatic leukaemia* where the overproduced small B-lymphocytes continue to circulate, and *lymphocytic lymphoma* where a small population remains confined to lymph nodes. This wide variety of pathological states certainly makes it difficult for the pathologist and clinician both diagnostically as well as in recommending therapeutic action.

It is possible to demonstrate a clone of abnormal cells within the circulating pool of lymphocytes. Thus peripheral blood can be diagnostic when architectural distortion of the lymph nodes or spleen is not diagnostic. This also serves to confirm that, even in well-differentiated lymphomas' the disease is usually systemic, and not just confined to the enlarged lymph nodes/organs.

Intermediate and high-grade lymphomas more typically destroy locally and invade, rather than migrate widely. They are also often highly sensitive to radiotherapy and chemotherapy. As they can grow quickly, disseminate late and are often noticed early by the patient, local therapy alone may be effective. It is because of this wide spectrum of presentation and variable systemic involvement that accurate clinical staging is imperative in the choice of therapeutic regimens. This is especially true, paradoxically, for the cytologically more 'benign' lower grade tumours, which are often metastatic at the time of initial diagnosis. The histopathology/classification of Hodgkin disease according to the revised European–American system is as follows:

- I–lymphocyte predominance
- II–provisional entity: lymphocyte rich–classical Hodgkin disease
- III–mixed cellularity
- IV–nodular sclerosis
- V–lymphocyte depletion.

It is important to stress that, in Hodgkin disease, a portion only of the lymph node may be involved and typically the spleen shows scattered foci of the disease. This is in sharp contrast to NHLs where there is total involvement of the nodes or the spleen. The classification of NHL according to the revised European classification of NHLs recognizes two main groups (B- and T-cell lymphomas) and several other rarer types.

-cell lymphomas

β-cell neoplasms: precursor B-lymphoblastic leukaemia/lymphoma.

- Peripheral -cell lymphomas

1 -cell chronic lymphocytic precursor leukaemia/small lymphocytic lymphoma

2 Lymphoplasmatoid lymphoma/immunocytoma
3 Mantle cell lymphoma
4 Follicle centre lymphoma
5 Marginal; zone -cell lymphomas extranodal (mucosa-associated lymphoid tissue (MALT) type monocytoid -cells) Subtype: nodal (monocytoid -cells)
6 Splenic marginal zone lymphoma (villous lymphocytes)
7 Hairy cell leukaemia
8 Plasmacytoma
9 -cell large lymphoma: subtype: primary mediastinal (thymic) -cell lymphoma
10 Burkitt's lymphoma
11 High-grade -cell lymphoma, Burkitt's-like

T-cell and natural killer (NK)-cell lymphomas

Precursor β-cell neoplasms: precursor T-lymphoblastic lymphoma/leukaemia.

- Peripheral T-cell and natural killer (NK) cell neoplasms

1 T-cell chronic lymphocytic leukaemia, prolymphocytic leukaemia
2 Large granular cell lymphocytic leukaemia
3 T-cell

- Subtype NK-cell type

4 Mycosis fungoides/Sezary syndrome
5 Peripheral T-cell lymphoma, unspecified
  - Subtype: hepatosplenic T-cell lymphoma
  - Subtype: subcutaneous T-cell lymphoma
6 Angioimmunoblastic lymphoma (AILD)
7 Intestinal T-cell lymphoma (enteropathy-associated)
8 Adult T-cell lymphoma/leukaemia
9 Anaplastic large-cell lymphoma, CD30, T- and null-cell types
10 Anaplastic large-cell lymphoma, Hodgkin's like

A special type of extranodal NHL arises from the MALT found in the respiratory epithelium, salivary glands and the gut. This may give rise to MALT-lymphomas or MALTomas, most commonly of the stomach (see Chapter 23).

Hodgkin disease spreads less often along contiguous groups of lymph nodes than NHLs. The disease initially appears as a small focus within an otherwise reactive lymph node (Figure 26.9), and although it metastasizes widely like a carcinoma, actual invasion of the lymphatics rarely occurs.

The more differentiated lymphocyte-predominant variety has a better prognosis than (in decreasing order) nodular sclerosing, mixed cellular or lymphocyte-depleted Hodgkin's. With the routine use of more aggressive radiotherapeutic and chemotherapeutic regimens, the exact cellular classification has become less important in the overall scheme of treatment.

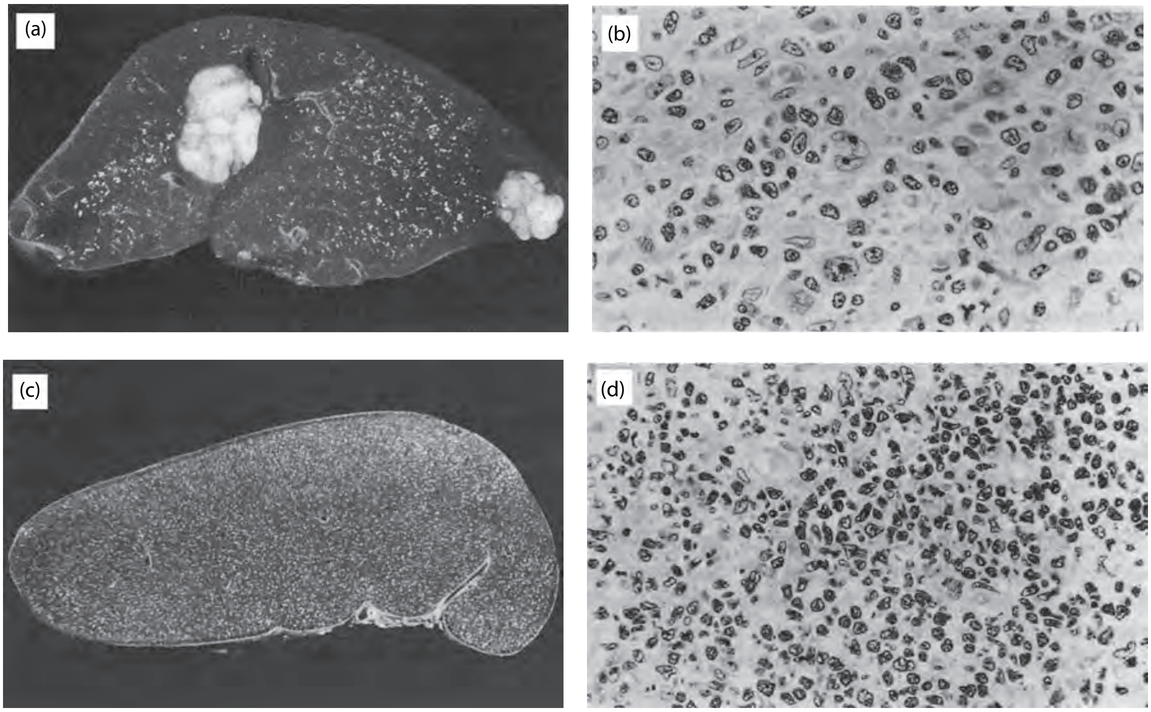

Figure 26.9 The spleen in Hodgkin disease and non-Hodgkin's lymphoma: (a) transverse section of a 200 g spleen removed at laparotomy for staging Hodgkin disease. Two discrete tumour foci are present and histology of the intervening tissue shows only non-specific reactive features. (b) Histology of one of the tumour nodules showing mixed cellular Hodgkin disease, note the central diagnostic 'mirror image' binucleated Reed–Sternberg cell, eosinophils (with bilobed nuclei and granules in the cytoplasm, e.g. three cells from the R-S cell at one o'clock) and plasma cells (e.g. three cells away at three o'clock); the large cells with stippled nuclei are histiocytes. (c) Transverse section of a 400 g spleen from a patient with non-Hodgkin's lymphoma, note involvement of every Malpighian body, histologically there was minimal disturbance of the architecture. (d) Tumour cells from the white pulp of the same spleen showing small cleaved follicle centre cells. This patient had a small number of similar cleaved cells circulating with his peripheral lymphocytes in the blood.

Secondary neoplasms, e.g. myeloid leukaemia, are a particular risk, however, when radiotherapy and alkylating chemotherapeutic regimens are combined.

Familial erythrophagocytosis (of Claireaux and Farquhar) involves sinus histiocytes and splenic macrophages that abnormally engulf and destroy red cells. A severe anaemia occurs, but there is little, if any, architectural destruction of the involved organ. The end stage of this disease evolves into a monocytic leukaemia. A similar non-selective phagocytosis is seen in *histiocytic medullary reticulosis.* While centred in lymph nodes and/or the spleen, the group of *histiocytosis X* diseases is probably not a primary disease of these organs.

Primary haematological disorders

Bloodborne 'haemic reticuloses' are less often found in biopsies of enlarged lymph nodes since such diagnoses are usually first made by other methods. Myeloid leukaemias may be associated with medullary lymph node proliferation or splenic red pulp enlargement and the diagnosis is readily made with stains specific to eosinophil granules (e.g. azo-eosin) or histochemical staining for chloracetate esterase (monocytes). In myelosclerosis, these same areas show a myeloid transformation with a high proportion of multinucleated giant cells, similar to those seen in bone marrow or to megakaryocytes. Erythroid cells, contrary to the lymphocyte lines, have a characteristically dense nucleus, so-called 'empty' cytoplasm, and a periodic acid–Schiff-positive spherical cell membrane. Both familial and acquired haemolytic anaemias may produce myeloid metaplasia of the spleen and lymph nodes.

Splenomegaly

As previously outlined, there are numerous causes of splenomegaly and its relative incidence varies in different parts of the world, but in Western hospital practice, the distribution is as follows:

- patients with hepatic diseases, most commonly cirrhosis – 36%
- patients with haematological disease – 35%
- patients with infectious diseases – 16%, increasingly AIDS
- patients with inflammatory non-infectious disease – 5%
- patients with primary splenic disease – 4%
- others – 3%, e.g. congestive heart failure, endocarditis.

During the past 20 years, AIDS has come to account for 55–60% of patients with splenomegaly caused by infectious disease. The spleen may enlarge transiently in a variety of acute bacterial and viral infections, chronic infections and in subacute bacterial endocarditis. Parasitic infections, e.g. malaria, can result in massive congestive splenomegaly such that rupture is a very real and well-documented risk in those affected.

Portal hypertension causes mild to moderate splenomegaly unless it is posthepatic (Budd–Chiari) or follows splenic vein thrombosis (sectorial, left-sided, sinistral portal hypertension) when massive splenomegaly may occur.

Splenomegaly accompanies both hereditary and acquired red cell defects. The increasing splenic size predisposes these patients to increased red cell surveillance and hence destruction on a volume basis alone. As such, a vicious cycle is established whereby increased destruction and splenomegaly produces even more rapid red cell destruction.

Splenomegaly occurs in about one-third of patients with megaloblastic anaemia, but less frequently in iron-deficiency anaemia. Splenomegaly is unusual in acquired aplastic anaemias, although for unexplained reasons it occurs in a significant number of children with congenital hypoplastic anaemia. It also occurs quite frequently in patients with dyserythropoietic anaemia or 'preleukaemic' states, e.g. sideroblastic anaemia.

Splenomegaly regularly accompanies myeloproliferative disorders. Although polycythaemia vera does not commonly exhibit extramedullary erythropoiesis, the process of myeloid metaplasia in myelosclerosis does and splenomegaly is often massive in this condition. Any form of leukaemia or lymphoma can also cause splenomegaly via the same mechanisms. As such, the splenomegaly that accompanies Hodgkin disease or NHL does not necessarily represent tumour involvement of the organ, raising the possibility of a false-positive clinical stage.

Clinical features

A left upper abdominal mass is often not splenomegaly. For this reason, a comprehensive history and good physical examination is necessary in the first instance to minimize the considerable expense and discomfort of a misdirected evaluation. The normal-sized spleen is not palpable but, when palpable, the spleen is at least two to three times the normal size. The important questions for history taking reflect the common causes of splenomegaly for the particular region. With the spectrum of diseases in mind, it is important to consider infectious (AIDS in particular) and neoplastic disease. A history of travel is often missed unless specifically questioned. Any suggestion of prior pancreatitis or abdominal pain with alcoholism should raise the suspicion of splenic vein thrombosis. The review of the systems enquiry should include questioning for pruritus, as this frequently accompanies myeloproliferative disorders.

The symptoms of splenomegaly itself (irrespective of cause) do not correlate with size, but in practice they tend to be marked only when the spleen becomes massively enlarged since most are due largely to mechanical displacement of adjacent organs and weight of the congested spleen. The symptoms of splenomegaly, as distinct from the manifestations of the underlying disease, include chronic dragging abdominal pain, or pain when lying on the side, abdominal discomfort and early satiety. In addition patients may complain of attacks of acute (colicky) left upper quadrant pains. In general, the bigger the spleen the worse the cytopenia (from hypersplenism) although there are exceptions to this, e.g. marked thrombocytopenia/neutropenia and immune (idiopathic) thrombocytopenia purpura where the splenomegaly is invariably mild. Thus the significant correlation between splenic size and blood counts is not always clinically significant.

The physical examination of a left upper quadrant mass starts with the examiner's hand well inferior in the right iliac fossa probing gently through each exhaled breath of the patient. In addition, the examiner's left hand is cupped posteriorly on the patient's back and flank so as to produce a 'bimanual' feel to the mass in question. If the mass is an enlarged spleen, it will be impossible to appreciate its superior limit. In contrast to the colon and stomach, the spleen lying against the abdominal wall is dull to percussion. Capsular inflammation of the spleen may produce a rub (with the stethoscope). Finally, the right lateral decubitus position may allow for easier examination of a left upper quadrant mass.

A renal mass can usually be distinguished from a splenic mass on physical examination since:

- the kidney moves inferiorly on respiration, whereas the spleen moves medially as well
- the organ shapes are quite different
- the colonic resonance in front of a renal mass is usually not present with splenic masses.

Colonic and gastric masses usually move less well with respiration as they are not as intimately attached to the diaphragm, are more irregular than splenic masses and often have a superior limit that is palpable. The physical examination must also include a careful search for lymphadenopathy, including the tissues of the posterior pharynx. A search for the stigmata of chronic liver disease as well as evidence of purpura or bruising mandates a complete head-to-toe examination.

Clinically splenomegaly depending on extent of enlargement may be:

- mild – up to 5 cm below the left costal margin
- moderate – enlargement up to the umbilicus
- marked (massive)–more than 8 cm or below the umbilicus.

Massive splenomegaly is defined as a spleen having a craniocaudal length greater than 18–20 cm or weighing more than 600 g. Sometimes the term supramassive splenomegaly is used for spleens with a craniocaudal length greater than 22 cm or weight more than 1600 g but the clinical relevance of this category is moot.

Investigation of splenomegaly

The cause of splenic enlargement can usually be identified by history, physical examination and a few appropriate tests. Those cases associated with haematological disorders are often fully characterized by a peripheral blood smear and a bone marrow biopsy. Lymphoreticular malignancies are defined by appropriate biopsy. Haematological or serological testing can identify most infectious causes of splenomegaly. Mononucleosis, a frequent cause, is diagnosed by the finding of atypical lymphocytes in the peripheral blood smear, a positive Paul–Bunnell test (or similar screen), and a rising anti-Epstein–Barr virus titre. Most patients with AIDS who develop splenomegaly are already known to have the disease, but when suspicion is aroused in previously undiagnosed patients, permission for the appropriate testing should be obtained. Patients with a history of travel or those living in endemic areas of disease should have blood smears looking for malaria or marrow for Leishman–Donovon bodies. Disseminated tuberculosis must be considered in all members of a community where there are also immigrants at risk. Laparoscopy may assist in this elusive diagnosis as the majority will have intestinal tuberculosis.

The size, shape and consistency of the spleen can be accurately visualized by CT, MRI or ultrasonography. The determination of splenic size is of crucial importance in determining the surgical approach when splenectomy is indicated in the management of the patient (see below). The spleen's blood vessels can be imaged using either duplex ultrasound, high-dose contrast helical CT and MRI or (rarely nowadays) with selective visceral angiography. The last is used almost exclusively for therapeutic embolization. It is no longer necessary to puncture the spleen directly for splenoportography, as other methods are usually sufficiently accurate. Fine ultrasound-guided needle splenic biopsy is carried out for specific lesions but only in specialized centres.

Ultrasound is the most widely used imaging modality in the investigation of patients with both acute and chronic disorders of the spleen. It is performed by scanning through the intercostal spaces with both greyscale and colour Doppler or power flow (splenic vasculature). Splenic ultrasound is useful for:

- detection of accessory spleens
- confirmation of splenomegaly but not the cause of the splenomegaly
- differentiation of solid from cystic intrasplenic focal masses
- detection of calcification, wall thickening, internal debris, and gas within cystic lesions
- detection of splenic cavernous haemangiomas
- diagnosis of splenic infarction
- diagnosis of splenic trauma and monitoring patients with splenic injuries managed conservatively.

An accurate assessment of the spleen's function can be obtained through injection of labelled platelets, cells (red, white) or carrier molecules and radiotracer studies. The splenic uptake rate of Tc–sulphur colloid or Tc–tin colloid provides a sensitive and quantitative function of splenic function and is based on tracer uptake by the spleen (measured splenic uptake rate divided by measured injected activity). The normal splenic tracer uptake rate is 0.0002–0.0006/s. Values lower than 0.0002/s indicate hyposplenism and values greater than 0.0006/s hypersplenism. There is good correlation between high splenic tracer uptake rates and the severity of the neutropenia and thrombocytopenia.

Undiagnosed splenomegaly

Patients are infrequently encountered where, despite all reasonable efforts, the cause of the splenomegaly remains cryptic. In an otherwise healthy person, this can be a vexing situation. When the organ is minimally enlarged and the patient otherwise healthy, the management consists of careful follow-up. If symptomatic, noticeably enlarging or already significantly enlarged at presentation (the more common situation), diagnostic splenectomy should be considered. In these patients, even if no specific pathological entity is found, one should continue careful surveillance as a lymphoma may develop years after such a splenectomy (possibly due to sampling error at pathological review). Nonetheless, many of the patients who require splenectomy will be found to have an occult lymphoma.

Splenectomy

Indications for splenectomy

There are definite, desirable and debatable indications for splenectomy.

- Definite indications
  - non-salvageable spleen injury (see text)
  - *en bloc* resection of adjacent neoplasms (usually proximal gastric cancer)
  - neoplasms of the spleen – usually lymphomas
  - splenic abscess
  - echinococcal cysts
  - bleeding gastric varices due to sinistral portal hypertension
  - rupture of diseased spleen
- Desirable indications– used selectively
  - hereditary spherocytosis
  - immune (idiopathic) thrombocytopenic purpura
  - AIDS-related thrombocytopenic purpura
  - autoimmune haemolytic anaemia
  - sickling syndromes (sickle cell disease and sickle-β-thalassaemia)
- Debatable indications
  - non-parasitic splenic cysts
  - thalassaemia syndromes
  - lymphoma with specific cytopenia or pancytopenia
  - Thrombotic thrombocytopenic purpura
  - myeloproliferative disorders.

Definite indications

Neoplasms of the spleen should be removed for accurate diagnosis and staging. Septic emboli to the spleen do not require splenectomy, but, when an abscess has formed, removal of the entire organ is the safest management course. Potential spillage of echinococcal cyst contents requires that the entire spleen be removed for this condition.

Bleeding gastric varices resulting from splenic vein thrombosis require splenectomy as does rupture of a splenic artery aneurysm that can occur catastrophically during pregnancy. Splenectomy may be required (*de nécessité*) during resection for proximal gastric cancer to obtain the necessary clearance and adequate regional lymphadenectomy. Although spontaneous rupture of the spleen does occur, it is most frequently seen at times of, or following an interval after, minor abdominal trauma; or as the presenting symptom of previously silent splenomegaly in an already diseased spleen, e.g. malaria, mononucleosis, myelosclerosis, etc. Rarely, a rapidly enlarging spleen in the aggressive forms of NHL may rupture spontaneously. Equally rare, a pseudocyst of the tail of the pancreas may cause splenic vein thrombosis, rapid enlargement and congestion of the organ and spontaneous rupture. In otherwise healthy patients, rupture of the spleen much more commonly follows blunt trauma of the chest and abdomen (see section Trauma) or as an iatrogenic injury during abdominal surgery. Because of concerns regarding OPSIs, every reasonable effort should be made to salvage an injured spleen during surgery and emergency laparotomy (splenic suture, partial splenectomy, etc.). However, there are situations when splenic salvage is ill advised and splenectomy is the sensible option for:

- hilar injuries or a shattered spleen (grade 4 or 5 injuries)
- blast injuries to the organs of the left upper quadrant
- multiple associated injuries where splenic salvage may prolong the procedure
- haemodynamically unstable and elderly patients
- marked intra-abdominal contamination
- rupture of a pathological spleen.

Non-operative conservative management of a known splenic injury, especially in the paediatric age group, is certainly an acceptable alternative to operative therapy in the first instance. Likewise, in an effort to avoid the many complications of splenectomy in patients with myelosclerosis, a small perisplenic haematoma may be closely observed in hospital, with frequent serial ultrasound examinations. But in either case, with any sign of haemodynamic instability or continued bleeding (need for persistent blood replacement), laparotomy is clearly indicated. The disadvantage of conservative management is that, in the event of failure, the potential for splenic salvage is reduced.

Desirable indications

In many of these patients, the decision regarding the need for splenectomy is made by the haematologist who refers the patient to the surgeon. It is usually desirable to perform splenectomy for hereditary spherocytosis, refractory immune (idiopathic) thrombocytopenic purpura and AIDS-related thrombocytopenia that have failed to respond to medical therapy (steroids and human IgG), and acquired haemolytic anaemia. Some cases of genetic red cell enzyme defects, such as pyruvate kinase deficiency, respond favourably to splenectomy. Splenectomy may reduce the blood transfusion requirements of haemoglobinopathies, such as the thalassaemia syndromes. It may also be useful in patients with neutropenia secondary to congestive splenomegaly, e.g. tropical or lymphomatous, for the same reason as in those with storage diseases.

In patients (usually children) with sickling disorders (sickle cell disease and sickle-β-thalassaemia) splenectomy is beneficial in the management of patients who develop large spleens with hypersplenism, major splenic sequestration crisis, recurrent minor splenic sequestration crises, splenic abscess and massive splenic infarction. A high proportion (25%) of these patients has concomitant gallstones and cholecystectomy may be considered at the time of the splenectomy.

Debatable/controversial indications

Splenectomy in the treatment of myeloproliferative disorders is controversial. Its value in the management of chronic myeloid leukaemia remains unproven. It may be occasionally indicated in myelosclerosis with massive splenomegaly, but only if the sequestration of red cells exceeds the spleen's erythropoiesis as measured by isotope tests. The 'rebound thrombocytosis' often seen after splenectomy is particularly severe in this situation. As myelosclerosis follows an unpredictable course of severity, splenectomy to avoid these complications is highly debated. Staging laparotomy for Hodgkin's and NHLs with splenectomy, lymph node harvest and liver biopsies is no longer performed, as accurate staging is possible with modern imaging tests (helical CT and MRI).

Splenectomy: surgical aspects

The first splenectomy in the human is said to have been done by Zaccarelli of Naples in 1649, for splenomegaly in a 24 year old female. The truth of this report has been questioned, as have reports of splenectomy performed in the sixteenth and seventeenth centuries. The first successful splenectomy in the USA was reported by O'Brien in 1816 for splenic evisceration following a knife wound. In 1866, Spencer Wells performed the first elective splenectomy in the UK. Common knowledge at that time held that the spleen was expendable and splenectomy had no untoward side effects. Laparoscopic splenectomy was first reported in several European and North American centres in 1989–1990.

Preoperative management and preparation

As previously mentioned, all patients undergoing elective splenectomy should be immunized against *Streptococcus pneumoniae and Haemophilus* spp. and this should be carried out 2 weeks before surgery. Otherwise, preoperative preparation for splenectomy should be routine as for any major abdominal operation and this includes prophylaxis against thromboembolic disease. Special consideration should be given to the patient's haematological findings, clotting parameters and liver enzymes. Patients with bone marrow dysfunction or with immune platelet destruction abnormalities may be markedly thrombocytopenic prior to operation. If the platelet count is low on the basis of bone marrow failure, then platelet transfusion to a level greater than 60 000 is indicated both prior to and following operation for the first few days, in an effort to prevent bleeding episodes. If the thrombocytopenia is on the basis of immune disease, e.g. immune thrombocytopenic purpura, then preoperative platelet transfusions will be less useful, whereas human IgG will increase the platelet count. Coagulopathies due to liver disease require replacement therapy with fresh frozen plasma or cryoprecipitate as determined by factor assay.

In patients with massive splenomegaly, it may be useful to consider immediate preoperative radiological embolization of the splenic artery. Otherwise, it is usually possible to ligate the splenic artery at the superior border of the pancreas via the lesser sac at the beginning of the operation. This allows for a period of 'autotransfusion' of the sequestered blood elements during the remaining dissection. As removal of a massive spleen may be accompanied by substantial blood loss, a cell-saver system for autotransfusion should be available. Particular attention should be made during the ligature and division of the splenic hilar vessels to avoid inadvertent damage to the tail of the pancreas.

Attention to exact haemostasis is critical for the reduction of postoperative complications. The bed of the spleen, especially the raw surface of the diaphragm, should be meticulously inspected for oozing and bleeders before closure. The use of the argon spray coagulation is very effective in ensuring a dry splenic bed. Drains should not be inserted after splenectomy as they are ineffective and enhance the risk of subphrenic infection.

Laparoscopic splenectomy

Because of its advantages (fewer perioperative complications, reduced morbidity and a shorter hospital stay), laparoscopic splenectomy has now replaced open operation for most disorders requiring splenectomy or splenic surgery. There is some evidence, however, that accessory spleens are more difficult to identify laparoscopically. This may result in a recurrence of the thrombocytopenia following laparoscopic splenectomy for idiopathic thrombocytopenia, although there are no comparative studies and the results of laparoscopic splenectomy in reversing the thrombocytopenia and for acquired haemolytic anaemia have been equivalent to those obtained by open splenectomy.

Laparoscopic splenectomy has also been performed for isolated traumatic splenic injuries although the reported experience is limited. There are some concerns in relation to laparoscopic splenectomy for neoplastic disease as fragmentation/morcellation of the specimen may promote tumour spillage and implantation and also render pathological examination more difficult.

Laparoscopic approaches

A totally laparoscopic approach is used when the diseased spleen although enlarged does not extend significantly below the left costal margin and short of the umbilical plane equivalent to a longitudinal long axis on ultrasound or CT not exceeding 15 cm. Above this size and with increasing weight (>1.0 kg) splenectomy by the total laparoscopic approach can be difficult and is attended by high conversion rates. Hence until the advent of effective devices that enable hand-assisted laparoscopic surgery (HALS), the correct and appropriate surgical treatment for these patients was open splenectomy. Nowadays, however, the majority of spleens of size ranging from 20 to 40 cm (longest diameter) can be safely removed by the HALS approach, which reduces considerably the technical difficulty of the procedure and enhances safe completion without conversion. It has replaced preoperative percutaneous embolization of the splenic artery. Thus the HALS approach is strongly recommended for all adult patients with massive splenomegaly (>20 cm on ultrasound or CT). These large spleens are most often caused by congenital haemolytic anaemias, hypersplenism (primary and secondary) and myeloproliferative disorders. As the HALS technique used differs from the classical splenectomy by the total laparoscopic approach, the two operations are described separately. It should be stressed that the postoperative morbidity of laparoscopic splenectomy is significantly higher in patients undergoing the procedure for massive splenomegaly, although there is some evidence that it is reduced when performed by the HALS approach. The hand access device favoured by the author is the Omniport (Figure 26.10) but there are others such as the Hand Port, the Lap Disk and the Gel Port.

Total laparoscopic splenectomy

The 'hanging spleen' technique is most commonly used with the patient placed just short of the right lateral position (left side up) with the operating table in a slight head-up tilt (20°) facing the surgeon and the camera person on the right, with the scrub nurse on the other side of the table by the patient's back. The operation begins with detachment of the stomach from the spleen and

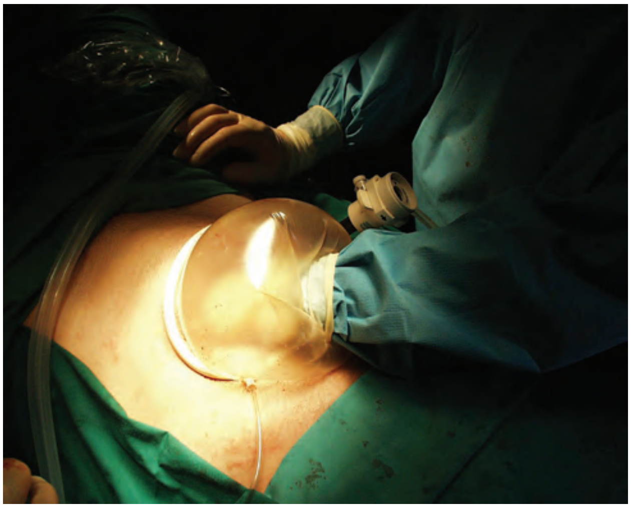

Figure 26.10 Omniport hand assist device for hand-assisted laparoscopic surgery splenectomy

division of the gastrosplenic ligament and short gastric vessels. An avascular window of the gastrosplenic ligament is identified for opening the lesser sac by scissors or ultrasonic dissection. The next step of the operation consists of dissection of the main splenic vascular pedicle which is made easier if the peritoneum overlying the pancreas is divided to expose the areolar tissue plane beneath the main splenic artery and the splenic vein. Careful dissection in this plane enables separation of the tail of the pancreas, which is at times closely applied to the main splenic vessels and risks being injured if cross stapling is carried out. Whenever possible, the author prefers to isolate the pancreatic segment of the common splenic artery along the upper border of the pancreas using curved coaxial scissors and duckbill forceps (Figure 26.11a,b); the artery is ligated in continuity intracorporeally or with an external slip knot (Figure 26.11).

The ligature in continuity of the pancreatic segment of the splenic artery achieves one important immediate benefit especially in large/massive spleens – reduction of the splenic volume aside from increase in the circulating blood volume as the splenic red pulp drains via the intact splenic vein. Additionally, it reduces the risk of major bleeding. The splenic vein is mobilized further down together with the now collapsed prehilar segment of the splenic artery (Figure 26.12a). The vein is then tied together with the collapsed prehilar artery (Figure 26.12b).

Alternatively no attempt is made to dissect and separate the artery from the vein. Instead the curved duckbill forceps or Maryland forceps is used to create the necessary space underneath the splenic pedicle lateral to the tail of the pancreas for the insertion of the linear cutting stapler mounted with vascular cartridges (Figure 26.13). To ensure accurate placement of the stapler limbs completely across the vessels, it is wise to insert a vascular sling which is then used to open the space. The stapling technique is obviously much quicker but may carry a risk of atriovenous fistula. Problems may be encountered with the stapling technique in spleens with a wide diffuse (magistral) pedicle such that more than one stapler application is necessary to secure it. Bleeding may then be encountered after the first stapler application is released. The best option to deal with this problem is suction with minimal delay before the second stapler application. The other potential problem with stapler transection of the splenic hilar vessels is risk of damage to the tail of the pancreas.

Following ligature/stapling of the vessels, the spleen is inspected closely. It should assume a uniformly dusky appearance. If not and segments are seen that are still relatively 'pink', a careful search must be made for accessory/segmental vessels, the most common of which arises from the left gastroepiploic artery (Figure 26.14).

The next step following splenic devascularization is division of the superior leaf of the lienorenal ligament. A fan or equivalent retractor is then placed on the dorsal surface of the spleen and used to displace the organ gently downwards to expose the superior peritoneal leaf of the lienorenal ligament. This is then divided with ultrasonic shears, scissors, electrosurgical hook knife or LigaSure starting at the lower pole of the spleen and including the splencolic peritoneal fold (Figure 26.15). This is followed by separation of the posterior areolar attachments of the spleen.

The fully mobilized spleen is captured in a bag such as the Endo Catch or equivalent (Figure 26.16). It usually requires finger morcellation. The neck of the bag is then exteriorized through the port wound after removal of the port. The rim of the opened bag is surrounded by Betadine swabs and the spleen fragmented by sponge forceps inside the bag and removed piecemeal.

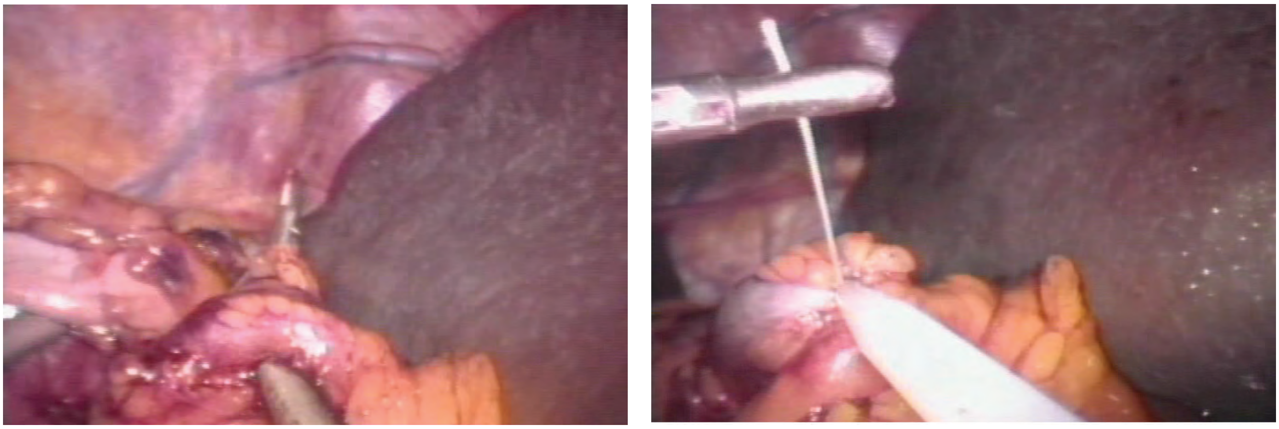

Figure 26.11 The curved coaxial duckbill forceps is under the dissected artery which is ligatured in continuity with an external slip knot. The pancreatic segment of the splenic artery may be clipped instead unless it is atherosclerotic, when clipping may be dangerous as the artery may with major bleeding requiring immediate emergency conversion.

HALS splenectomy

The incision for the placement of the HALS device is vertical along the linea alba at a variable distance from the umbilicus depending on the size of the spleen. The non-dominant hand is then inserted through the HALS device into the peritoneal cavity. The internal hand is used to elevate the hilar surface of the spleen to enable the insertion and deployment of a fan retractor which is then fixed to and held in position by the Martin's arm clamped to the rail along the left side of the operating table. The internal hand is then used to stretch the gastrosplenic ligament and an avascular window is identified for opening the lesser sac by scissors or ultrasonic dissection (Figure 26.17).

Once inside the lesser sac, the splenic artery is identified running sinuously along the upper border of the pancreas towards the hilum of the spleen. The stomach is then detached from the spleen by LigaSure/ultrasonic division of the gastrosplenic ligament and short gastric vessels. Whatever technique is used, the detachment of the top end of the gastrosplenic ligament can be difficult because of the enlarged splenic pole with resulting foreshortening of the ligament such that the stomach wall approximates the splenic parenchyma and can be damaged unless extreme care is taken (Figure 26.18).

The pancreatic segment of the splenic artery is exposed by division of its peritoneal and fascial coverings with the electrosurgical hook knife, and the artery then separated from the pancreas by curved duckbill or Maryland's forceps. The mobilized pancreatic segment of the splenic artery is then clipped or tied in continuity (Figure 26.19).

The division of the peritoneum overlying the pancreas and the areolar tissue attaching the spleen to the Gerota's fascia, perinephric fat and pancreas (inferior layer of the lienorenal ligament) is a crucial technical point in HALS splenectomy as it identifies the areolar tissue plane and avoids all the major branches of the splenic artery and tributaries of the splenic vein. This step is best carried out with the electrosurgical hook knife (Figure 26.20). Although largely avascular, occasional small vessels may cross this areolar plane but these are easily secured with ultrasonic dissection or clips.

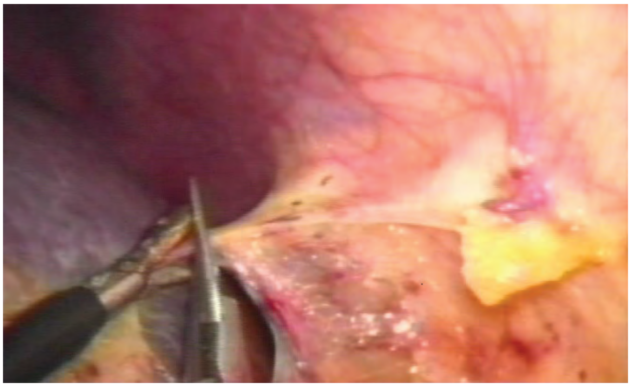

Figure 26.15 Division of the superior leaf of the lienorenal ligament starts at the lower pole and includes the suspensory ligament.

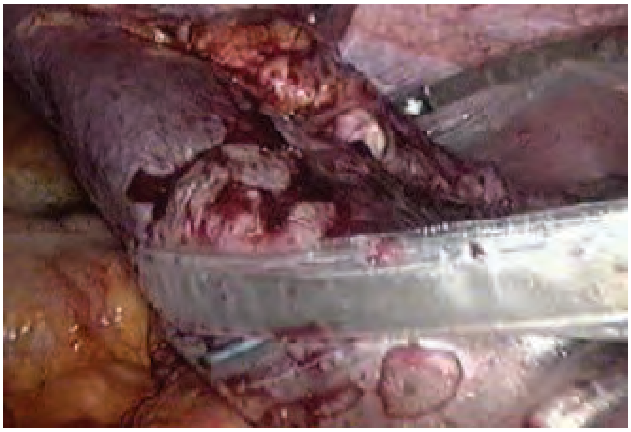

Figure 26.16 Capture of the spleen by an End Catch bag.

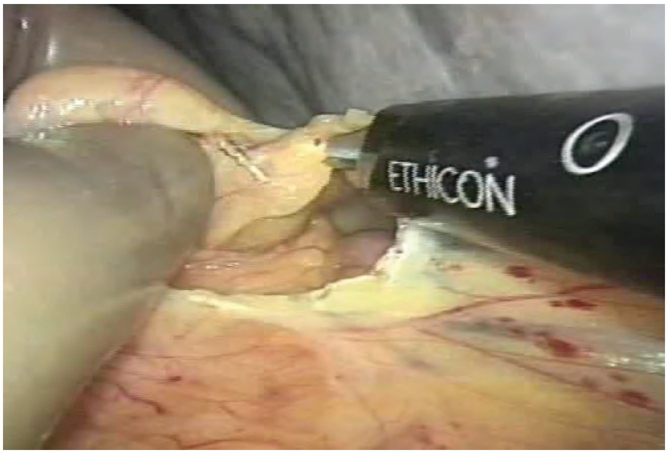

Figure 26.17 Opening the lesser sac.

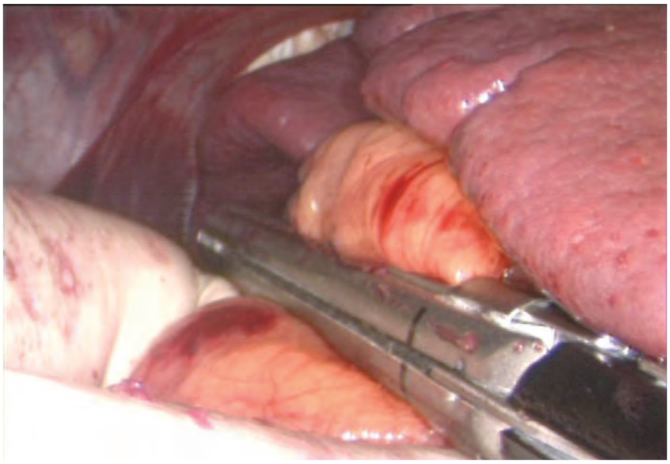

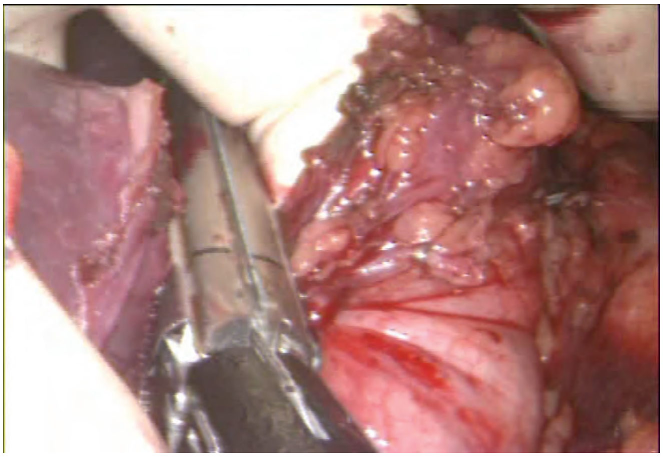

Figure 26.18 Detachment of the gastrosplenic ligament and short gastric vessels by a linear cutting angulated endostapler using a vascular cartridge. This step can be done by LigaSure (Atlas) or ultrasonic dissection.

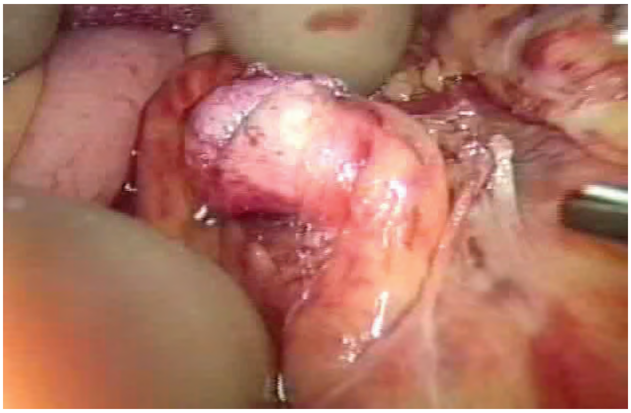

Figure 26.19 Ligature/clipping of the splenic artery in continuity.

The separation of the inferior border and surface of the spleen from the pancreas and perinephric fat is continued through the areolar tissue separating the peritoneal leaf reflected down from the hilum of the spleen (inferior leaf of the lienorenal ligament) to the perinephric fat and pancreas (Figure 26.21).

This separation must be sufficient to ensure that the pancreatic tail is not damaged when the main hilar vessels are ligated. The space created should enable the passage of a curved coaxial grasper or Maryland forceps behind the hilar vessels (arteries and veins), followed by the tip of the index finger of the dissecting hand. The splenic vessels are best tied intracorporeally. Alternatively, the vessels may be secured using external slip knots of braided 1/0 polyester.

The splenic artery and vein are then divided with curved coaxial scissors between the ligatures and the clips (Figure 26.22).

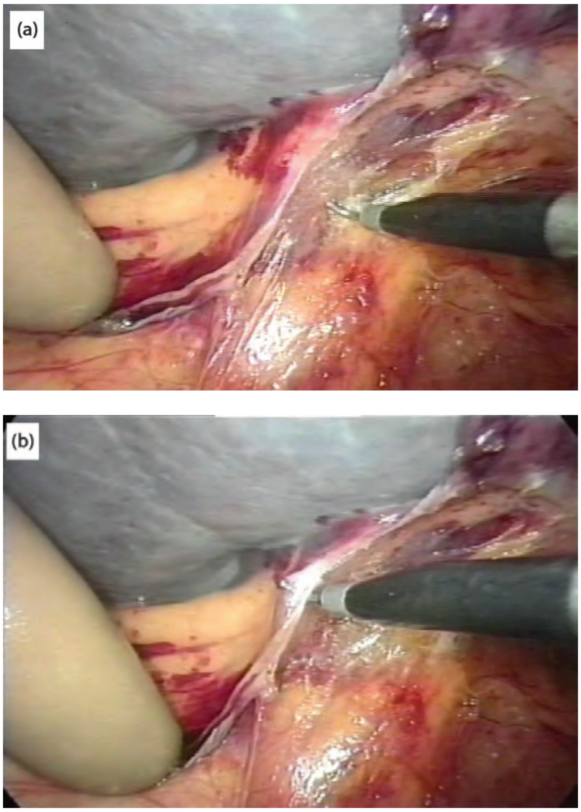

Figure 26.20 (a,b) Division of the inferior leaf of the lienorenal ligament and the areolar tissue plane binding it to the perinephric fat and pancreas.

Special measures for securing a diffuse (magistral) splenic vascular pedicle in large spleens

These can pose a major risk of bleeding, especially when the magisterial system forms a thick fat-laden bunch of interwoven arteries and veins too wide to be encompassed by the open stapler arms which cannot be made to embrace the whole pedicle. This situation requires a different technique which consists of blunt gentle dissection with the index and ring finger of the internal assisting hand in the areolar tissue plane behind the tail of the pancreas and adjoining splenic magistral vascular pedicle so that this comes to be encircled between the fingers behind and the thumb of the assisting hand in front (Figure 26.23).

Following splenic devascularization, the hand is placed on the surface of the spleen and is used to displace the 'vascularly detached' spleen gently downwards to expose the superior peritoneal leaf of the lienorenal ligament. This is then divided with ultrasonic dissection or LigaSure or an electrosurgical hook knife starting at the lower pole of the spleen and including the splenocolic peritoneal fold (Figure 26.24).

The last step (separation of the posterior areolar attachments of the spleen) can be tedious if the spleen is very large. The trick is to elevate the head of the table further and to use the fingers and thumb of the internal hand to pick up and stretch the remaining areolar tissue attachments so that they can be visualized and divided.

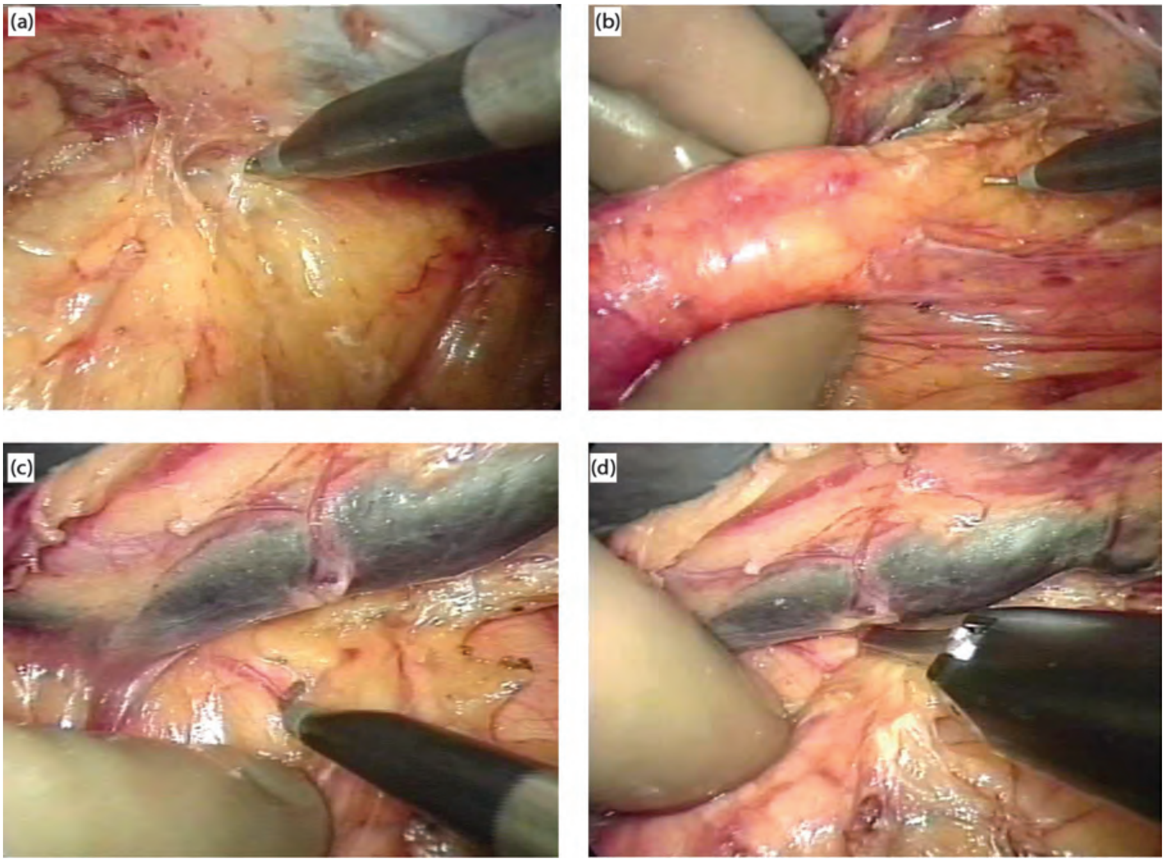

Figure 26.21 (a–d) Separation of the inferior surface of the spleen from the perinephric fat and pancreas.

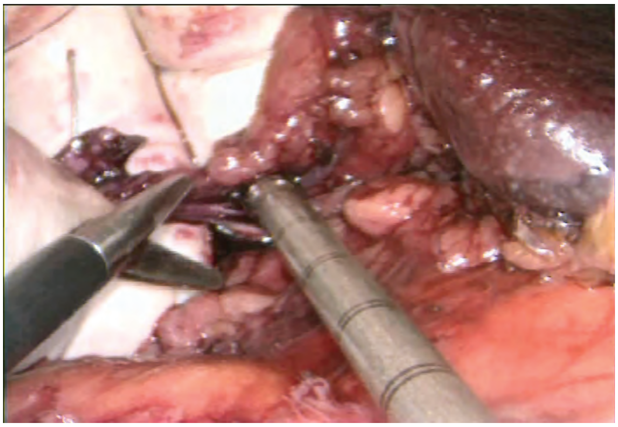

Figure 26.22 The splenic artery and vein are cut distal to the ligatures.

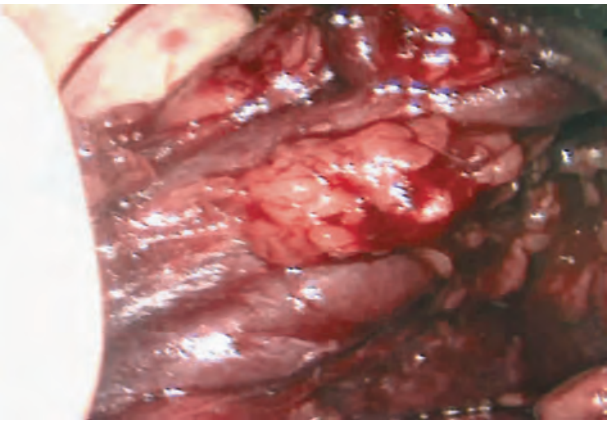

Figure 26.23 Magistral fat-laden vascular splenic pedicle with intertwining veins and arteries held and compressed for dissection between the fingers in the retropancreatic/splenic areolar plane behind and the thumb in front.

Delivery of a large spleen constitutes the most difficult part of the procedure and is also hazardous in patients in whom the splenectomy is carried out for malignancy (usually lymphoma, chronic leukaemia). Currently, the only option is to place the mobilized and completely detached spleen inside a large sterile plastic bag (e.g. used for organ donation). The problem is threefold: (1) difficulty in placing large spleens inside organ donation bags, which has to be achieved largely by the internal hand with very limited visual control; (2) during delivery of the neck of the bag through the hand access wound the large spleen often comes to lie horizontally rather than end-on, with respect to the plane of the wound; and (3) the bag is fragile and, unless great care is taken, it can be damaged during the delivery and morcellation of the splenic tissue.

The delivery steps are as follows.

1. Replacement of the HALS device with the organ retrieval bag through the wound with the base of the bag first.
2. The internalized bag is placed behind and beneath the lower pole of the spleen by the internal hand aided by atraumatic graspers introduced through one of the ports.
3. The rim of the bag is then moved proximally by the internal hand (aided by the grasper) to envelop and capture the spleen, at which point, the draw-strings are grasped by the internal and then gently exteriorized through the wound. This entire process must be unhurried and the exteriorization of the bag to approximate the spleen to the undersurface of the wound must be undertaken without any undue force. It is also a wise precaution to take out all the ports at this stage to ensure against port-induced damage to the bag during the morcellation and retrieval of the splenic tissue.
4. The area surrounding the opened neck of the bag and the wound itself is completely protected by gauze swabs soaked in povidone iodine (Betadine).
5. Morcellation is then commenced with a combination of fingers, sponge holders and scissors after a decent piece of splenic tissue is obtained for histology.
6. The morcellated splenic tissue is collected in a basin and weighed.

An alternative technique entails the use of a large plastic ring wound protector (22.5 cm). The protector is converted to a sleeve by a strong purse-string 1/0 100 mm suture (SurgiWhip, Tyco) which is tied using slip a knot. After removal of the HALS device the plastic sleeve formed from the wound protector is inserted through the wound by the push rod leaving the O ring externally and used to ensheath the spleen, at which point the purse-string is closed converting the sleeve into a closed bag holding the spleen. Approximation of the spleen inside the bag to the wound is obtained by graded withdrawal of the push rod since this lifts the closed end of the sac eccentrically up towards the parieties. Morcellation starts at this stage. As the spleen volume is reduced, tension is kept by further graded withdrawal of the push rod. Once the closed purse-string section is exteriorized, the push rod is cut to open the sac, when morcellation begins.

Complications of splenectomy

The complications of splenectomy include those common to upper abdominal operations (wound and chest infections, etc.) in addition to specific early and late complications. Major complications are encountered in 10% of patients after open splenectomy reflecting the high-risk patients with serious haematological disease undergoing this procedure. The mortality varies with the nature of the underlying disease.

Early complications

Postoperative bleeding is most commonly due to oozing from the raw surface of the diaphragm and retroperitoneum, especially after removal of large spleens and in the presence of low platelet counts or impaired platelet function. Additionally, patients with prior episodes of splenic infarction may have densely adherent yet vascular adhesions, which exacerbate postoperative bleeding. A similar problem is encountered after splenectomy in patients with portal hypertension.

Minor postoperative bleeding results in a subphrenic collection, and this complication is common in patients whose platelet count does not rise above 5×10^9/dL following the operation. Careful monitoring of the platelet counts and clotting parameters in those with hepatic dysfunction may prevent some of these collections which may become infected.

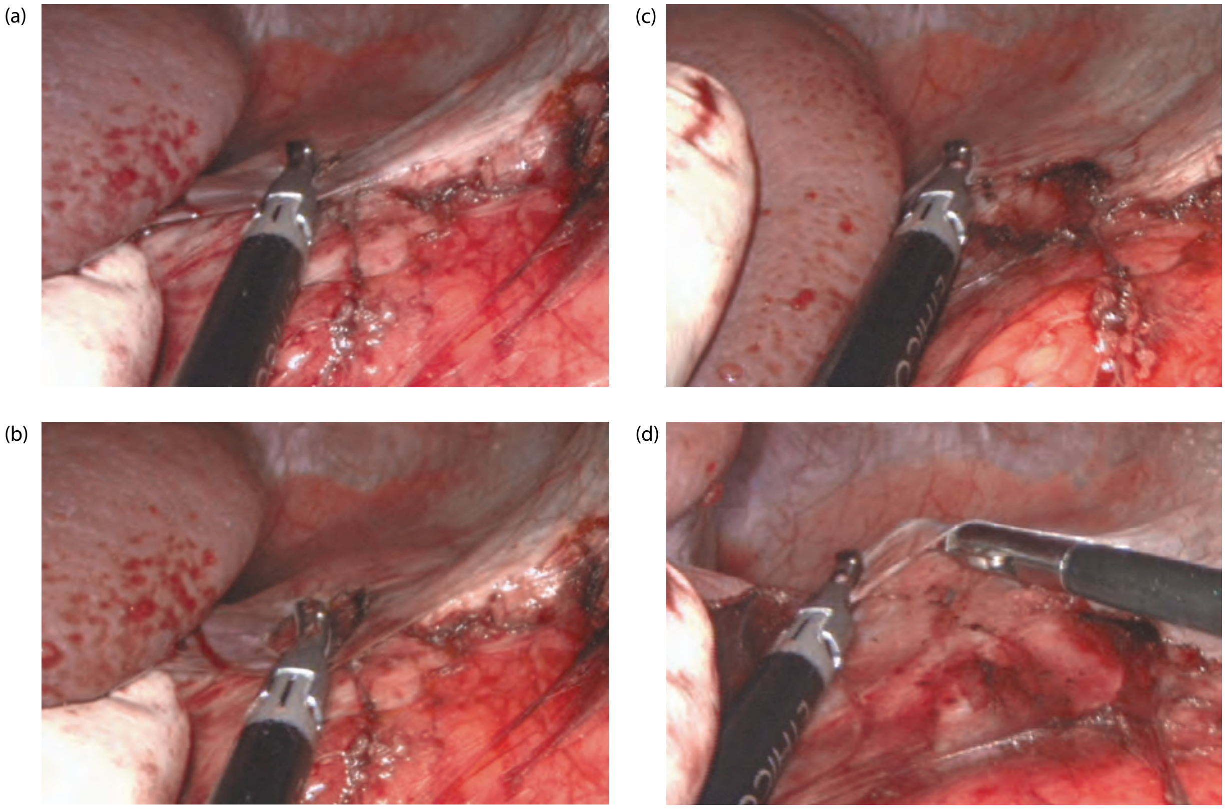

Figure 26.24 (a–d) Division of the superior leaf of the lienorenal ligament

Thrombocytosis with a hypercoagulable state may occur after splenectomy. This ‘rebound’ phenomenon is more common following splenectomy for myeloproliferative disorders. If the platelet count is in excess of 100×10^9/dL, aspirin or anticoagulants should be administered. With adequate prophylaxis (heparin and graduated compression stockings) postoperative deep vein thrombosis and pulmonary embolism should be minimized.

Iatrogenic trauma to the surrounding viscera can occur during splenectomy. During the ligation of the short gastric vessels, if the stomach wall is inadvertently included in the ligature, necrosis of the gastric wall with subphrenic abscess and gastric fistula formation will ensue. The tail of the pancreas is always intimately associated with the hilum of the spleen. For this reason, extreme caution must be exercised during dissection and ligature of the splenic hilar vessels. The current widespread practice, especially during laparoscopic splenectomy, of stapling the splenic arteries and veins together is particularly prone to this complication. Furthermore, this technique incurs the late risk of arteriovenous fistula. Surgical trauma to the tail of the pancreas during splenectomy may result in pancreatic ascites, subphrenic fluid collection/abscess and pancreatic fistula. Complications such as these can be life-threatening in an already debilitated patient with serious underlying haematological disease. Prompt recognition with percutaneous CT/ultrasound-guided drainage with appropriate antibiotic therapy and somatostatin (in the case of pancreatic ascites/fistula) is essential in these patients. A less common but equally disastrous complication is damage to the splenic flexure of the colon, which results in subphrenic abscess formation and faecal fistula. There is a documented high incidence (6%) of portal vein thrombosis after splenectomy for massive splenomegaly, and for this reason postoperative Doppler ultrasound scanning is recommended in these patients. When confirmed fully anticoagulation is instituted initially with heparin and subsequently with warfarin.

Late complications

A small number of patients develop migratory thrombophlebitis or complications of deep vein thrombosis late after splenectomy. This is more likely to occur following splenectomy for haemolytic anaemia or myeloproliferative disorders. Especially in those patients in whom the anaemia does not respond (much like an inverse relationship), thrombocytosis and associated complications may ensue. These patients may require long-term anticoagulant therapy. Late recurrence of the disease may complicate splenectomy. The usual cause of recurrent anaemia or thrombocytopenia is hypertrophy of a missed accessory spleen. If suspected, the accessory spleen can be imaged with a radiolabelled nuclear scan, and curative surgical removal. The most important late complication is, however, postsplenectomy overwhelming sepsis, which was discussed earlier.

Miscellaneous disorders of the spleen

Splenic abscess

Splenic abscess may result from contiguous spread of infection from neighbouring viscera, e.g. diverticulitis or via infection of an infarcted spleen or post-traumatic splenic haematoma. Multiple abscesses may occur in the end stage of overwhelming sepsis or with bacterial endocarditis, in patients with leukaemia and in premature infants. Multiple splenic abscesses are often fatal, even with aggressive management.

The recognition of splenic abscess is commonly delayed and for this reason carries a significant mortality. It should always be suspected in patients with established splenic infarction whose pain, fever and signs do not settle with conservative management. The clinical features of a splenic abscess are essentially non-specific, i.e. fever, pain and left upper quadrant tenderness. Splenomegaly is recognized in less than 50% of patients. The chest radiograph may show a left pleural effusion, and ultrasound scanning, an immobile hemidiaphragm and gas/debris in the abscess cavity. CT scanning is diagnostic. The management options include percutaneous drainage or splenectomy which is necessary if the abscess is large or multiple. Untreated, splenic abscesses can rupture with an invariably fatal outcome.

Treatment

When diagnosed, supportive care and parenteral broad-spectrum antibiotics active against Gram-negative bacteria (usually mixed infection) and intravenous fluid therapy are instituted. Although medical management as the only treatment has been advocated, this does not reflect the consensus view as many patients with splenic abscess often have other intra-abdominal contiguous infections. In immune-compromised patients infections with mycobacterial species, *Candida* and *Aspergillus* are well documented. There are three options used in the definitive treatment of splenic abscess: (1) percutaneous drainage, (2) open or laparoscopic splenectomy and (3) open drainage. Radiologically guided percutaneous drainage is indicated for accessible uniloculated or biloculated abscesses and for surgical patients at very high risk unfit for general anaesthesia and surgery. The procedure however carries risks of iatrogenic injury of the spleen, splenic flexure, stomach, left kidney in addition to haemorrhage, empyema and pneumothorax

Splenectomy is the standard treatment of splenic abscess and in experienced hands can be performed laparoscopically. Rarely, dense perisplenic adhesions preclude splenectomy, when open splenotomy to drain the collection is the only option. Open drainage, when selected as the appropriate treatment, can be performed by one of three approaches:

- transpleural – after resection of the twelfth rib in the posterior axillary line and drainage of the abscess through the diaphragm
- abdominal extraperitoneal – abscess drained through the lateral abdominal wall and between the peritoneum and the flat abdominal muscles
- retroperitoneal – used when the abscess extends to the flank.

Complications

The complications of untreated splenic abscess (missed or delayed) include free rupture into the peritoneal cavity with generalized peritonitis, rupture into the colon and erosion of the abscess through the diaphragm. The mortality in these patients approaches 100%.

The complications which may follow treatment include:

- life-threatening haemorrhage from the splenic parenchyma or hilar vessels
- pneumothorax
- left-sided pleural effusion
- subphrenic abscess
- perforation of the colon, stomach or small intestine
- pancreatic pseudocyst or fistula
- overwhelming, postsplenectomy sepsis
- atelectasis and pneumonia.

Ectopic (wandering, floating, pelvic) spleen

Ectopic spleen is a rare condition, which is not genetic and seems to occur more commonly in women (7:1) between 20 and 40 years of age and is also encountered in children. It is due to lax attachments of the spleen to the retroperitoneum and long splenic vessels, such that the spleen 'wanders' and may become located in the lower abdomen, most commonly in the pelvis. The diagnosis of the condition is difficult in view of its rarity. It may present with an abdominal or pelvic mass with or without recurrent attacks of pain presumably due to torsion which resolves. However, by far the commonest presentation is with sudden acute abdominal pain due to torsion (which may progress to infarction; Figure 26.25). Other patients may present with hypersplenism due to congestion associated with an abdominal or pelvic mass. The diagnosis is confirmed by imaging studies, CT and duplex ultrasonography being the preferred modalities. Treatment of ectopic spleen is operative and consists of splenopexy (non-infarcted spleen). Splenectomy is only indicated (usually as an emergency) if splenic blood flow cannot be restored after detorsion of the splenic pedicle. If the spleen is viable, then splenic fixation is indicated. A variety of techniques has been described for splenopexy of the wandering spleen, if the condition is diagnosed before infarction when splenectomy is necessary. These include:

- suturing the splenic capsule to the left upper quadrant – difficult and unreliable
- placement of the spleen in a posterolateral extraperitoneal pocket at the level of the twelfth rib – safe and effective

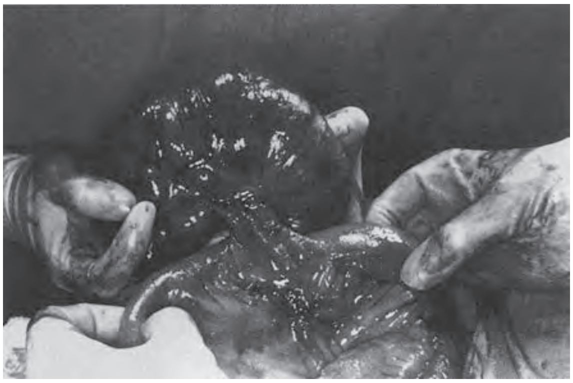

Figure 26.25 Infarcted wandering spleen. The patient presented as an emergency with acute upper abdominal pain

- positioning the left transverse colon in front of the replaced spleen, and suturing the greater curvature of the stomach to the anterior abdominal wall
- use of a polyglycolic mesh to anchor the spleen
- when the ectopic spleen is adherent to the greater omentum, this is used to anchor the organ in the left upper quadrant – possible only in cases with fortuitous adherent omentum.

Splenic cysts

Splenic cysts are primary or secondary. The latter constitute the common ones and these develop after splenic injuries, especially when treated conservatively, hence the name traumatic splenic pseudocysts (no lining epithelium).

Splenic traumatic pseudocysts may be totally asymptomatic but they have a tendency to enlarge although the natural history of these lesions is not fully understood. The time interval between the initial injury and presentation or diagnosis is extremely variable and cases are reported when this exceeded 30 years. Some traumatic pseudocysts of the spleen remain asymptomatic and are discovered accidentally during investigation by ultrasound. Others develop abdominal pain and a palpable mass or non-specific symptoms. Acute presentation with rupture is well documented. Surgical treatment is only necessary for large symptomatic cysts after confirmation of the diagnosis by ultrasound or CT. Spleen-preserving excision is possible unless the cyst is very large or presents acutely with rupture and bleeding.

True splenic cysts have an epithelial lining. There are several types:

- pseudocysts (80%) due to trauma or embolic infarction with subsequent liquefaction
- congenital epidermoid (epithelial) cysts (25%): contents may be clear or viscous from previous haemorrhage and contain proteinaceous material and cholesterol crystals
- epithelial in an accessory intrapancreatic spleen
- dermoid: rare subtype of congenital epithelial
- lymphangiomatous
- mucinous cystic lesions
- parasitic – hydatid (8%): may calcify
- necrotic splenic metastasis (rare): breast, pancreas, ovarian, endometrial, melanoma.

The commonest are pseudocysts (no epithelial lining) followed by epithelial cysts which are (Figure 26.26) lined with epithelium and are filled with straw-coloured to brownish fluid, but this may be dark and viscid following previous haemorrhage. Immunohistochemical studies have shown that the epithelial cells of the cysts express keratin, epithelial membrane antigen, carcinoembryonic antigen (CEA), carbohydrate antigen (CA) 19-9 but not BerEP4 (positive in cells of epithelial origin). These findings suggest that the origin is from epithelial metaplasia of the mesodermal undifferentiated cells from exposure to an unidentified irritant. Epithelial cysts can occur in both children and adults and can reach a large size. Some present with splenomegaly, others with left upper quadrant pain and/or non-specific symptoms (fever and non-bilious vomiting) and many are discovered accidentally during ultrasound scanning. Some have elevated serum levels of CEA and CA19-9. Small asymptomatic cysts do not require treatment but should be followed up by serial ultrasound.

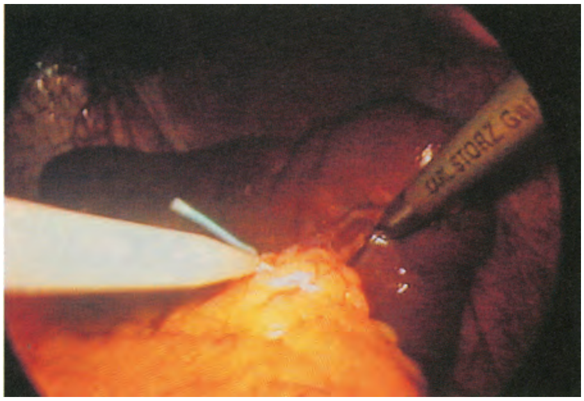

Figure 26.26 Laparoscopic splenectomy for epithelial cyst of the upper pole of the spleen.

Larger symptomatic cysts require treatment, and, unless the cyst is very large, this should consist of partial splenic decapsulation with preservation of the spleen, especially in children. Similar epidermoid cysts have been reported in intrapancreatic accessory spleens. These are also lined by non-keratinizing stratified squamous epithelium and can be multilocular. They are thought to arise from embryonic inclusion cysts of the mesothelium.

Lymphangiomas of the spleen may occur as part of lymphangiomatosis or may be solitary lesions. Solitary splenic lymphangiomas tend to form subcapsular, multicystic proliferations that are often incidental findings. Some are not true lymphangiomas and immunohistochemical studies suggest a mesothelial derivation. Splenic lymphangiomas have a distinctive CT appearance with multiple, low-attenuation lesions that do not enhance with intravenous contrast material or give a 'mottled spleen' appearance. They rarely give rise to symptoms or splenomegaly and do not require treatment if the diagnosis is certain.

All mucinous cystic lesions of the spleen are associated with malignant pseudomyxoma peritonei (peritoneal mucinous carcinomatosis) with the immunophenotype (cytokeratin 7 negative; cytokeratin 20 and CEA positive) of the cystic splenic lesions indicative of a gastrointestinal primary, most commonly the appendix (Chapter 21). The intrasplenic mucinous epithelial lesions cause splenomegaly and may thus be the presenting feature of malignant pseudomyxoma peritonei or develop as evidence of recurrent disease.

Congenital or epithelial splenic cysts

Congenital or epithelial splenic cysts are mainly seen in children and young adults. They are usually solitary, but can be multiple. Although their exact pathogenesis is unknown, several mechanisms have been proposed: involution of pluripotent cells in the splenic parenchyma during development with subsequent squamous metaplasia, entrapment of peritoneal endothelial cells or coelomic mesothelium within the developing spleen, and invagination of the surface mesothelium or dilatation of normal lymph spaces.

The cyst may be lined with columnar, cuboidal or squamous epithelium. Epithelial cysts are further subdivided as dermoid, mesothelial and epidermoid, with dermoid cysts being extremely rare. Congenital epithelial splenic cysts are usually asymptomatic. Occasionally, they cause symptoms as they enlarge often following trauma or haemorrhage from the cyst wall. Complications include infection, rupture and haemorrhage. The treatment of symptomatic splenic cyst is partial or total splenectomy.

On ultrasound scanning splenic epithelial cysts appear as round, homogeneous, anechoic lesions with a smooth thin wall, although septation, irregular cyst walls, internal debris or haemorrhage and calcifications may contribute to an inhomogeneous appearance. On CT, splenic cysts are typically spherical well-defined lesions with an attenuation value close to water and a thin or imperceptible wall with no enhancement after an injection of contrast. On MRI, the cyst is hypointense on T_1 weighted images and strongly hyperintense on T_2 weighted images, with a signal intensity equal to that of water and no enhancement after injection of contrast.

Splenic tumours

Apart from lymphomas, both primary and secondary tumours of the spleen are rare. The vascular tumours include primary angiosarcoma, haemangioma, haemangioendotheliomas and benign vascular neoplasms with myoid and angioendotheliomatous features. Splenic angiosarcomas constitute less than 1% of all sarcomas and less than 100 cases have been reported. They can present acutely with severe abdominal pain and intraperitoneal bleeding from spontaneous rupture (30%) and carry a uniformly poor prognosis.

Secondary tumour deposits are equally rare with a reported frequency of 2–5%. Although all malignant tumours can metastasize to the spleen, the most frequent site of the primary is the breast, lung, pancreas and ovary. Cutaneous melanoma has also been documented to metastasize to the spleen, and direct involvement from pancreatic and retroperitoneal sarcomas can occur.

Benign tumours of the spleen

Most common primary tumours of the spleen are benign and originate from the vascular endothelium.

Haemangiomas

Haemangiomas are the most common benign tumour of the spleen and are commonly found incidentally as the majority are asymptomatic. Most are small (less than 2 cm in diameter), but large haemangiomas carry a risk of spontaneous rupture with haemorrhage and therefore require treatment even if asymptomatic. Splenic haemangiomas are usually solitary but may be multiple or associated with haemangiomas of other sites (angiomatosis). Two principal types are recognized: the cavernous variety (most frequent) and capillary haemangioma.

Capillary haemangioma is hyperechoic on ultrasound scanning, whereas cavernous haemangioma appears as a heterogeneous hypoechoic mass, sometimes containing areas of calcification or multiple cystic spaces. On CT, capillary haemangiomas appear as small homogeneous iso- or hypodense masses with homogeneous contrast enhancement. Cavernous haemangiomas are usually bigger and cystic with occasional iso- or hypodense areas following injection of contrast. Calcifications when present may be either peripheral and curvilinear or central.

Hamartoma

Hamartoma is a rare benign tumour of the spleen, with a reported autopsy incidence of 0.13%. Some are diagnosed in children but the majority present in adult life. They are usually small (<3 cm in diameter), but can reach up to 18 cm in size. Histologically, hamartomas are composed exclusively of red pulp components, but may also contain cystic or necrotic components and areas of calcification. Spontaneous rupture of a hamartoma with acute abdominal pain in adults has been reported, but most patients are asymptomatic and the lesion is discovered incidentally during routine investigations. Ultrasound scanning may show a solid mass, which is usually heterogeneous with multiple hyperechoic areas due to punctate calcifications and cystic changes. On CT, hamartomas appear as well-demarcated, solid, hypodense masses. MRI demonstrates a well-defined homogeneous mass which is isointense on T_1 weighted images.

Littoral cell angioma

Littoral cell angioma (LCA) is a rare benign tumour of the spleen which originates from the lining cells of the red pulp sinuses (littoral cells). Although considered benign, there are well-documented reported cases with disseminated disease but these are nowadays regarded as littoral cell haemangioendotheliomas. The majority of patients are middle aged and present with anaemia, pyrexia of unknown origin and a variable degree of splenomegaly causing hypersplenism. However, many cases are asymptomatic and the exact diagnosis is only established after splenectomy. LCAs are invariably located within the red pulp of the spleen and are usually multinodular. Histologically, they are composed of anastomosing vascular channels with irregular lumen featuring cyst-like spaces and lined by tall endothelial cells.

Ultrasound scanning depicts a lobulated splenomegaly with heterogeneous echogenicity.

Lymphangioma

Lymphangioma is relatively uncommon and may present as a solitary splenic mass or as part of systemic lymphangiomatosis usually in young patients. The majority are cystic but solid lymphangiomas with sclerotic change and papillary endothelial proliferation have been reported. Cystic lymphangioma is characterized by a honeycomb of large and small thin-walled cysts containing lymph-like clear fluid. Ultrasound scanning shows multiple hypoechoic cysts of various sizes with hyperechoic septa, debris and areas of calcification. Colour Doppler ultrasound shows a fan-shaped displacement of the intrasplenic vessels extending from hilus to periphery.

Inflammatory myofibroblastic tumour (pseudotumour, plasma cell granuloma)

Inflammatory myofibroblastic tumour (IMT) is a fibroinflammatory process mainly occurring in liver and spleen. It is characterized histologically by spindle cell proliferation mixed with inflammatory cells consisting of lymphocytes and plasma cells. The proliferating spindle cells show a myofibroblastic phenotype, hence the current favoured designation as IMT. However the condition encompasses several entities with different aetiologies. Thus some IMTs are reparative, others are associated with infection by the Epstein–Barr virus, and some are neoplastic and can recur after excision and even metastasize. At presentation, the tumour may vary in size from 3.5 to 20 cm, with a median of 10 cm.

On ultrasound, IMTs appear as well-circumscribed hypoechoic lesions. CT shows a hypodense mass with delayed enhancement and a central scar. MRI shows hypointense lesions on T_1 weighted images and hyperintense lesions on T_2 weighted images.

Splenic vein thrombosis

This under-recognized condition occurs most often following either acute or chronic inflammation of the pancreas. It is also seen in infants who have had umbilical vein catheterization or from direct extension of a pancreatic neoplasm.

Isolated splenic vein thrombosis (i.e. without portal vein thrombosis) results in splenomegaly and sectorial or left-sided (sinistral) portal venous hypertension. This condition is characterized by the development of varices involving the short gastric and gastroepiploic veins. The most common presentation is with bleeding gastric varices in patients with normal or good liver function (Figure 26.27). As oesophageal varices may be absent, central portal pressures normal and gastric varices are easily overlooked at endoscopy, this condition can be missed. For this reason, gastrointestinal bleeding in the setting of prior pancreatitis should always raise the suspicion of splenic vein thrombosis. The diagnosis can be confirmed by high-dose helical CT or duplex ultrasonography, and these imaging tests have replaced direct visceral angiography and splenoportography.

Recognition of splenic vein thrombosis is critical, as otherwise the gastrointestinal haemorrhage may prove fatal. The treatment is splenectomy. Venous shunt procedures are contraindicated as central portal hypertension is not a feature of the disease, and the sectorial hypertension is not relieved by any type of central portosystemic shunt.

Splenosis

The peritoneum of patients who have sustained rupture or trauma to the spleen can be 'seeded' with splenic fragments that autotransplant. This pathological curiosity led to attempts at salvaging splenic function by intentional transplantation of fragments into the omentum. That such transplants survive is unchallenged, as demonstrated by animal studies, but the surveillance function of the spleen is lost. As such, the enthusiasm for surgical autotransplantation has declined in recent years.

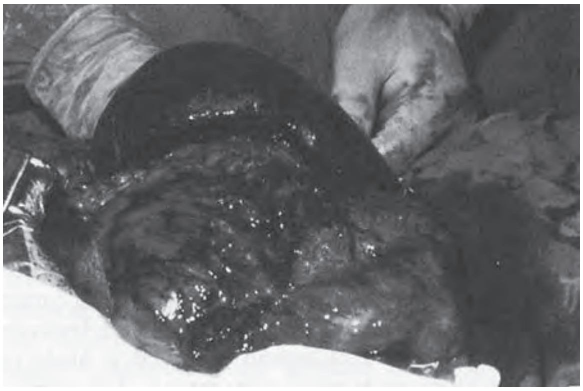

Figure 26.27 Sectorial portal hypertension caused by chronic pancreatitis with splenic vein thrombosis. The patient presented with severe haematemesis. The spleen was enlarged. Endoscopy showed bleeding gastric varices. Note the distended veins along the greater curvature and fundal region of the stomach (short gastric and left gastropepiploic).

Differentiation between splenosis and accessory spleens is not usually difficult. Accessory spleens are found in recognized locations, most often at the hilum of the spleen, tail of pancreas and omentum. They number less than 10 and have hilar vessels with normal splenic architecture. The splenic implants of splenosis often number more than 20, have antecedent traumatic events, are scattered over the surface of the peritoneum and do not have a co-ordinated circulation. Splenosis does not require treatment.

Gaucher disease

Hypersplenism and massive splenomegaly can occur due to this hereditary disorder of lipid metabolism. The three types of the disorder are due to a specific inherited enzyme defect (β-glucocerebrosidase). Type I is the most commonly encountered adult form, type II is the routinely fatal infantile form and type III the intermediate form. Patients surviving into adulthood exhibit splenomegaly, thrombocytopenia, brownish discoloration of the limbs and pingueculae. The typical Gaucher's fat-laden cells can be found on marrow aspirate, and long-bone abnormalities occur in approximately 50% of patients. Splenectomy is indicated for symptoms or complications of hypersplenism.

Disorders of lymph nodes

Palpable subcutaneous lymph nodes should be considered diseased until proved otherwise. The enlargement (lymphadenopathy) may be a transitory self-limiting process, or the harbinger of a life-threatening illness. Lymph node enlargement may be localized (regional) or generalized. It may be purely reactive (enlarged lymph nodes exhibiting sinus histiocytosis) or the nodes may be diseased (infection or involvement by tumour).

Localized lymphadenopathy

Many acute bacterial and viral infections produce localized tender lymphadenopathy. With streptococcal or staphylococcal infections the overlying skin and subcutaneous tissue is often inflamed and oedematous, although antibiotic therapy usually prevents progression to suppurative lymphadenitis. By contrast, the periadenitis is minimal in lymphadenitis caused by viral disease, although the enlarged nodes are usually tender, e.g. infectious mononucleosis.

Chronic infections and parasitic infestations may produce considerable lymphadenopathy without or with minimal signs of acute inflammation. Primary bovine tuberculosis may produce a chronically enlarged group of matted deep cervical lymph nodes that suppurate and form a 'cold' collar stud abscess as it penetrates the investing layer of the deep cervical fascia, and eventually discharges through the skin forming a tuberculous sinus. Syphilis, leprosy, fungal infections and lymphogranuloma venereum can all produce chronic indolent lymphadenopathy.

The site of the enlarged lymph nodes may be of diagnostic help. Enlarged occipital nodes usually indicate a chronic scalp infection and posterior auricular node enlargement is common in rubella. Anterior auricular lymphadenopathy is most often bacterial in origin from infection of the eyelids and conjunctivae. Cervical painless lymphadenopathy is a frequent presentation of nasopharyngeal cancer and the commonest presentation of both Hodgkin's and NHLs. Axillary adenopathy is common in breast cancer and in upper limb infections, and less frequently Hodgkin disease. Painless epitrochlear lymphadenopathy is commonly seen in childhood viral illness, secondary syphilis or generalized tuberculosis, but is rare in sarcoidosis. Palpable small 'shotty' lymph nodes in the groin do not necessarily signify disease, as they are often prominent in children and thin athletic adults. Larger fleshier nodes however should raise suspicion of disease and merit investigation.

In the chest, mediastinal or hilar lymph nodes do not become noticeably enlarged on the chest radiograph with bacterial and viral pneumonias, but pulmonary tuberculosis can produce unilateral hilar lymphadenopathy. Infectious mononucleosis may cause persistent mediastinal lymphadenopathy lasting for several months, but the most common causes of hilar lymphadenopathy are bronchial carcinoma and sarcoidosis.

Regional intra-abdominal lymphadenopathy is of paramount importance in all intra-abdominal cancers and may be due to sinus histiocytosis or secondary deposits (lymph node-positive cancers). Secondary involvement of the lymph nodes (on pathological staging) is an important feature of the pathological staging of all cancers. It affects the prognosis and may indicate the need for adjuvant therapy.

Generalized lymphadenopathy

When there is noticeable lymph node enlargement in more than one drainage region, the most common cause is a viral infection. Common viral illnesses causing generalized lymphadenopathy include infectious mononucleosis, viral hepatitis, influenza, cytomegalovirus infection, rubella, infectious lymphocytosis and AIDS. Excision biopsy of the affected node or nodes is often useful in AIDS patients in directing supportive therapy. The findings in AIDS patients having lymph node biopsy, in decreasing order of frequency, include tuberculosis, Kaposi syndrome, reactive hyperplasia, *Cryptococcus*, *Mycobacterium avium* complex, lymphoma and lymphoepithelial cysts.

Fever and generalized lymphadenopathy occurs in patients with secondary syphilis, acute leptospirosis, salmonellosis, typhoid, paratyphoid and generalized haematogenous tuberculosis. Protozoal infections, e.g. toxoplasmosis, can resemble illnesses such as infectious mononucleosis.

Non-infective and non-neoplastic illnesses producing generalized lymphadenopathy include the autoimmune haemolytic anaemia, collagen vascular disorders, hypersensitivity reactions, hyperthyroidism and a variety of skin disorders, e.g. exfoliative dermatitis.

Lymph node imaging studies

The early attempts at lymph node imaging to detect nodal involvement were performed in relation to staging of Hodgkin disease and NHLs using pedal lymphangiography. The lymphatics in the webs of the toes were identified after intradermal injection of a vital blue dye and then cannulated for contrast injection. In this fashion, proximal pelvic and abdominal lymph nodes could be imaged and involvement detected (Figure 26.28).

This method of staging of lymphomas is rarely used nowadays, but the related technique of *sentinel lymph node mapping* is practised and has been shown to provide accurate nodal staging in patients with melanoma, and, more recently, in patients with breast cancer. The original technique described by Morton *et al.* used a vital blue dye injected intradermally at the periphery of the primary tumour and this resulted in the sentinel node becoming stained blue and thus easily identified with minimal dissection. The technique has been modified by use of ^{99m}Tc-labelled human albumin colloid, 0.3 mL of which is injected intradermally at the edge of the tumour. Lymphoscintigraphy is then performed using an external dual-head gamma camera at 30 minutes and 2 hours and the site of the sentinel node marked on the skin. A special sterile radioprobe connected to a Geiger counter is also used to aid in precise location of the node during

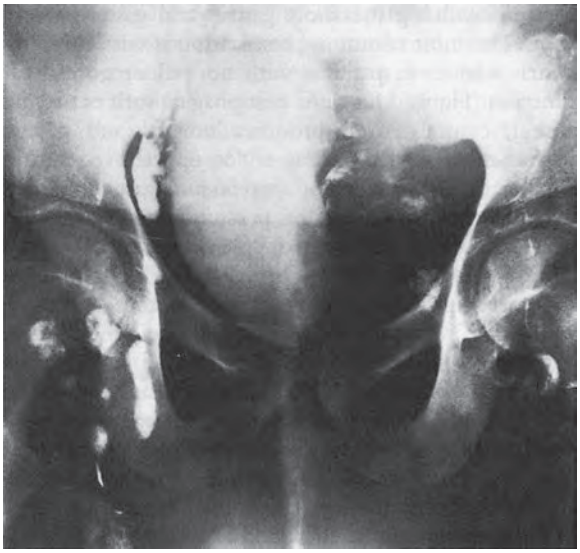

Figure 26.28 Lymphangiogram and intravenous pyelogram in a patient with non-Hodgkin's lymphoma. The very large lymph nodes on the left have filled poorly and are demonstrated as large masses indenting the urinary bladder.

surgical harvest. The combined technique where the vital blue dye is mixed with the radiolabelled albumin colloid gives the best results. Sentinel node biopsy has been shown to yield an accurate assessment of the nodal status of the regional lymph nodes and to provide a strong prognostic factor. It carries a false-negative rate of around 10% , is well established in the staging of breast cancer and is used in some centres for other tumours, e.g. melanoma, stomach, colon.

Hodgkin disease: clinical features

Hodgkin disease typically presents in middle-aged male adults. The neck is the most common site of primary presentation, as a group of painlessly enlarged anterior cervical nodes. Because of the dominant lymphatic drainage, the left side is the more common side of presentation. Axillary nodes are the site of presentation in less than 20% of patients, with the mediastinal or inguinal nodes being the first site in less than 15% of patients.

Hodgkin disease is considered to be unicentric in origin and spreads via contiguous lymphatic channels to adjacent lymph nodes or lymphoreticular organs. The rate of growth of the involved lymph nodes varies between patients, and pain is uncommon in those patients with a slow-growing lymphoma. Enlarged nodes may fluctuate in size with inflammation or necrosis, but rarely shrink enough to escape careful palpation. Systemic symptoms may appear early or late, and variably include general malaise, listlessness, anorexia, weight loss, sweating, intermittent fever and pruritus. Clinically apparent hepatosplenomegaly appears late. Unchecked, the disease may involve any organ system. It is not uncommon to discover obscure involvement of the retroperitoneal, para-aortic, iliac and deep inguinal nodes, as well as diffuse infiltration of the bone marrow. In the late stages of the disease, lymphomas may spread to the meninges, pleura, thyroid, breasts, kidneys, urinary tract and gonads. Local node masses or organ involvement may produce mediastinal obstruction, neurological syndromes, e.g. Horner's, intestinal obstruction or renal failure.

The diagnosis of Hodgkin's, as with any lymphoma, begins with biopsy of a diseased lymph node. The biopsy should be excisional since the histological pattern of the disease is critical to the management of the individual patient. The corollary to exact pathological diagnosis is accurate staging of the disease, i.e. deciding on objective evidence based on staging tests which nodal areas require treatment. For all patients this includes bone marrow biopsy, full blood count and biochemistry and high-quality imaging with helical CT or MRI of the chest and abdomen. In the past, laparotomy was an integral part of staging and included lymph node harvest, liver biopsies and splenectomy. Although it yielded valuable information that altered the stage of the disease, and hence influenced the nature of the treatment, it was attended by a significant morbidity. The very significant improvement in CT and MRI has now virtually abolished the need for staging laparotomy and lymphangiography.

The clinical stages of Hodgkin disease are as follows:

- Stage I
  - Involvement of a single lymph node region, or a single extralymphoid organ or site (IE)
- Stage II
  - Involvement of two or more lymph node groups on the same side of the diaphragm, or localized involvement of an extralymphoid organ or site and one or more lymph node groups on the same side of the diaphragm (IIIE)
- Stage III
  - Involvement of lymph node groups on both sides of the diaphragm, which may be accompanied by localized involvement of an extralymphoid organ (IIIE), spleen (IIIS) or both (IIISE)
- Stage IV
  - Diffuse involvement of one or more extralymphoid organs with or without associated lymph node involvement: sites denoted: N (lymph nodes), H (liver), M (marrow), P (pleura), S (spleen), L (lung), O (bone), D (skin)

A = asymptomatic
B = >10% body weight in 6 months, unexplained fever above 38°C, or night sweats.

Stages I–IV are further subdivided into asymptomatic patients (A), and those with systemic symptoms (B). Clinically apparent hepatomegaly does not necessarily represent infradiaphragmatic disease unless accompanied by elevated liver enzymes or abnormal scan, but a palpable spleen nearly always represents involvement. Questionable involvement of the spleen is confirmed by CT/MRI. In the past patients deemed to be in clinical stage I or IIa were subjected routinely to staging laparotomy with splenectomy which revealed stage III disease in up to 20% of patients. As mentioned previously, this is rarely undertaken nowadays because of the increased reliability of clinical staging. Splenectomy is, however, carried out for splenic involvement as this removes a radiotherapy portal that is potentially very morbid, avoiding radiation injury to the lung, kidney and intestines in the left upper quadrant.

Non-Hodgkin's lymphomas: clinical features

NHLs are a heterogeneous group of tumours of the immune system with different origins, different natural histories and different prognoses. This diversity requires multiple treatment strategies. In contrast to Hodgkin disease, NHLs tend to present more insidiously, with up to 25% of patients harbouring abdominal complaints because of retroperitoneal adenopathy. The majority of these patients present with painless enlargement of one or more superficial node groups. Less commonly, extranodal regions are the primary site of the disease, including the skin, orbit, pituitary, thyroid, tracheobronchial tree, gastrointestinal tract and central and peripheral nervous systems. Approximately one-half of patients at presentation have no systemic complaints, but with disease progression, similar complications and symptoms may occur as in Hodgkin disease.

In 1956, Rappaport proposed a classification scheme that proved both reproducible to pathologists and prognostically relevant. This system was used through the 1970s, when several new schemes were introduced with no scheme being clearly superior. Increasingly, the joint American–European classification is used for classification of the tumours based on morphological, immunological and molecular characteristics of the tumours. Two broad types are recognized: (1) -cell lymphomas and (2) T-cell and putative NK-cell tumours. Within each category, some subtypes are still regarded as a 'provisional entity'. Unlike Hodgkin disease, the stage of the disease and spectrum of NHLs are accurately predicted on clinical grounds, and staging laparotomy has never been proven to be of value, and for this reason is not practised. Patients whose tumours show histiocytic morphology tend to develop systemic symptoms earlier than other varieties of lymphoma. Malaise, weight loss, superficial lymphadenopathy and hepatosplenomegaly occur early in this form of the disease. In 'fulminant' cases, fevers, rapid tissue wasting, massive lymphadenopathy and marked hepatosplenomegaly occur with alarming speed (Figure 26.29). There is a significant danger of spontaneous rupture of the spleen in some of the more clinically aggressive forms of NHL, e.g. histiocytic medullary reticulosis. Mycosis fungoides and Sézary syndrome are two forms of NHL that present with early cutaneous manifestations and later with generalized lymphadenopathy and/or systemic complaints.

Treatment strategies for non-Hodgkin's lymphomas and Hodgkin disease

The treatment options for Hodgkin disease and NHLs are multiple and varied. Indeed, treatment of these disorders is one of the relatively few areas where recent advances have had a major impact upon survival and cure rates (up to 90% 5 year survival for Hodgkin disease). Critical to successful management is the accurate staging of the disease. This is especially true for patients with Hodgkin disease.

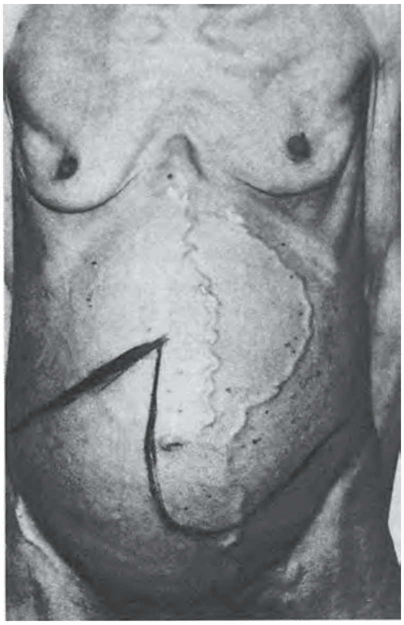

Figure 26.29 Patient with a low-grade malignant non-Hodgkin's lymphoma. Note enlargement of the left groin nodes and hepatosplenomegaly. Clinically there was obstruction of the left common iliac vein with dilatation of veins on the anterior abdominal wall.

Patients with stages I and II Hodgkin disease are treated initially with wide-field megavoltage radiotherapy. This is in the form of 'mantle' and 'inverted Y' fields to cover the known areas of the disease. Patients with IIIA and more advanced disease are treated with combination chemotherapy. The early stages of NHL are treated in similar ways to Hodgkin disease. Local radiotherapy is the first-line treatment of stage IA, or stage II with extranodal disease, bone lesions and/or some of the lymphomas of the gastrointestinal tract. In addition, NHLs of the mediastinum in children and adolescents are offered radiotherapy as a first-line therapy. Wide-field radiation is given, totalling 3000–4000 cGy over a 4 week period. Relapses occur most commonly within the first 2 years following such therapy. More advanced stages and patients with recurrent disease are given combination chemotherapy. There is no one 'standard' regimen for the treatment of NHLs, but combinations of cyclophosphamide, vincristine and prednisone are usually employed in pulses over several months. The nodular and diffuse lymphocytic varieties carry a more favourable prognosis than the histiocytic malignancies. Patients with stage I histiocytic lymphomas, therefore, usually receive primary radiotherapy to the affected region but, because of the poorer response rates, patients with stage II or greater disease are also given chemotherapy in the first instance.

All regimens of chemotherapy produce varying degrees of neutropenia and/or thrombocytopenia. Severe, life-threatening infections are frequent. All neutropenic patients need regular oral inspection and maintenance hygiene with a prophylactic fungicide mouthwash. Rectal infections must be recognized early and treated with broad-spectrum antibiotics and surgical drainage as required. Bleeding during thrombocytopenic episodes must be treated with platelet transfusions. Often, anaemia complicates the clinical picture because of bleeding complications, underlying disease and/or bone marrow suppressions. Replacement component therapy is therefore given as needed.

It should be remembered that some chemotherapeutic agents, notably vincristine, cause peripheral and autonomic neuropathies. As such, paralytic ileus with constipation is common, and should not be confused with mechanical obstruction, nor should it be ignored. Typhlitis is a condition of these patients where transmural necrosis of the caecum occurs, probably as a result of bacterial overgrowth within the setting of a paralytic ileus. Patients requiring surgery for this complication have a mortality exceeding 50%.

Mediastinal obstruction

Mediastinal lymph node involvement with lymphoma can occasionally cause mediastinal obstruction. This is particularly true of Hodgkin disease, diffuse histiocytic tumours, or undifferentiated lymphomas of childhood. Highly differentiated mediastinal tumours in children (Sternberg's sarcoma) frequently develop into acute lymphoblastic leukaemia after initial treatment.

Patients with mediastinal obstruction present a therapeutic challenge. It is very important to obtain sufficient tissue for accurate histological diagnosis (anterior mediastinotomy, mediastinoscopy, thoracoscopy). If respiratory distress complicates the presentation, urgent treatment with corticosteroids, radiotherapy or vinca alkaloids may be necessary during the staging process. Hodgkin disease presenting in this way is often associated with a good outcome. However, childhood lymphomas that are complicated by the development of acute lymphoblastic leukaemia carry a particularly poor prognosis.

CHAPTER 27

Disorders of the pancreas

SIR ALFRED CUSCHIERI AND ABDOOL RAHIM MOOSSA

Surgical anatomy of the pancreas

Durmen has summarized the anatomical relationship of the pancreas as follows: 'The pancreas cuddles the left kidney, tickles the spleen, hugs the duodenum, cradles the aorta, opposes the inferior vena cava, dallies with the right renal pedicle, hides behind the posterior parietal peritoneum of the lesser sac and wraps itself around the superior mesenteric vessels.'

The pancreas is relatively inaccessible and, without some dissection, very little of it can be seen or palpated even at laparotomy. For this reason, it is much more difficult to manage surgically than all other abdominal viscera. Its retroperitoneal location in the upper abdomen means that it is almost completely hidden by the stomach, transverse colon and mesocolon (Figure 27.1).

The pancreas derives its blood supply from numerous arteries arising from major branches of the coeliac and superior mesenteric arteries. A full understanding of the local vascular anatomy and its possible variations is essential for any surgeon operating on the pancreas. In the thin patient, a part of the head of the gland may be seen directly behind the peritoneum of the supracolic and right infracolic compartments, and the inferior border of the body and tail may be visualized from the left infracolic compartment at the root of the transverse mesocolon. These views are very limited and are usually obscured by mesocolic and omental fat. The neck of the pancreas may be palpated by a finger passed through the epiploic foramen and directed inferiorly.

In order to inspect and palpate the pancreas properly three surgical manoeuvres are necessary.

- The hepatic flexure of the colon is mobilized downwards and medially by dividing its attachments to the duodenum and anterior aspect of the pancreatic head. The peritoneum lateral to the second part of the duodenum is incised and the duodenum and pancreatic head are elevated by blunt dissection (Kocher manoeuvre) from the posterior parietal structures. In this way, the right kidney, right renal vein, inferior vena cava and the root of the left renal vein are exposed. The head of the pancreas, the duodenum and retroduodenal and pancreatic portions of the common bile duct can thus be palpated between thumb and finger.
- Limited visualization of the superior part of the body of the pancreas may be obtained by opening an avascular part of the lesser omentum and retracting the lesser curvature of the stomach inferiorly. This manoeuvre also brings the coeliac axis into view. The body of the pancreas can only be adequately visualized by widely opening the gastrocolic omentum, retracting the transverse colon and mesocolon inferiorly and the greater curvature of the stomach superiorly. By extending this opening to the right, into the pyloric region, the right gastroepiploic vessels can be divided near their origins and the anterior aspect of the neck of the pancreas can be visualized. Care must be taken to avoid damage to the middle colic vessels in this region. The opening can also be extended to the left and the gastrosplenic ligament with its contained short gastric vessels can be divided to permit complete visualization of the anterior surface of the tail of the pancreas at the splenic hilum.
- Downward and medial retraction of the dome of the spleen will tense the peritoneal leaf known as the lienorenal ligament and this can be divided to allow the spleen, splenic vessels and tail of the pancreas to be mobilized *en bloc*, allowing inspection of the posterior aspect of the body and tail of the pancreas and more careful palpation of the distal portion of the gland.

All three manoeuvres should be carried out safely, quickly and with little risk of damage to vital structures or troublesome bleeding. They will allow evaluation of all areas of the pancreas

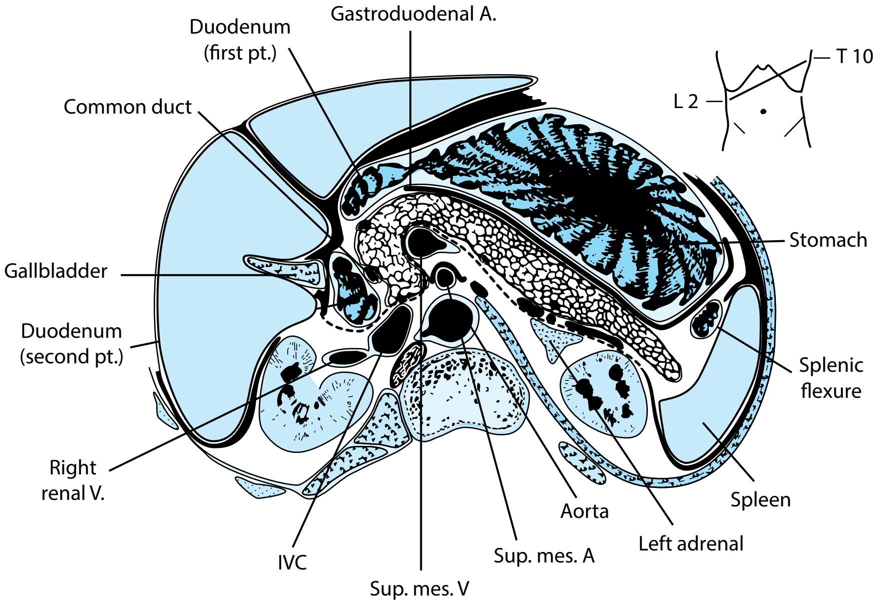

Figure 27.1 Oblique transverse cross-section of the upper abdomen viewed from below. Section passes through the long axis of the pancreas at approximately the levels indicated in the inset figure. The disposition and relations of structures shown approximate those seen in the oblique transverse scanning. A, artery; IVC, inferior vena cava; Sup. mes, superior mesenteric; V, vein.

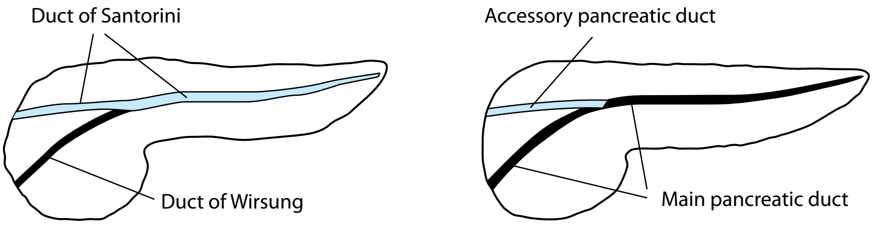
except the region of the neck and uncinate process. Further dissection and mobilization is usually necessary to assess the resectability of a pancreatic tumour. For this, a detailed knowledge of the pancreas and peripancreatic vasculature and its variations is essential.

The coeliac axis and the superior mesenteric artery and their branches vary a great deal in both their site of origin and their direction. The same applies to the venous drainage of the foregut, its appendages and the midgut into the portal venous trunk. The most demanding part of a pancreatic resection is dissection of the neck and head of the gland from the superior mesenteric and portal veins and the uncinate process from the superior mesenteric artery. Hence, it was formerly considered mandatory to have a coeliac and a superior mesenteric arteriogram (as well as a venous phase) prior to planning any major pancreatic resection. Recent refinement in CT (multidetector helical CT scan) and MRI (3.0 T MRI) has rendered diagnostic pancreatic angiography largely obsolete.

As with the blood vessels, pancreaticobiliary ductal anatomy is very variable and the concept of a ‘normal duct anatomy’ is unsafe. The terminology which is widely applied to describe the main pancreatic ductal system is explained in Figure 27.2. The variations of the terminations of the main and accessory pancreatic ducts and their relationship to the lower end of the common bile duct are depicted in Figure 27.3.

The pancreas occupies a central position at a complex anatomical crossroads and its lymphatic drainage is radially disposed along several major routes, namely the coeliac, splenic, hepatic and superior mesenteric nodal basins. It is thus hard to design an adequate ‘cancer operation’ which, in an orderly manner, removes the primary tumour *en bloc* with primary, secondary and tertiary lymphatic nodal territories. Moreover, the intimate anatomical association of the pancreas with major vessels at once limits the extent of the procedure and dictates what must be removed. Thus, when a tumour of the pancreas spreads a short distance, it involves the portal vein, superior mesenteric artery or coeliac axis, and usually becomes incurable. Similarly, if the gland is removed in radical fashion, the need to excise the vessels and lymph nodes associated with it makes removal of the spleen, duodenum, gallbladder,



Embryological basis **Functional basis**

Figure 27.2 Terminology variously applied to describe the pancreatic ductal system. An understanding of ductal embryology, particularly with regard to the development of the more unusual variations, may be served by the terms given in (a). For clarity and practicality the terms given in (b) are preferred.

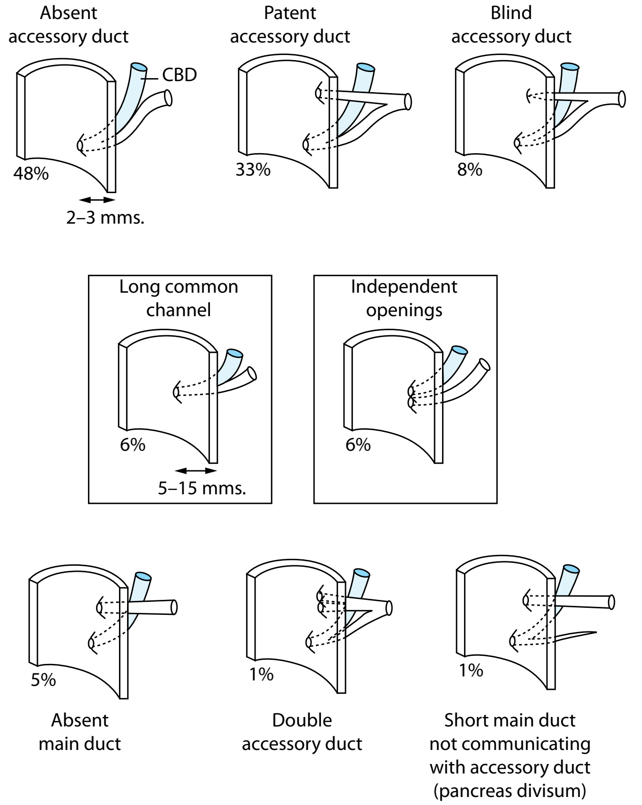


Figure 27.3 Variations of the main and accessory pancreatic ducts and their relationship to the common bile duct (CBD).

common bile duct, upper jejunum and part of the stomach necessary.

Where only part of the pancreas is excised or even if the gland is incised, safe management of any draining pancreatic juice becomes a matter of primary importance since enzymes, if allowed to accumulate in the peritoneal cavity, may cause local damage. A first principle of pancreatic surgery is the provision of adequate drainage. Similarly, the collection of serum, lymph and blood following a pancreatic resection needs to be drained. Second, absorbable suture material should not be used for ligature of major vessels, or as a suture material for anastomosis, or for closure of the abdomen during pancreatic surgery. Non-absorbable material, such as silk, nylon prolene, etc., is essential for safety.

Cellular composition and physiology of the exocrine pancreas

The exocrine pancreas consists of acinar and ductal systems which drain its secretions into the duodenum. The exocrine tissue accounts for 98% of the pancreas by weight. Under the influence of neural and hormonal controls, the exocrine pancreas secretes water and bicarbonate from the ductal system and enzymes from the acinar cells. The parasympathetic vagal fibres have ganglia in the interlobular septa, and postganglionic fibres are distributed to acinar cells and to smooth muscle cells in the ducts. The sympathetic fibres appear to be entirely distributed to the blood vessels and to be concerned solely with regulation of pancreatic blood flow rather than in the direct control of pancreatic secretion.

Fluid and electrolyte secretion from the pancreas is a ductal function and is an energy-requiring process. The cationic composition of pancreatic fluid is similar to that of plasma. Sodium and potassium concentrations are identical to those in plasma and are independent of flow. During states of fluid and electrolyte secretion, calcium appears to enter the ducts passively. However, under the influence of cholecystokinin (CCK), it appears to be actively secreted in parallel with enzyme secretion. Anionic secretion consists almost entirely of bicarbonate and chloride. The sum of concentrations of these two anions remains constant – a high chloride concentration occurs at low flow rates and chloride is replaced by bicarbonate as the flow increases.

Pancreatic enzyme secretion originates in the acinar cell and accounts for virtually all the protein (2–8 g/day in man) in pancreatic juice. Many of the enzymes are secreted in their inactive or zymogen forms together with inhibitors. This mechanism protects the pancreas from autodigestion by its own proteolytic enzymes. Enzyme activation begins after the zymogen enters the duodenum, where mucosal enterokinase cleaves trypsinogen into trypsin, leaving trypsin to activate the other enzymes. The large list of enzymes secreted in pancreatic juice includes amylase, lipase, cholesterol ester hydrolase, phospholecithinase A, trypsin, chymotrypsin A and B, elastase, carboxypeptidase A and B, collagenase, leucine aminopeptidase, ribonuclease and, undoubtedly, other enzymes for which a function has yet to be described.

Control of pancreatic exocrine secretion

Basal pancreatic secretion results either from an intrinsic autonomy of the gland or from a low level of activity of neurohormonal regulators. A complete neurohormonal control mechanism is at work and secretin, CCK and gastrin play the dominant roles. Secretin is released in response to duodenal acidification and there is also an increase in secretin release in man in response to alcohol and, to a lesser extent, after a meal. Secretin produces a secretion of fluid and electrolytes which is initiated within 30 seconds of an administered dose, the bicarbonate concentration of the fluid increasing as flow increases. It is now generally accepted that secretin is also a weak stimulant of enzyme secretion.

The stimulus for release of CCK appears to be entry of amino acids, fatty acids, hydrochloric acid and food into the duodenum. It causes an increase in the release of enzymes and a small increase in fluid and electrolyte output. In man, pancreatic secretion is initiated by CCK at a dose lower than that required for gallbladder contraction.

Gastrin has a varying effect on pancreatic secretion but, in man, it causes an increase in enzyme secretion. The action of glucagon and vasoactive intestinal peptide (VIP) on human pancreatic secretion has yet to be defined. Chymodenin appears to selectively induce chymotrypsin secretion. Somatostatin, pancreatic polypeptide (PP) and motilin have unidentified roles, but may act as a feedback control.

Hormonal and neural interaction

Combinations of two or more hormones have differing effects on the acinar and ductal cells. Secretin is a strong stimulant of fluid and electrolyte secretion and a weak stimulator of enzyme secretion; acting with CCK, however, marked augmentation occurs. These hormones have different receptor sites on the acinar cell and the site of interaction is probably intracellular. Such augmentation probably has an important physiological role since only small amounts of secretin are released into the circulation in response to a meal.

The interaction between the exocrine and endocrine cells of the pancreas is still being elucidated. Insulin is trophic to the peri-insular cells and a loss of insulin secretion in diabetes mellitus results in progressive damage to the acinar cell. The blood supply to the human pancreas first passes the islets and then forms a capillary network around the acinar cells, allowing maximal effects of islet hormones on the acinus. Thus, insulin, glucagon, somatostatin and other islet cell secretions may affect exocrine pancreatic secretion.

In man, vagal reflexes in response to gastric distension result in a juice rich in enzymes, and this effect is abolished by truncal vagotomy. It is likely that the role of vagal stimulation is a permissive one, allowing secretin and CCK to exert their full effect. Thus, atropine, by blocking acetylcholine, depresses the responsiveness of the acinar and ductal cells to CCK in animals.

Anatomy and physiology of the endocrine pancreas

The islets of Langerhans form the endocrine portion of the mammalian pancreas and consist of cells arranged in spherical or ovoid clusters which are well circumscribed and irregularly distributed throughout the gland. Although variable, the total number of islets in the adult human pancreas is estimated to be 1 million. The average weight of the entire pancreas in the adult approximates 100 g. The islets weigh about 1–2 g and thus form, at best, only about 2–3% of the weight of the whole gland.

Our knowledge of the cellular composition of the islets is still incomplete but the existence of four cell types has been largely accepted in mammalian islets based on ultrastructural characteristics of their secretory granules (Figure 27.4). These are the A-, B-, D- and F (D1)-cells.

A-cells form approximately 20% of the normal islet cell population, -cells 75%. In the various pathological conditions affecting the islets, including diabetes mellitus, the proportion of different cell types varies. A-cells (α-cells) synthesize, store and secrete glucagon. They are concentrated in the periphery of the islets. -cells (β-cells) synthesize, store and release insulin. Islet amyloid-associated polypeptide, or amylin, and pancreastatin are also formed in the pancreatic -cells. The physiological function of the former is unclear. However, pancreastatin has an inhibitory role on insulin secretion as well as glucagon and pancreatic acinar cell secretion in animal models. The role in humans is not well defined. -cells are concentrated in the centre of the islets. D-cells supply the tetradecapeptide somatostatin and also probably gastrin. They tend to be located in the periphery of the islets. F- also referred to as D1-cells are the rarest cell type encountered in normal islets and they are thought to be responsible for the secretion of PP. The F-cells constitute approximately 15–20% of cells within the islets of the ventral pancreas but are uncommonly found in the dorsal pancreatic islets. The number of F-cells probably increases with age and in association with injury to pancreatic tissue. An increase in the number of F-cells has been documented in such conditions as diabetes, pancreatitis, mucoviscidosis, haemochromatosis and various exocrine or endocrine pancreatic tumours.

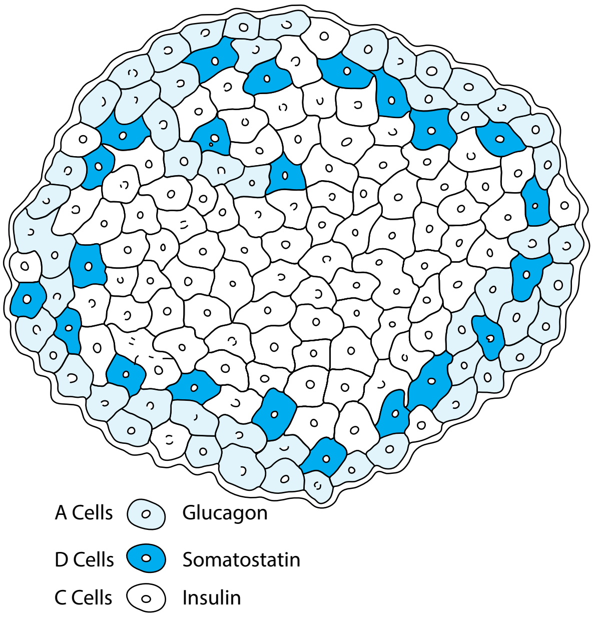

Figure 27.4 Schematic representation of an islet of Langerhans showing distribution of the three main cell types (From Orci, Unger, *Lancet* 1975; ii:1243, with permission.)

The pancreatic islets consist of cell types in close topographical relationship, which produce hormones with different but related actions. Gaps and tight junctions have been demonstrated between islet cells of the same as well as different types. This arrangement may play a role in co-coordinating the activity of the different cell types, e.g. somatostatin-containing cells are topographically closely related to B- and A-cells. As somatostatin inhibits insulin and glycogen release, it is possible that it serves a paracrine function by regulating the local (within the islet) release of these hormones from the appropriate cells. It is likely that the islets function as a well-integrated unit and further elucidation of such mechanisms will enhance the understanding of various pathological conditions arising in this endocrine organ.

Insulin

Insulin is secreted only by the -cells whereas the other hormones are also secreted by the gastrointestinal mucosa, and somatostatin is also found in the brain. Both insulin and glucagon are important in the regulation of carbohydrate, protein and lipid metabolism with insulin functioning as an anabolic hormone (increases the storage of glucose, fatty acids and amino acids in cells and tissues), and glucagon antagonizing insulin by its function as a catabolic hormone mobilizes glucose, fatty acids and amino acids from stores into the bloodstream.

Insulin has a molecular weight of 5800 and consists of two peptide chains A and B which are connected by two disulphide bridges (Figure 27.5). In man, the A-chain has 21 amino acids and the B-chain is composed of 30 amino acids. There are structural variations from species to species. It is known that insulin is formed in a precursor form, proinsulin, which comprises the insulin A and B chains linked by a polypeptide segment consisting of 30–35 amino acids. This connecting peptide (C-peptide) helps in the formation of the native structure of the insulin molecule by ensuring the correct pairing of the cysteine residues during formation of the disulphide linkages between the A- and B-chains. Proteolytic cleavage of proinsulin by enzymes including kallikrein in the secretory granules results in the separation of insulin from the C-peptide. In this conversion, a C-peptide chain is removed from the proinsulin molecule producing the disulphide-connected A- and B-chains of insulin.

These two products are thus released in equimolar amounts from the -cells. Proinsulin-like components (PLCs) constitute 15% of the immunoreactive insulin concentration. The kidney is an important site of proinsulin degradation; hence levels of PLCs are markedly elevated in chronic renal failure. Raised serum proinsulin concentrations have been found in both benign and malignant insulinomas. Neither insulin nor insulin antibodies interfere in the immunoassay for the estimation of C-peptide concentration. Since insulin and C-peptide are formed in equimolar amounts following cleavage of proinsulin, the circulating levels of C-peptide provide a measure of -cell secretory activity, especially in the presence of circulating insulin antibodies produced in response to exogenous insulin. Thus it gives an indication of endogenous insulin production from the β-cell. C-peptide measurement therefore has a vital role in the diagnosis of surreptitious injection of insulin and in the follow-up evaluation of patients who have undergone total or near-total pancreatectomy for nesidioblastosis or a malignant insulinoma. Following resection of the latter, significant C-peptide levels indicate residual pancreatic tissue or the presence of functioning metastases. Recurrence may be heralded by a rise in C-peptide levels.

The main stimulus to insulin secretion is an increase in glucose levels. The insulin will thus cause a fall in glucose concentration and, by a negative feedback effect, this leads to a decrease in insulin release. Other stimuli for insulin release are the amino acids arginine and lysine, glucagon, growth hormone, cortisol, placental lactogen and the sex hormones (especially oestrogens). Glucagon releases insulin both by direct stimulatory effect on the -cells and also indirectly by mobilizing glucose from the liver. The remaining hormones mentioned above act by causing resistance to the actions of insulin and thus generate a compensatory increase in insulin secretion. A number of gastrointestinal hormones including gastrin, secretin, gut glucagon, CCK-PZ (pancreozymin) and gastric inhibitory polypeptide may also be stimulants for insulin secretion. Insulin release is also enhanced by free fatty acids to prevent ketoacidosis which would otherwise occur during fasting in normal individuals.

Vagal stimulation is also a potent stimulus to insulin release, although no impairment in insulin release can be demonstrated following vagotomy. Adrenergic β-receptors also stimulate insulin release, but epinephrine (adrenaline) and norepinephrine (noradrenaline), acting via α-receptors, have an inhibitory effect on insulin secretion. The ventromedial nucleus of the hypothalamus is believed to be important in the cephalic phase of insulin release. Finally, insulin secretion is influenced by various drugs. Tolbutamide and chlorpropamide have a stimulatory effect while alloxan and streptozotocin impair insulin secretion by directly damaging the -cells.

Secretion and actions of insulin

Insulin secretion is pulsatile (occurs in bursts), regulated by a variety of stimulatory factors, most of them related to glucose metabolism and the effects of cyclic adenosine monophosphate (cAMP). Insulin secretion is stimulated by high blood glucose levels and reduced by hypoglycaemia. Other stimulants include several amino acids, intestinal hormones, acetylcholine (parasympathetic stimulation). Inhibitory factors for insulin secretion include somatostatin and norepinephrine (noradrenaline) (sympathetic stimulation). Once released in the circulation, insulin is degraded within minutes in the liver and kidneys. C-peptide and kallikrein are also present in the circulation, having been secreted with insulin. Antibodies to components of islet cells develop in most patients with insulin-dependent diabetes.

The major role of insulin is to promote entry of glucose and amino acids in cells. Glucose enters cells by facilitated diffusion along a concentration gradient created by low intracellular free glucose and by the availability of a specific glucose transporter. Insulin exerts its action by binding with specific membrane receptors found on the surface of cell membranes. The insulin receptor, a tetramer, is made up of two α and two β-glycoprotein subunits. The β-subunit is a protein kinase that catalyses the phosphorylation of proteins. This phosphorylation increases the activity and number of glucose transporters (protein carriers of glucose). As the intracellular glucose concentration is low, some glucose enters the cell even in the absence of insulin. With insulin, however, the rate of glucose entry is considerably accelerated by the process of facilitated diffusion mediated by the transporters. After the insulin receptor complex enters the cell it is transported to the lysosomes where it is cleaved, and the receptor recycled. Raised circulating levels of insulin reduce the number of receptors (downregulation), whereas decreased insulin levels has the opposite effect – upregulation of the number of receptors. The density of receptors per cell is increased in starvation and decreased in obesity and acromegaly. The receptor affinity is decreased by excess glucocorticoids.

The major actions of insulin are:

- facilitation of glucose transport through cell membranes
- stimulation of the enzyme system involved in conversion of glucose to glycogen in liver and muscle
- depression of gluconeogenesis in liver and muscle cells
- regulation of lipogenesis in liver and adipose tissue
- promotion of protein synthesis and growth.

In the liver, insulin promotes glycogen deposition through glycogen synthetase and thus increases in glucose uptake. Insulin suppresses the synthesis of key gluconeogenic enzymes and induces the synthesis of key glycolytic enzymes such as glucokinase. Insulin likewise increases the activity of enzymes involved in lipogenesis.

Glucagon

Glucagon is a secretory product of the A-cell and is a linear peptide composed of 29 amino acids with a molecular weight of approximately 3500. Gel filtration of acid alcohol extracts of pancreatic tissue has revealed two peaks of immunoreactivity, one with a molecular weight in excess of 9000 (believed to represent proglucagon) and another which is a globulin-sized fraction that has been referred to as big plasma glucagon, which may be a precursor of glucagon or simply glucagon bound to a larger protein.

Glucagon has catabolic actions. Hypoglycaemia (a fall below 90 mg/dL) produces a rise in plasma glucagon concentration, and an increase in glucose concentration leads to a drop in glucagon levels. Glucagon activates adenyl cyclase which increases hepatic cAMP to initiate breakdown of glycogen into glucose (glycogenolysis). It also inhibits the process of glycogenesis. It increases glucose formation from non-glucose precursors, e.g. glycerol, lactate and amino acids of the glycogenic type. Glucagon also enhances the breakdown of fat into free fatty acids and glycerol. It stimulates gluconeogenesis and, thus, its infusion lowers plasma amino acids. Finally, glucagon inhibits protein synthesis. There is evidence that glucagon, through its gluconeogenic, ketogenic and lipolytic effects, and not lack of insulin alone, is partly responsible for the development of fulminant diabetic ketoacidosis in man.

The inter-relationship between insulin and glucagon is a complex one which is only partly understood. In general, an inverse relationship exists between insulin and glucagon levels. When glucose is needed, insulin levels fall and glucagon levels rise, producing an increased hepatic glucose production. The reverse is true in states of hyperglycaemia. Following a protein meal, a parallel change is observed in the levels of insulin and glucagon. The rise in glucagon level prevents the hypoglycaemia that would result from enhanced insulin secretion alone by amino acids. CCK-PZ, which stimulates insulin secretion, is also believed to facilitate glucagon secretion following the stimulus of a protein meal and is responsible for the buffer mechanism against hypoglycaemia arising from ingestion of protein.

Somatostatin

This tetradecapeptide is secreted by the D-cell. It inhibits the release of growth hormone from the anterior pituitary and was first isolated from the hypothalamus. Its other actions include inhibition of insulin and glucagon secretion, gastrin secretion, acid and pepsin secretion from the stomach, as well as the release of pancreatic enzymes. It suppresses intestinal motility and contraction of the gallbladder. It also has a suppressive effect on glucose uptake from the gut and on appetite and may play a role in nutrient homeostasis. Infusion of somatostatin diminishes splanchnic blood flow. In view of its inhibitory effect on the exocrine pancreas, the long-acting somatostatin analogue is used in the treatment of patients with pancreatic fistula and acute pancreatitis. Somatostatin has been isolated from a variety of tissues and organs, including the gastrointestinal tract and pancreatic islets. Its exact and full spectrum of function is as yet unknown but it is thought to be involved locally in the regulation of the secretion of the other pancreatic hormones. Somatostatin may act as a neurotransmitter in the brain (hypothalamus) and spinal cord.

Pancreatic polypeptide

PP is a member of the neuropeptide Y family, the structure of which includes a carboxy-terminal tyrosine amide and a chain of 36 amino acids. The family includes PP, peptideYY (PYY) and neuropeptide Y (NPY). They are found in different locations throughout the gastrointestinal tract and in the nervous system; and despite structural similarity, they have different biological actions. PP is expressed in endocrine cells of the gut and pancreas, PYY is located in enteroendocrine mucosal cells of the ileum and colon and nerves of the enteric nervous system, and NPY acts as a neurotransmitter in both central and peripheral nervous systems. PYY occurs in high concentration in the ileum and colon in two different cell types: L cells of the ileum where it is collocalized with enteroglucagon and H-cells of the colon and rectum. All three peptides exert their biological action by binding to various G protein-coupled receptors known as 'Y' receptors. They signal through the GTP-binding proteins Gi/Go and inhibit adenyl cyclase. The PP family of peptides functions as endocrine, paracrine, and neurocrine transmitters. PYY and PP are hormones acting in both a paracrine and an endocrine fashion. Following a meal, PP is released into the blood from PP cells of the pancreas via vagal cholinergic stimulation. PP blood concentrations also fluctuate with the myoelectric activity of the gastrointestinal tract. In humans PYY is released primarily in response to fatty meals. All disorders causing malabsorption increase blood levels of PYY. Additionally, surgical interventions which increase the delivery of food to the distal ileum and colon (small bowel resection, vertical band gastroplasty, Roux-en-Y gastric bypass, jejunoileal bypass) induce elevation of the circulating PYY.

PP is synthesized by the pancreatic islet F-cells with a 29 amino acid sequence and a 66 amino acid prohormone that contains the 36 amino acid PP hormone, and a 20 amino acid icosapeptide of unknown function and C-terminal prosequence. It is released into the circulation following a meal (protein and fat). PP slows gastric emptying and insulin secretion and is thought to inhibit further intake of food. As most of the PP is in the pancreas, it becomes almost undetectable in pancreatectomized patients. Its secretion is believed to be largely due to vagal cholinergic stimulation. PP is thought to play a role in promoting intraislet homeostasis and to modulate gastrointestinal function.

In pharmacological doses, PP inhibits pancreatic secretion caused by CCK-PZ and secretin, stimulates gastric emptying and intestinal transit, inhibits relaxation of the gallbladder and increases the tone of the choledochal sphincter. It has been suggested as a possible causative agent in the watery diarrhoea–hypokalaemia–achlorhydria (WDHA) syndrome. Significant elevated levels of PP are found in both maturity-onset and juvenile diabetics. This observation has also been extended to patients with chronic pancreatitis. Many endocrine tumours of the pancreas and their metastases have also been found to contain numerous PP cells and also to have a high tumour content of PP.

Methods of investigating the pancreas

Because of its deep-seated and inaccessible location, the pancreas is a difficult organ to investigate and to visualize. A precise diagnosis of pancreatic disease is often only possible through the use of a wide battery of tests. The results of such tests should be viewed in the light of the clinical information since all available procedures may not yield concordant data.

Procedures which are employed in the investigation of patients with suspected pancreatic disorders may be classified into five groups:

- Procedures which outline the gland to delineate enlargement, masses, irregularities in contour and calcification. These include:
  - indirect imaging of the pancreas:
    - standard radiological studies to visualize the effect of the pancreas on adjacent organs such as stomach, duodenum, small bowel, transverse colon and bile duct; these studies are largely outdated and have been replaced by other more modern imaging techniques
  - direct imaging techniques to visualize
    - the pancreatic parenchyma, e.g. ultrasonography, CT, magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS).
    - the pancreatic duct system – endoscopic retrograde cholangiopancreatography (ERCP).
    - the pancreatic and peripancreatic vasculature – angiography, contrast CT scan, MRI.
- Procedures to define pancreatic exocrine function:
  - faecal fat excretion
  - pancreatic function tests.
- Procedures to define pancreatic endocrine function:
  - measurement of fasting blood levels of glucose and/or hormones which are secreted by the pancreatic islets under normal and/or abnormal conditions; these include serum insulin, proinsulin, C-peptide, glucagon, somatostatin and gastrin
  - provocative tests to measure the serum level of the above substances if the fasting levels are not conclusive:
    - calcium infusion test (insulinoma and gastrinoma)
    - tolbutamide tolerance test (insulinoma)
    - glucagon test (insulinoma)
    - insulin suppression test (insulinoma)
    - secretin test (gastrinoma).
- Analysis of serum for markers of pancreatic disease:
  - enzymes, such as amylase, lipase, trypsin, ribonuclease
  - tumour-associated antigens, such as carcinoembryonic antigen (CEA), pancreatic oncofetal antigen (POA) and carbohydrate antigen (CA) 19-9.
- Pancreatic biopsy and cytology:
  - percutaneous fine-needle aspiration (FNA) cytology using ultrasonography or CT for guidance
  - endoscopic transgastric or transduodenal needle aspiration cytology or brush cytology
  - laparoscopic visualization and direct vision biopsy or aspiration cytology of the pancreas
  - operative visualization, palpation and biopsy of the pancreas.

Standard radiological investigations

Standard or routine radiological investigations rely on the detection of anatomical abnormalities by the displacement or distortion of adjacent viscera, such as the pancreas. Maximum information may be obtained from each type of examination if the radiologist involved is alerted to the possibility of pancreatic disease prior to the actual procedure. The main value of the various investigations to be described is that they provide important information in a clinical setting suggestive of disease in the upper abdomen. They should be employed principally to identify and/or to exclude common disorders such as peptic ulcer, gallstones, hiatus hernia, gastric cancer and colon cancer. They may, however, show a wide range of abnormalities suggestive of pancreatic disease. Two common pitfalls need to be emphasized: (1) the presence of a common benign disorder, such as hiatus hernia or gallstones does not preclude the simultaneous presence of pancreatic disease; (2) normal routine radiological studies do *not* necessarily signify the absence of pancreatic disease.

A *plain radiograph of the abdomen* may show changes suggestive of *pancreatic disease*, the most important of which is pancreatic calcification. Radiating ‘sun-burst’ calcification is pathognomonic of cystadenomas or cystadenocarcinomas of the pancreas. Numerous other lesions of the pancreas may also show calcifications. These include chronic pancreatitis, with or without pancreaticolithiasis, lymphangiomas, haemangiomas and, occasionally, mucin-secreting adenocarcinoma or islet cell carcinoma. In hereditary pancreatitis, the incidence of pancreatic calcification is higher than in other types of pancreatitis and the incidence of pancreatic malignancy is also increased. In general 2–4% of all patients with pancreatic calcification have a coexisting pancreatic carcinoma but, conversely, over 95% of all patients with pancreatic calcification will have benign disease.

Contrast studies of the gastrointestinal tract

Pancreatic disease may reflect changes in the oesophagus, stomach, small bowel and colon. A pancreatic pseudocyst may present in the posterior mediastinum and compress the oesophagus. Occasionally, a tumour arising in the tail of the pancreas will also deform and involve the distal oesophagus. Alternatively, metastatic lymphadenopathy in the posterior mediastinum may also occlude the oesophagus. Gastric and/or oesophageal varices occasionally accompany pancreatitis or any type of pancreatic cancer as a result of splenic vein occlusion.

Radiological examination of the stomach and duodenum

Changes produced in the stomach and duodenum can be considered under the headings of extrinsic compression and indentation, rugal and mucosal abnormalities, enlarged retrogastric space and gastric varices. If a double contrast examination is performed, some of the more subtle mucosal changes may be seen to better advantage. Motility changes of the stomach, particularly the antrum, may be seen when the posterior stomach wall is invaded by an inflammatory process or a malignant disease of the pancreas.

Pancreatic disease may reflect on the duodenum in a number of different ways and these may be seen on contrast radiography as pressure defects, abnormalities of duodenal fold pattern, widening of the duodenal C-loop, displacement of the angle of Trietz, postbulbar ulceration of the duodenum (Zollinger–Ellison syndrome), disorders of duodenal motility under fluoroscopy, enlargement of the ampulla of Vater and duodenobiliary reflux. It should be emphasized that by the time the presence of a pancreatic carcinoma is reflected by diagnosable changes on contrast radiology of the gastrointestinal tract, the lesion is advanced and incurable.

Radiological examination of the small bowel

Mass lesions of the pancreas may produce displacement of the duodenojejunal area and of the small bowel. These appearances are usually seen with pancreatic pseudocysts and large tumours. Chronic pancreatic disease associated with exocrine insufficiency and steatorrhoea may show a malabsorption pattern of the small bowel with thickened, clubbed or effaced folds. The classic appearance is seen in cystic fibrosis. Patients with the Zollinger–Ellison syndrome may show thickening of the folds in the duodenum and proximal jejunum and hypersecretion of fluid with dilution of the barium. Multiple peptic ulcerations may also be seen.

Radiological examination of the colon

In pancreatitis, characteristic changes have been described in the transverse colon and the region of the splenic flexure. These include ileus of the transverse colon (colon cut-off sign), displacement of the transverse colon and, sometimes, colonic strictures, fistulas and necrosis. Some of these appearances may simulate carcinoma of the colon. Rarely, a pancreatic pseudocyst may present in an unusual location and has even been described presenting as a presacral mass indenting the rectum. Intraperitoneal seeding from metastatic pancreatic carcinoma may cause indentation of any part of the colon.

Cholangiography and isotope biliary excretion scintigraphy

Patients with pancreatic disease (cancer and/or pancreatitis) may present with biliary tract obstruction and jaundice. If the serum bilirubin exceeds 51 μmol/L (3 mg/100 mL), then the outdated oral or intravenous cholangiography and Tc-HIDA scan no longer plays a role in the investigation. If ultrasonography or CT shows dilated biliary radicles, then percutaneous transhepatic cholangiography has a place in the investigation of biliary obstruction. However, when the biliary obstruction is suspected to be in the pancreatic region, ERCP or MRCP are the preferred methods of visualizing the biliary tree since they can provide valuable additional information.

Direct imaging of the pancreas

Ultrasonography

Ultrasonography is probably the most important advance in pancreatic investigation of the past three decades. The following features are indicators of pancreatic disease on ultrasonography.

- Diffuse or localized enlargement of the gland may be due to inflammation, tumour or pseudocysts. Atrophy of the entire pancreas usually indicates chronic pancreatitis.
- Alteration of the texture or 'pattern of internal echoes' within the pancreas may provide a *subjective* impression of pancreatic disease.
- Indirect signs outside the pancreas but readily traced to the pancreatic area are dilatation of the biliary system and displacement of the vessels adjacent to the pancreas.
- Abnormal dilatation of the pancreatic duct may be the result of cancer or chronic pancreatitis.
- Metastases and ascites are also indirect signs of pancreatic disease which by themselves do not necessarily imply the presence of an abnormal pancreas.

The distinction between pancreatic cancer, chronic pancreatitis and a variety of other pancreatic tumours can be difficult without knowledge of the clinical situation. External abdominal ultrasonography is relatively inexpensive, non-invasive and free of radiation hazards. It can be repeated as often as necessary but requires good equipment and expert staff for its performance and its interpretation. In spite of this, technical failure which prevents proper visualization of the whole pancreas occurs in about 10–15% of patients and can be attributed to obesity, gastrointestinal gas and previous operations in the upper abdomen as well as massive ascites.

Computed tomography (Figures 27.6 and 27.7)

CT scanning obtained by the current generation of multidetector CT machines (helical CT) is highly successful in demonstrating the pancreas and allows complete visualization of between 93% and 100% of all glands. The most valuable sign of disease shown by CT scan is the presence of localized or diffuse enlargement of the gland. As with ultrasonography, this finding is non-specific as to the type of disease. The pancreas may be abnormal without recognizable enlargement and, conversely, normal variants of size exist which may suggest abnormalities when none is present. An abnormally small pancreas may be a sign of chronic pancreatitis. The lower limit of normal is said to be one-half of a vertebral body width for the head of the pancreas and one-third for the body of the gland. Nevertheless, when the size of the gland falls below these standards, the pancreas is often actually normal. Calcifications are readily identified by CT scanning. Other signs of pancreatic disease include dilatation of the hepatobiliary tree, dilatation of the pancreatic duct and liver metastases.

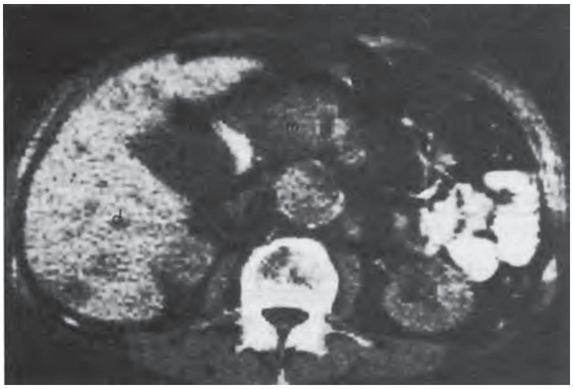

Figure 27.6 CT scan showing typical appearance of carcinoma of the pancreas, consisting of a mass (m) in the head of the pancreas, a distended gallbladder (g) and dilated intrahepatic ducts (d). Incidental note is made of an aortic aneurysm which was better seen in more caudal sections.

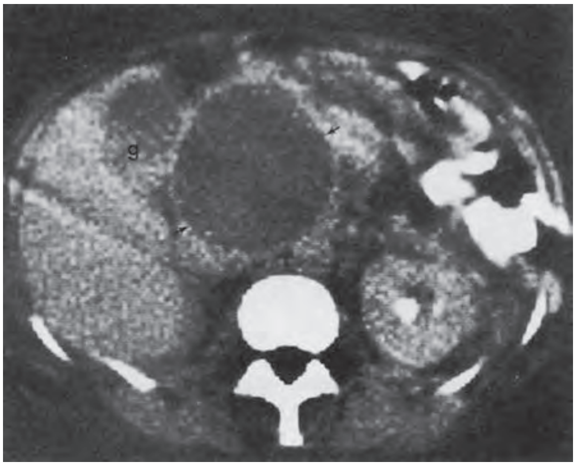

Figure 27.7 Scan shows typical pseudocyst (arrows) near the head of pancreas. The gallbladder (g) is also visualized.

The accuracy of ultrasonography and CT scan in detecting abnormalities in the pancreas varies. The reported figures are dependent on the type and spectrum of diseases included in the population studied, on the nature of the equipment employed, and on the skill of the individuals involved in the study. Chronic pancreatitis produces more problems for ultrasonic detection – only about 50% of cases of chronic pancreatitis may show changes detectable by ultrasound. One major difference between ultrasonography and CT scan is the frequency with which the gland can be seen. Ultrasonography has a non-visualization rate that averages 15–20% when conventional techniques are used. What is more subtle, and not known, is the frequency with which significant portions of the pancreas are hidden, even though the investigator thinks the entire gland is seen. On the other hand, failure rates for CT are significantly lower and range from 0% to 10%. CT scan has a higher chance of visualizing the gland when ascites or extreme obesity is present. On the other hand, when the patient cannot remain motionless or suspend respiration during the scanning, CT study is usually inadequate but the ultrasound examination may produce diagnostic results. Recognition of pancreatic calcification and small intrapancreatic pseudocysts is clearer with CT scan and this facilitates diagnosis of pancreatitis. Finally, detection of gas and of the thicker walls of pancreatic abscesses is easier with a CT scan. CT examinations are two to four times more expensive than pancreatic ultrasound. When serial or multiple studies are required, the small but potential risk of radiation exposure has to be taken into account with the CT scan.

Contrast-enhanced helical CT is nowadays extensively used for the diagnosis and staging of pancreatic neoplasms, especially pancreatic ductal adenocarcinoma (PDAC) (the commonest cancer). The non-ionic contrast agent (300 mg of iodine/mL) used is injected intravenously in doses ranging from 120 to 150 mL at rates ranging from 1.5 to 5 mL/s with a time delay between start of the injection and scanning of 25–70 seconds. The pancreatic phase during which the pancreatic parenchyma is most enhanced usually occurs following infusion of 150 mL of contrast injected at 3 mL/s but this period varies with the injected rate. As PDACs are hypovascular, the detection rate especially of small cancers depends on maximum enhancement of the pancreatic parenchyma. A study has confirmed that higher doses and fast injection rates produce the best enhancement and thus the highest diagnostic yield.

Endoscopic retrograde cholangiopancreatography

Endoscopic diagnosis at ERCP

ERCP endoscopy provides direct visual observation of the oesophagus, stomach, duodenum and ampulla of Vater. Inflammatory or neoplastic lesions visualized in any part of the upper gastrointestinal tract may entirely explain the clinical picture.

Tissue diagnosis at ERCP

Conventional endoscopic biopsy with forceps, brush cytology, aspiration of pancreatic juice for cytology or direct transduodenal needle aspiration cytology may be possible and provides valuable information if positive for malignant disease. In addition, aspirated pancreatic juice may be assayed for research into tumour markers such as CEA and POA.

Radiological diagnosis at ERCP (Figures 27.8–27.10)

Retrograde pancreatogram and/or retrograde cholangiogram often provide information indicative of the presence of tumour, inflammatory disorders or stone disease.

The main disadvantage of ERCP is that it requires the combined team effort of an endoscopist, an assistant who is thoroughly familiar with the equipment and technique (including disinfection procedures and the handling of specimens), a radiology technician and, ideally, a radiologist. It is time-consuming and expensive. It is an invasive procedure which carries a small but definite risk of complications. ERCP is unsuitable for screening patients with unsuspected pancreatic disease.

The complications of ERCP include the following.

- Injection pancreatitis – this can be prevented by careful injection of the medium into the pancreatic duct without too much pressure and without attempting to obtain an acinar phase of the pancreatogram.

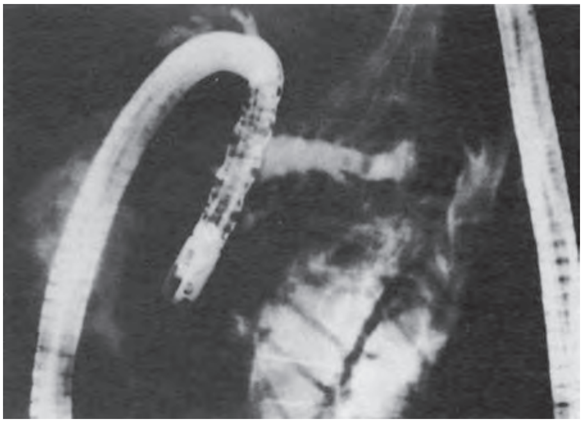

Figure 27.10 Endoscopic retrograde cholangiopancreatography showing grossly dilated main pancreatic duct due to chronic pancreatitis.

- Sepsis – pancreatic and biliary sepsis can be induced or precipitated by ERCP. Whether the sepsis is of endogenous or exogenous origin is a debatable and academic point. Suffice to say that ERCP sepsis is most frequently related to injection into an obstructed pancreatic duct, a pseudocyst or an obstructed common bile duct.

ERCP sepsis can be largely prevented or abolished if the following precautions are taken:

- disinfection of the endoscope tip and the cannula with 2% glutaraldehyde
- prophylactic systemic antibiotics intravenously for 24–48 hours
- addition of antibiotics (chloramphenicol or gentamicin) to the contrast material
- the patient should be operated on within 24 hours of ERCP if a pseudocyst or an obstructed duct is demonstrated.

Other rare complications of ERCP are drug reactions, instrumental injury to the upper gastrointestinal tract and aspiration pneumonia which is associated with the amount of sedatives given to the patient.

Angiography

Percutaneous transfemoral catheterization for coeliac and superior mesenteric angiography is, occasionally, a valuable method of studying the vasculature of the pancreas. With improvement in and refinement of catheter design, various techniques of superselective catheterization may be enhanced by magnification radiography and, in some instances, by the intra-arterial injection of various drugs which improve the visualization (pharmacoangiography) of pancreatic vessels. Vasodilators (bradykinin, tolazolin) and/or vasoconstrictors (epinephrine, norepinephrine, angiotensin) and hormones (secretin and pancreozymin) have all been tried.

The single most useful and reliable angiographic sign of a malignant tumour of the pancreas is arterial encasement. Encasement is seen as a narrowing and/or irregularity of a vessel and is caused by invasion of the vessel by tumour or its compression by surrounding tissues. Arterial encasement may be irregular or smooth or may be serrated or serpiginous. The smooth encasement is much less specific for cancer and may be seen in pancreatitis. Large artery (splenic, hepatic, superior mesenteric, left gastric) encasement is highly suggestive of an unresectable tumour. Small artery encasement is a term applied when more distal branches supplying the pancreas are involved. In connection with the assessment of tumour resectability, the gastroduodenal artery is considered to be borderline between the two groups. A second angiographic sign of unquestionable value in the diagnosis of pancreatic cancer is the presence of major venous involvement. An adequate venous phase angiogram frequently reveals obstruction and narrowing or deformity of the veins. However, non-visualization of the splenic or portal vein alone, although suggestive, is not diagnostic of venous obstruction. Arterial occlusion or arterial displacement may also be caused by pancreatic tumours. Neovascularity is only *rarely* seen in pancreatic carcinoma because the cancer is avascular. However, hyperaemia or increased vascularity in the region of the pancreas may be seen in cases of pancreatic cancer and is usually due to secondary inflammatory changes around the tumour. Finally, an angiogram may occasionally disclose the presence of hepatic metastases, thereby suggesting the malignant nature of a pancreatic abnormality.

Islet cell tumours are typically vascular. A fine network of small vessels may be seen in the early arterial phase and, occasionally, feeding arteries and draining veins may be identified. With larger tumours, displacement of neighbouring arteries may be seen and larger, irregular 'tumour vessels' have been reported. It is difficult to correlate angiographic visualization of islet cell tumours with their malignant potential unless hepatic metastases are obviously seen or encasement (or occlusion) of arteries is a striking feature. When angiography does demonstrate a solitary islet cell tumour, the surgeon must be aware that there may be a second lesion not shown angiographically. When angiography shows multiple islet cell tumours, the likelihood of there being others not shown is very real. In this respect, angiography does not remove the surgeon's obligation to carry out a complete exploration of the whole pancreas.

A major value of angiography is to delineate variations in the foregut vasculature, especially the hepatic blood supply. The desirability of obtaining angiographic studies before embarking on a major pancreatic resection has previously been emphasized since ligation of a major hepatic arterial blood supply in a jaundiced patient may lead to fatal liver ischaemia.

Complications of angiography

Complications at the femoral puncture site include haemorrhage, haematoma, arterial occlusion, pseudoaneurysms and arteriovenous fistula. Embolization of thrombus formed at the puncture site, subintimal dissection of an atheromatous plaque with secondary thrombosis, distal embolization of catheter or guide wire fragments have all been described. Postangiographic renal failure is well documented, especially in patients with pre-existing renal disease. The injected contrast media are hypertonic and may be a real hazard, especially if the patient has been dehydrated for several hours. The jaundiced patient is particularly at risk from both bleeding problems and renal failure. They should be kept well hydrated and their coagulation abnormalities should be treated prior to angiography. The spectrum of adverse sequelae is indeed very broad and this invasive procedure should not be undertaken without good indication, by inexperienced personnel or where facilities are inadequate, but when planned and performed with care, abdominal angiography is an acceptably safe procedure. It is occasionally a useful part of the diagnostic armamentarium in patients with pancreatic disorders, but its value has dwindled and its place has been usurped by the recent improvements of other less invasive imaging techniques such as the modern CT scan, MRI and EUS.

Pancreatic angiography remains of value in two preoperative situations:

- arterial embolization of feeding vessels to large vascular tumours
- splenic artery embolization for lesions around the tail of the pancreas obstructing the splenic vein and causing splenomegaly and left-sided portal hypertension.

In both instances, the angiographic manoeuvre facilitates the subsequent surgical excision by significantly reducing intraoperative blood loss.

Endoscopic ultrasonography
